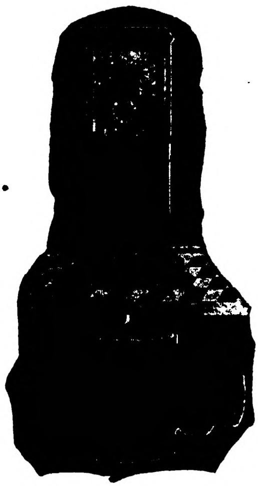
WATER METERS

Manufacturers of various types of meters and recording apparatus for waterworks, including Venturi Meters, Weir and Flume Recorders, Electrical and Mechanical Level Recorders, etc.

DEACON'S RECORDING METER,
for waste detection and bulk supplies (sizes 3" to 18").



INTEGRATING AND RECORDING DEACON BULK METERS.
Sizes 10" to 30".

The Deacon's Recording Waste Detecting Metering system conserves water supplies by :—

(1) Ensuring systematic waste detection.

(2) Employing inspectors to the best advantage.

(3) Obtaining accurate records of peak and night flows into each area.

(4) Preventing the misappropriation of water.

THE SCAFFOLDING WITH THE DOUBLE STRENGTH

BURTON'S

PATENT DOUBLE-GRIP STEEL TUBULAR SCAFFOLDING

DOUBLE-GRIP

BURTON'S patent Scaffolding Fittings afford maximum strength and safety with ease of operation and minimum weight.

A single spanner is the only tool necessary.

The ideal form of modern safety first utility scaffolding for shipyards, ship-repair establishments, engine and boiler shops, aircraft works, etc., etc.

Suitable structures readily and simply erected for fixed exterior stagings, interior stagings, fixed and hanging, travelling horses for dry-dock work, launching platforms, gangways, temporary buildings, water towers, storage racks, etc., etc.

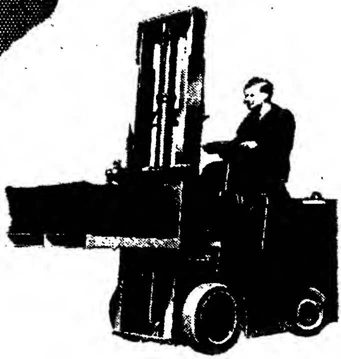
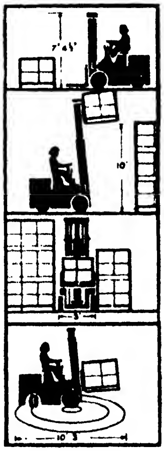
IMPORTANT ANNOUNCEMENT

THE **Ransomes**

NEW FORKLIFT 20 *Electric* TRUCK



CAPACITY
1 TON ON
30″ FORKS



- Designed to meet the demand for a modern high-lift fork stacking truck, having all the advantages of electric battery drive. Handles goods or materials on pallet or direct on forks.
- Capacity—20 cwts. at 1′ 3″ centre from heel of forks.

  Minimum height—7′ 4½″. Wheel base 3′ 6″.
- Height of lift—10′. Tilting 10° back and 3° forward.

  Speed of lift—22′ per minute (20 cwt. load).

  Illustrated leaflet and all information will be sent on application.

SUSTAINED PRESSURE AROUND THE CLOCK
BRISTOL'S RECORDING
PRESSURE GAUGE
PATENT SUSTAINED PRESSURE PUMPS
are particularly suited to plastic moulding where pressure has to be maintained for several hours' cure.
They operate direct without hydraulic accumulator. The valve can be set to any predetermined pressure, and this is sustained indefinitely, the pump running unloaded except when making-up leakage or following-up creep in the moulded material.
Lower power consumption during cure; no blow-off valves; no heating or frothing of oil.
Capable of a working pressure of 3 tons per square inch.
ELECTRAULIC
HIGH SPEED
HYDRAULIC PUMPS
97% Volumetric efficiency

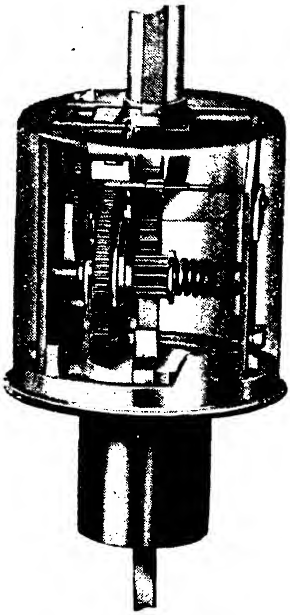
TIME LAGS



THE important part in so many processes played by delayed action timing mechanisms, has led to a demand for much greater accuracy than is afforded by the Oil Dash Pot Method. Many engineers have found such problems completely answered by Rotherham Time Lags. For accuracy and reliability these ingenious instruments are worthy products of the famous House of Rotherham & Sons of Coventry.

Details of the various types available, and also of Instruments, Recording Clocks, Pressure Gauge Movements, Eight Feed Lubricators, Grease Cups, Brass Taps and Unions, Pumps, etc., will gladly be supplied on request.

Printed in Great Britain

PREFACE TO FIFTY-FIFTH EDITION, 1949.

SLOWLY the business of publishing 'Kempe' is becoming less troublesome. But normality in the publishing trade is still far off. If we had been able, we should have liked this year to have subjected the whole of 'Kempe' to complete revision. But fate, the printers and the binders forbade it. Were we to have made so wholehearted an attempt, we were assured that 'Kempe' was unlikely to appear at all in 1949, so much delay must full revision have imposed.

But do not let it be thought that we have been idle! Last year, 'Kempe' appeared in a new guise, divided into two volumes with a single index. This year we have found it possible, without creating too great a delay in publication, to make a very complete revision of the second of the two volumes. Moreover, following the modern fashion, we have drawn up a 'plan' for 'Kempe.' This year, as we have just noted, Volume Two has been fully revised and Volume One has received only minor attention. Next year, it will be Volume One that will receive full revision whilst Volume Two gets only the slight revision that a year's developments in engineering may demand. In 1951 we shall rest content only with minor revision of the whole. But in 1952 the cycle will begin again with a full revision of Volume Two.

In this way we plan to ensure that every part of the book will receive proper full scale revision regularly at three year intervals. But there is always, of course, Burns' oft quoted remark about the plans of mice and men. We have not forgotten it! If engineering developments require it —and at times developments have been very rapid—any section that may be concerned will receive attention whether or not the 'plan' requires it to be done that year or not. We intend to keep 'Kempe' up to date so that any engineer consulting it, whether he lives in a Western community with every engineering facility in easy reach, or far from civilisation where he must depend upon the few tools he has available, will have available to guide him information based upon the very latest practice.

B. W. PENDRED.

PREFACE TO FIRST EDITION (1894).

THE importance and value of such a work as THE ENGINEER'S YEAR BOOK need hardly be insisted on. Perhaps there is no professional man who *needs* a YEAR-BOOK more than the Engineer of the present day, seeing that his duties are so multifarious and the requirements of his position so constantly varying. Yet, while other professions have their Year-Books, until now none has been provided for the Engineer; it is confidently believed that the present volume will meet a want that is constantly experienced by Practical Men in every branch of Engineering.

The aim of the compiler has been to produce a work which, being carefully brought up to date, shall take its place as the standard Book of Reference in the profession, and include only such Modern Formulæ, Rules, Tables, and Data as are required by the Engineer from day to day in the practical work of his calling, including Civil, Mechanical, Marine. Electrical, and Mine Engineering. The work is accordingly divided into Thirty-one Sections, each Section forming practically a complete treatise on its particular subject, and the whole embracing the present practice of Engineering.

The great advances made in Science, as applied to Engineering, during the last quarter of a century have fixed immutably many new principles, laws, and practical data. These, as well as the like particulars of older practice, have been carefully compiled from the best authorities, and find their place in THE ENGINEER'S YEAR-BOOK, whilst a large amount of original matter, presented in a handy and concise form, is also included in the volume.

In the work of compilation, most valuable assistance has been rendered by numerous practising Engineers, including those of the principal English Railway Companies, and of the Queensland Government, as well as by

Girder Manufacturers, Boiler and Engine Makers, and many other persons of experience. Every available work has been searched through and consulted for information, but in making use of particulars so obtained the compiler has been at pains to trace the matter to its original source, so as to determine its authoritative value, and in every case where it appeared necessary he has redrawn existing figures and verified current formulæ, so that clearness and accuracy might be ensured.

Obviously a work of this nature, to fulfil its purpose of being kept up to date, will require periodical revision, and it is accordingly intended to REISSUE IT FROM YEAR TO YEAR. The facilities thus afforded for thorough revision throughout the volume will make it practicable to *insert every year new matter of importance in any Section*, and render the book at all times a safe and reliable DAILY REFERENCE BOOK for the PRACTICAL ENGINEER.

Kindly criticism and help towards making the work as complete and as useful as possible are earnestly invited, and any suggestions, addressed to the care of the Publishers, with this object, will be gladly received, and, as far as possible, acted upon.

I have to thank Mr. H. HARTNELL Technical Officer of the Engineer-in-Chief's Office, for great assistance rendered in the work of compilation.

Finally, I think more than a word of thanks is due to the printers, Messrs. SPOTTISWOODE & Co., for the able manner in which they have executed the difficult task of concisely and clearly arranging the letter-press.

H. R. KEMPE.

LENGTH.

English.

Legal Definition of Standard.

The length of the standard yard of 36 inches is such that a pendulum vibrating seconds of mean time, temperature 62° F., at the level of the sea and latitude of Greenwich, has a length of 39·1393 inches.

Equivalent Measures of Length.

Miles.	Furlongs.	Chains.	Rods.	Yards.	Feet.	Inches.
1	8	80	320	1,760	5,280	63,360
·125	1	10	40	220	660	7,920
·0125	·1	1	4	22	66	792
·003125	·025	·25	1	5·5	16·5	198
·00056818	·0045454	·045454	.181818	1	3	36
·00018939	·00151515	·01515151	·060606	·33333	1	12
·000015783	·000126262	·001262626	·0050505	·0277777	·083333	1

1 micro-inch = 1 millionth of an inch.
1 mil = 1 thousandth of an inch.

Gunter's Surveying Chain.

7·92 inches = 1 link. 100 links = 1 chain, 4 rods or 22 yards. 80 chains = 1 mile.

Ropes and Cables.

1 cable-length = 120 fathoms = 720 feet. 1 fathom = 6 feet.

Geographical and Nautical Measures.

1 nautical mile = 6,080 feet = 1·1515 statute miles. 1 degree of a great circle around the equator = 69·17 statute miles = 60·07 nautical miles. 1 point = 11¼ degrees of arc.

Log-line.

The log-line should be about 150 fathoms long and 10 fathoms from the log to the first knot on the line. If half-minute glass is used, it will be 50·66 feet between each succeeding knot. For 28-seconds glass it will be 47·29 feet = 7·88 fathoms per knot. This is the length of knot by calculation but practically it is shortened to 7·5 fathoms per knot for a 28-seconds glass.

1 knot = 1 nautical mile per hour.

Miscellaneous.

10 penny diameters = 1 foot halfpenny = 1 inch ; 5-shilling piece = 1½ inch

INCHES REDUCED TO DECIMALS OF A FOOT.

Myriametre		32808·43	10936·143	6·213718

* Nearly the $\frac{1}{25}$th part of an inch. † Full $\frac{3}{8}$ inch.

‡ Very nearly 3 ft. $3\frac{3}{8}$ ins., which is too long by only 1 part in 8,056.

1 micron (otherwise 'μ') = 0·001 millimetre.

Relation between English and Metric Units.

The legal relations of English Imperial to International Metric Measures are thus given by the Standards Office of the Board of Trade:

1 inch = 25·399978 mm.; 1 metre = 39·370113 inches; 1 gallon = 4·5459631 litres; 1 litre = 1·75980 pint; 1 pound = 0·45359243 kilogram; 1 kilogram = 2·2046223 pounds.

In 1893 the United States of America recognised the metre as the fundamental standard of length, and adopted the conversion value of 1 metre = 39·37 inches.

Conversion of English Inches into Centimetres.

WEIGHT.

English.

Legal Definition of Standard.—The *pound* is the weight in a vacuum of a platinum cylinder called the *Imperial Standard Pound.*

One cubic inch of distilled water (weighed in air against brass weights) at temperature 62° F., the barometer being at 30 ins., weighs 252·326 grains, of which 7,000 go to the pound avoirdupois, and 5,760 to the pound troy.

Weight—Metric.

Legal Definition of Standard.—The *gramme* is $\frac{1}{1000}$ of the *International Prototype Kilogramme* which is the mass of a cylinder of platinum-iridium kept at Sèvres.

1 gramme = 15·432356 grains, and is the weight of a millilitre of distilled water at 4° Centigrade, or 39·2° Fahr., and 760 mm. of mercury pressure.

The Metric Carat.

By decision of the Standards Department of the Board of Trade, the metric carat of 200 milligrams, and its necessary multiples and sub-multiples, are standard weights in the United Kingdom.

CAPACITY.

English.

Legal Definition of Standard.

Gallon.- The standard Imperial gallon (*International Bureau of Standards, Paris,* 1921) contains 10 lbs. (avoir.) weight of distilled water (weighed in air against brass weights) at the temperature of 62° F., the barometer being at 30 ins.

1 Imperial gallon = 277·420 cubic inches. 1 U.S. gallon = 231·0 cubic inches.

Dry Measure.

·0036047	·014419	·028837	·11535	1

Apothecaries' Measures.

Gallon (C) = 8 pints (O); 1 pint = 20 fluid ounces (oz. weight of water).
Ounce (f℥) = 8 drachms (fʒ) = 480 minims (♏) = 720 drops (gtt).
One wine-glass = 4 tablespoonfuls = 16 teaspoonfuls = 2 ounces.
Symbols.—f. or fl., fluid; ss., one half; aa., for each. Thus, f℥ss. means ½ a fluid ounce.

Metric.

Definition of Standard.—The litre, the metric standard of volume, is the volume occupied by 1 kg. of distilled water at 4° C. and 760 mm. of mercury pressure.

1 litre (1,000 millilitres) = 1,000·028 cubic centimetres.

The original standard kilogramme was intended to be equal to the mass of one cubic decimetre of water under certain standard conditions. It was later found that the standard differed slightly from this original definition, but it was decided to adhere to the standard as the unit of mass, and to define the litre afresh as above.

The difference between the millilitre and the cubic centimetre is thus negligible for ordinary purposes.

VARIOUS FOREIGN WEIGHTS AND MEASURES WITH THEIR APPROXIMATE BRITISH EQUIVALENTS.

(Compiled by the Board of Trade (July 1923) from information published by the respective Governments.)

[NOTE.—In the case of fractional equivalents the last figure shown is uncertain.]

Country.	Length.	Area.	Weight.	Capacity.	Approximate British Equivalent.
1. United States of America	—	—	Barrel (flour)	—	196 lbs. avoir.
	—	—	Short Ton	—	2,000 lbs. avoir.
	—	—	Long ,,	—	2,240 ,, ,,
	—	—	—	Bushel (Winchester)—dry	0·96897 imperial bushel.
	—	—	—	Gallon (Old English)—wet	0·83268 ,, gallon.
	Metre	—	—	—	1·09361 yards.
	Kilometre	—	—	—	0·62137 mile.
2. Austria	—	Sq. Kilometre = 100 Hectares	—	—	0·38610 square mile.
	—	Are	—	—	0·024711 acre.
	—	Hectare	—	—	2·4711 acres.
	—	—	Kilogramme	—	2·20462 lbs. avoir.
	—	—	Quintal métrique (Centner) = 100 kilogs	—	220·462 lbs. avoir.
	—	—	Tonne	—	2204·62 lbs. avoir.
	—	—	—	Cubic metre	1·30795 cubic yards.
	—	—	—	Hectolitre (liquid)	21·9975 imperial gallons.
	—	—	—	,, (cereals)	2·74969 ,, bushels.
3. Belgium	—	As No. 2	—	—	—
4. Bulgaria	—	,, ,,	—	—	—
5. China	Ch'ih (= 10 Ts'un)	—	—	—	*14·1 inches.
	Chang (= 10 Ch'ih)	—	—	—	*11·75 feet.
	—	—	Tael (Liang)	—	*1⅓ ozs. avoir.
	—	—	Catty	—	*1⅓ lbs. avoir.
	—	—	Picul	—	*133⅓ lbs. avoir.
6. Czechoslovakia	—	As No. 2	—	—	—
7. Denmark	Weights and measures as No. 2 have been compulsory since April 1922.				
8. Egypt	Pic for textiles (0·58 metres) (Diraa Baladi)	—	—	—	22·83466 inches
	—	Feddan (land)	—	—	1·038 acres.
	—	—	Oke (400 Dirhems) = 1·248 kilogs.	—	2·751367 lbs. avoir.
	—	—	Kantar (36 Oke) = 44·928 kilogs.	—	99·049272 ,,
	—	—	—	Ardeb (198 litres)—dry	5·444391 bushels.
9. Esthonia	—	As No. 2	Russian weights and measures as No. 24 also in use.		
10. Finland	—	,, ,,	—	—	—
11. France	—	,, ,,	—	—	—
12. Germany	—	,, ,,	—	—	—
13. Greece	Metric system (as No. 2) compulsory since 1922.		Ocque = 1·280 kilogs.	—	2·82 lbs. avoir.
			Stater (Quintal = 56·320 kilogs.	—	124·16 ,,

13. Greece—*cont.*	—	—	Livre (Great Venetian)	—	1·06 lb. avoir.
	—	—	Drachme (Dram)	—	⅛ oz. avoir.
14. Holland	—	As No. 2	—	—	—
15. Hungary	—	,, ,,	—	—	—
16. Italy	—	,, ,,	—	—	—
	Ri	—	—	—	2·4403 miles.
	Cho	—	—	—	5·423 chains.
	Ken	—	—	—	1·9834 yards.
	—	Square Ri	—	—	5·95505 square miles.
	—	Cho (land)	—	—	2·4507 acres.
	—	Tsubo	—	—	3·9538 square yards.
17. Japan	—	—	Kwan	—	8·26733 lbs. avoir.
	—	—	Kin	—	1·32277 ,,
	—	—	—	Koku (wet)	39·7033 gallons.
	—	—	—	,, (dry)	4·9629 bushels.
	—	—	—	,, (capacity of vessel)	$\frac{1}{10}$ of a measurement ton.
	—	—	—	Sho (wet)	1·5881 quarts.
	—	—	—	,, (dry)	0·1985 peck.
18. Latvia	As No. 2.	—			
19. Lithuania	Russian system as No. 24, but at same time metric system is in use. Arrangements are being made for making latter compulsory.				
20. Norway	—	As No. 2	—	—	—
	Lokieć	—	—	—	0·62992 yard.
	—	Square lokieć (łokieć kwadretowe)	—	—	0·39680 square yard.
	—	Morg	—	—	1·3835 acres.
21. Poland	—	—	Funt	—	0·893983 lb. avoir.
	—	—	Center = 100 funt	—	89·3983 lbs.
	—	—	—	Cubic lokieć (łokieć szescienne)	0·24995 cubic yard.
	—	—	—	Kwarta (wet and dry) = 1 litre	0·21998 gallon.
22. Portugal	—	As No. 2	—	—	—
23. Roumania	—	,, ,,	—	—	—
	Verst	—	—	—	0·6629 mile.
	—	Square verst	—	—	0·4394 square mile.
	—	Dessiatine	—	—	2·6997 acres.
24. Russia	—	—	Pood	—	36·113 lbs. avoir.
	—	—	Berkovets (= 10 pood)	—	361·13 ,,
	—	—	—	Tchetverik (dry)	5·7717 imperial bushels.
	—	—	—	Vedro (wet)	2·705 ,, gallons
25. Jugoslavia	As No. 2	—	—	—	—
26. Spain	,, ,,	—	—	—	—
27. Sweden	,, ,,	—	—	—	—
28. Switzerland	,, ,,	—	—	—	—

* As fixed for foreign trade by treaty between Great Britain and China in 1902. Customary weights and measures of the same name vary in every province and trade in China.

(Revised by S. A. Wood, M.Sc., M.I.Mech.E.)

MECHANICS.

Definition.—Centre of Gravity: the point of application of the resultant gravitational force acting on a body; its position is independent of the attitude of the body.

Areas, Volumes and Positions of Centre of Gravity for Plane Figures and Solids.
(Centre of Gravity (C.G.) denoted by G.)

Figure.	Description.	Area or Volume.	Distance X.
	Trapezium	$\frac{h}{2}(a+b)$	$\frac{h}{3}\left(\frac{2a+b}{a+b}\right)$
	Triangle (Area)	$\frac{hb}{2}$	$\frac{h}{3}$
	Triangle (Perimeter)	—	$\frac{h}{2}\left(\frac{a+c}{a+b+c}\right)$
	Circular sector	$\frac{ar}{2}$ $\left[\frac{r^2\theta}{2}\right]$	$\frac{2}{3}\frac{br}{a}$ $\left[\frac{2}{3}r\frac{\sin\frac{\theta}{2}}{\frac{\theta}{2}}\right]$
$\angle\ \theta$ is in radians $\left(1 \text{ radian} = \frac{180^\circ}{\pi}\right)$	Circular arc	—	$\frac{br}{a}$

Areas, Volumes and Positions of Centre of Gravity for Plane Figures and Solids.
(Centre of Gravity denoted by G).—*cont.*

Figure.	Description.	Area or Volume.	Distance X.
 ∠ θ is in radians	Circular Segment	$\frac{r}{2}\times \text{arc} - \frac{c}{2}\times(r-h)$ $\left[\frac{r^2}{2}(\theta-\sin\theta)\right]$	$\frac{c^3}{12\times \text{area}}$ $\left[\frac{4r}{3}\cdot\frac{\sin^3\theta/2}{\theta-\sin\theta}\right]$
	Parabolic Segment	$\frac{2}{3}bh$	$\frac{2}{5}h$
	*Spherical Sector—* Surface Solid	$2\pi rh+\pi r\sqrt{r^2-(r-h)^2}$ $\frac{2}{3}\pi r^2h$ $h = r\left(1-\cos\frac{\alpha}{2}\right)$	$\frac{h^2+(r-h)\left(2h+\frac{c}{3}\right)}{2h+\frac{c}{2}}$ $\frac{3}{4}\left(r-\frac{h}{2}\right)$ $\left[\frac{3}{8}r\left(1+\cos\frac{\alpha}{2}\right)\right]$
	*Spherical Segment—* Convex surface Solid	$2\pi rh$ $\frac{1}{3}\pi h^2(3r-h)$	$\frac{h}{2}$ $\frac{h}{4}\left(\frac{4r-h}{3r-h}\right)$
 X = height of G above base	*Pyramid (or Cone)—* Slant surface Volume	$\frac{1}{2}$ slant height × perimeter of base $\frac{1}{3}Ah$	$\frac{h}{3}$ $\frac{h}{4}$ (G is on line joining apex to CG of base)

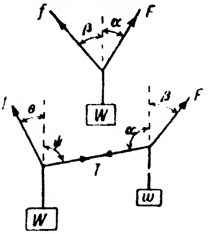
AREAS, VOLUMES AND POSITIONS OF CENTRE OF GRAVITY FOR PLANE FIGURES AND SOLIDS.

(Centre of Gravity denoted by G.)—*cont.*

Figure.	Description.	Area or Volume.	Distance X.
 X = Height of G above base	*Pyramidal Frustum*— Solid	$\frac{h}{3}(A + a + \sqrt{Aa})$	$\frac{h}{4}\left[\frac{A + 3a + 2\sqrt{Aa}}{A + a + \sqrt{Aa}}\right]$
	*Conic Frustum*— Convex Surface	$\pi(R+r)\sqrt{h^2 + (R-r)^2}$ $[\pi(R^2 - r^2)\operatorname{cosec}\alpha]$	$\frac{h}{2} - \frac{h}{6}\left[\frac{R-r}{R+r}\right]$
	Solid	$\frac{\pi h}{3}(R^2 + r^2 + Rr)$ $\left[\frac{\pi\cot\alpha}{3}(R^3 - r^3)\right]$	$\frac{h}{4}\left[\frac{R^2 + 3r^2 + 2Rr}{R^2 + r^2 + Rr}\right]$
 (Point B is centre of gravity of base)	*Wedge*— Solid	$\frac{(2a + c)bh}{6}$	$\frac{h}{2}\left(\frac{a + c}{2a + c}\right)$
	*Cylinder open at one end*— Surface	$\pi r(2h + r)$	$\frac{h^2}{2h + r}$

STATICS.

Weights suspended by inclined strings.



Case I

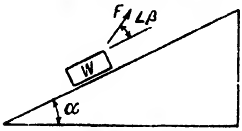
$$f = \frac{W \sin \alpha}{\sin(\alpha + \beta)}, \quad F = \frac{W \sin \beta}{\sin(\alpha + \beta)}.$$

$$W^2 = F^2 + f^2 + 2Ff \cos(\alpha + \beta)$$

Case II

$$T = \frac{W \sin \theta}{\sin(\theta + \psi)} = \frac{w \sin \beta}{\sin(\alpha + \beta)}$$

The Inclined Plane.



Coefficient of friction $= \mu$.
Limiting angle of friction $= \phi$.

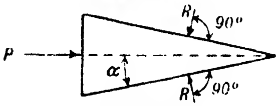
$$F = \frac{W(\sin \alpha + \mu \cos \alpha)}{\mu \sin \beta + \cos \beta} = \frac{W \sin(\phi + \alpha)}{\cos(\beta - \phi)},$$

$(\mu = \tan \phi)$.

If $\mu = 0$, $F = \dfrac{W \sin \alpha}{\cos \beta}$.

If $\beta = 0$ also, $F = W \sin \alpha$.

The Wedge.

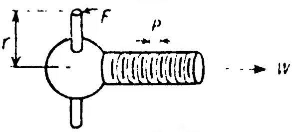


Coefficient of friction $= \mu$.

$$P = 2R(\mu \cos \alpha + \sin \alpha).$$

If $\mu = 0$, $P = 2R \sin \alpha$.

The Screw.

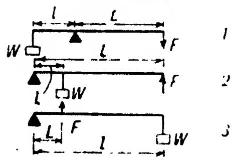


F = force applied to arm.

$$W = \frac{2\pi r F}{p + 2\pi \mu r_s},$$

where μ = coefficient of friction of screw thread, and r_s = radius of thread.

The Lever.

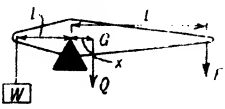


LIGHT LEVER.

In cases 1, 2 and 3,

$$F = \frac{Wl}{L}.$$

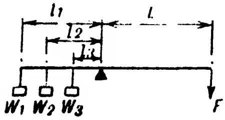
$$W = \frac{FL}{l}.$$



HEAVY LEVER.

Centre of gravity of lever at G.

$$F = \frac{Wl - Qx}{L}, \quad W = \frac{FL + Qx}{l}$$

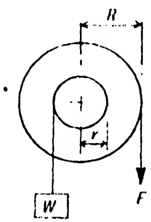


LEVER WITH SEVERAL WEIGHTS.

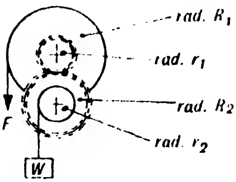
$$L = \frac{W_1 l_1 + W_2 l_2 + W_3 l_3 + \ldots}{F}$$

The Pulley.

(v_1 = velocity of point of application of force F, v_2 = velocity of weight W.)



Case I



Case II

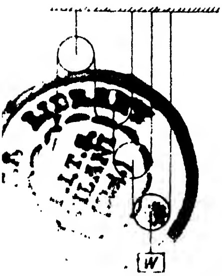
Case I.—2-diameter pulley.

$$F = \frac{Wr}{R}.\quad v_2 = \frac{v_1 r}{R}.$$

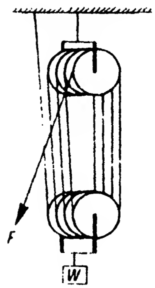
Case II.—2-diameter geared pulleys.

$$F = \frac{Wr_1r_2}{R_1R_2}.$$

$$v_2 = v_1\frac{r_1r_2}{R_1R_2}.$$



Case III



Case IV

Case III.—Compound single pulleys.

n = no. of movable pulleys.

$$F = \frac{W}{2^n}.\quad v_2 = \frac{v_1}{2^n}.$$

Case IV.—Movable multiple pulley.

n = no. of pulleys in movable block.

$$F = \frac{W}{2n}.\quad v_2 = \frac{v_1}{2n}.$$

Coefficient of Friction.

Definition.—The coefficient of static friction between two solid surfaces is the ratio of the tangential force required to produce relative sliding movement to the reaction between the surfaces

Owing to the variation in friction with the condition of the rubbing surfaces, and the contact pressure, it is impossible to specify accurate values without individual experiments. The following approximate values are those generally accepted:

Surfaces.	Coefficient of Friction.
Dry masonry on brickwork	0·6–0·7
Masonry on dry clay	0·5
Masonry on wet clay	0·3
Earth on earth	0·25–1·0
Timber on stone	0·4
Timber on timber	0·5–0·2
Timber on metals	0·6–0·2
Iron on stone	0·7–0·3
Metals on metals (dry)	0·25–0·15
Oiled metal surfaces	0·2–0·1

Once movement has begun, the coefficient of friction usually falls slightly. The following addition values are given for sliding friction:

Surfaces.	Coefficient of Friction.
Rubber on asphalt (wet)	0·25–0·75
" " " (dry)	0·5–0·8
Rubber on concrete (wet)	0·45–0·75
" " " (dry)	0·6–0·85
Brake lining on metal	0·3–0·7

These values fall with increase of rubbing speed. The value of the coefficient of friction may exceed unity.

DYNAMICS.

Definitions.

Mass is the amount of matter in a body.

Weight is the force exerted on the mass of a body by gravity.

Velocity is the distance travelled per unit time.

Acceleration is the increase of velocity per unit time.

Momentum is the product of mass and velocity.

Force is the product of mass and acceleration, thus force is the time-rate of increase or loss of momentum.

If the equation 'force = mass × acceleration' is to hold when force is expressed in pounds weight, mass must be expressed in *slugs*, or $\frac{\text{pounds mass.}}{g}$

Moment of Inertia or *Second Moment.*—If m_1, m_2, etc., are the masses of the particles composing the body, and r_1, r_2, etc., their perpendicular distances from the axis, the moment of inertia about the axis is

$$(m_1r_1^2 + m_2r_2^2 + \ldots .)$$

Radius of Gyration or *Swing Radius.*—The distance from the axis of rotation at which the whole mass of a body must be concentrated so that the moment of inertia will be unchanged.

Thus $$(\text{Radius of gyration})^2 = \frac{\text{moment of inertia}}{\text{mass}}.$$

Motion under Gravity.

Type of Motion.	Velocity (v).	v^2 (at distance s)	Distance Travelled (s).
Motion under gravity from rest	gt	$2gs$	$\frac{1}{2}gt^2$
Motion under gravity, with initial *downward* velocity V.	$V + gt$	$V^2 + 2gs$	$Vt + \frac{1}{2}gt^2$
Motion under gravity, with initial *upward* velocity V.	$V - gt$	$V^2 - 2gs$	$Vt - \frac{1}{2}gt^2$

g = acceleration due to gravity (= 32·2 feet per second per second).
t = time from beginning of motion.

THE PENDULUM.

(1) Simple Pendulum.

Definition.—A weight concentrated at one end of a weightless string, the other end of which is fixed.

If l = length of string in ft.

g = acceleration due to gravity (ft. per sec. per sec.).

Time for a complete oscillation (to and fro)

$$= 2\pi\sqrt{\frac{l}{g}} \text{ sec.}$$

$$= \text{period of oscillation} = \frac{1}{\text{frequency of oscillation}}$$

If L is the latitude of the point of observation, the length of the simple pendulum with a period of 1 sec. (in ins.) is

$$= 39{\cdot}0265 + 0{\cdot}1608 \sin^2 \text{L}.$$

Values of g and l in Various Localities.

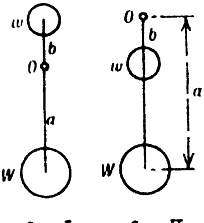
g in cm. per sec. per sec.; l in cm.

Place.	Latitude.	g.	l.
Equator	0	978·1	99·103
Greenwich	51° 29′	981·17*	99·413†
Paris	48° 50′	980·94	99·39
Berlin	52° 30′	981·25	99·422
Dublin	53° 21′	981·32	99·429
Glasgow	55° 52′	981·44	99·442
Edinburgh	55° 57′	981·54	99·451
North Pole	90°	983·11	99·61

* Equals 32·1902 ft. per sec. † Equals 3·2615 ft.

(2) Compound Pendulum.

Definition.—A rigid body suspended at a horizontal axis under the influence of gravity.



Case I *Case II*

If O is the centre of suspension, length of equivalent simple pendulum

$$= \frac{Wa^2 + wb^2}{Wa - wb}. \quad \text{(Case I.)}$$

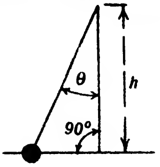
$$= \frac{Wa^2 + wb^2}{Wa + wb}. \quad \text{(Case II.)}$$

$$= \frac{\text{moment of inertia about centre of suspension}}{\text{mass} \times \text{distance of C.G. from centre of suspension}}.$$

The *Centre of Oscillation* is the point at which if all the mass were concentrated, the period of oscillation would be unchanged. Thus the length of the equivalent simple pendulum is the distance between the centres of suspension and oscillation, which are interchangeable.

(3) Conical Pendulum.

Definition.—A heavy particle suspended from a fixed point and made to move in a horizontal circle at constant speed.



If h = height in feet,
and g = gravity in feet per sec. per sec.

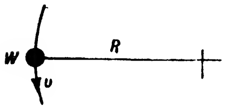
Period of revolution $= 2\pi \sqrt{\frac{h}{g}}$ sec.

i.e. period is independent of length of suspending rod or string.

CENTRIFUGAL FORCE.

Definition.—The radial force acting on a body travelling on a curve, due to the tendency of the body to continue travelling in a straight line.

Centrifugal Force acting on a Concentrated Mass.

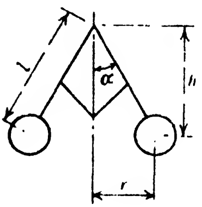


Velocity on curve $= v$; radius of curvature $=$ R.

Centrifugal force $= \mathrm{F} = \frac{\mathrm{W}v^2}{g\mathrm{R}}$ lb.

If n = revolutions per minute,

$$\mathrm{F} = \frac{\mathrm{WR}n^2}{2933} \text{ lb}$$



The Centrifugal Governor.

$$\text{R.P.M.} = n = \frac{60}{2\pi}\sqrt{\frac{g}{h}} = \frac{54{\cdot}16}{\sqrt{l \cos \alpha}}.$$

$$h = \frac{2933}{n^2}.$$

Centrifugal Tension.

n = R.P.M.

Circumferential tension in a hoop $= mv^2 = m\omega^2 r^2$,

where m is the mass of unit length; v its linear velocity;
ω its angular velocity (same for all particles);
r its radius.

Body.		Centrifugal Tension (in Lb.). W = mass in lb.
	Ring about centre.	$\frac{\mathrm{W}n^2 \ (\mathrm{R}^2 + r^2)}{4150}$

CENTRIFUGAL TENSION—*cont.*

Body.		Centrifugal Tension (in Lb.). W = mass in lb.
	Disc about centre.	$\frac{Wn^2R}{4150}$
	Cylinder about diameter of one end.	$\frac{Wn^2\sqrt{4l^2+3r^2}}{10260}$

IMPACT OF BODIES.

Mass of the two bodies = M and m.

Velocities before and after impact = V and v, V′ and v' respectively.

1. *Inelastic Bodies.*—(v' = V′, no separation after impact).

$$v' = \frac{MV + mv}{M + m}.$$

2. *Elastic Bodies.*—(K = coefficient of restitution between the bodies, i.e. $v' - V' = K(V - v)$)

$$V' = \frac{V(M - Km) + vm(1 + K)}{M + m},$$

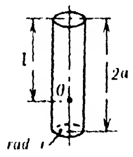
$$v' = \frac{v(m - KM) + VM(1 + K)}{M + m}.$$

(N.B.—The velocities must be taken as positive in one direction and negative in the opposite direction. The above formulæ cover all cases if this rule is observed.)

CENTRE OF PERCUSSION.

Definition.—When a body receives a blow on a line passing through the centre of percussion, the resulting motion is purely one of translation and not rotation.

Cylinder suspended at one end.



Centre of percussion is at O, where

$$l = \frac{4a}{3} + \frac{r^2}{4a}.$$

If r is small, $l = \frac{4a}{3}$.

O is also the centre of oscillation (see p. 23).

WORK AND ENERGY.

Definitions.—1. The *work* done by a force is equal to the product of the force and the distance travelled by its point of application in the direction of the force.

2. (*a*) *Potential energy* is the energy possessed by a body in virtue of its position relative to some zero position.

(*b*) *Kinetic energy* is the energy possessed in virtue of its motion (either rotatory or translatory). Potential energy of a body of mass W lb. at height h feet above the zero position = Wh ft.-lb.

Translation.—If linear velocity is V ft. per sec., kinetic energy of body = $\frac{\frac{1}{2}WV^2}{g}$ ft.-lb.

Rotation.—If angular velocity is ω radians per sec., kinetic energy of body = $\frac{\frac{1}{2}I\omega^2}{g}$ ft.-lb.

(I = moment of inertia in lb. × ft.²)

RADIUS OF GYRATION AND MOMENT OF INERTIA FOR PLANE SECTIONS AND SOLID BODIES.

Moment of Inertia of plane section = area × (radius of gyration)².
Moment of Inertia of solid body = mass × (radius of gyration)².

PLANE SECTIONS.

Figure.		Radius of Gyration.	Moment of Inertia.
	Axis parallel to side B	$0{\cdot}289D$	$\frac{1}{12}BD^3$
	Axis perpendicular to plane of figure through centre	$0{\cdot}289\sqrt{B^2+D^2}$	$\frac{1}{12}(BD^3+DB^3)$
	Axis a diagonal	$0{\cdot}289S$	$\frac{1}{12}S^4$
	Axis a diagonal	$0{\cdot}228D$	$0{\cdot}0338D^4$
	Axis perpendicular to plane of figure	$0{\cdot}323D$	$0{\cdot}0676D^4$
	Axis a diameter.	$0{\cdot}25D$	$\frac{\pi D^4}{64} = 0{\cdot}0491D^4$
	Axis perpendicular to plane of figure	$0{\cdot}354D$	$\frac{\pi D^4}{32} = 0{\cdot}0982D^4$
	Axis	$0{\cdot}289\sqrt{\frac{BD^3-bd^3}{BD-bd}}$	$\frac{1}{12}(BD^3-bd^3)$

PLANE SECTIONS—*cont.*

Figure.		Radius of Gyration.	Moment of Inertia.
	Axis a diameter	$0.25\sqrt{D^2+d^2}$	$\frac{\pi}{64}(D^4-d^4)=0.0491(D^4-d^4)$
	Axis perpendicular to plane of figure	$0.354\sqrt{D^2+d^2}$	$\frac{\pi}{32}(D^4-d^4)=0.0982(D^4-d^4)$
Narrow ring (Mass = M) **Axis a diameter.**		$0.354\,D$	$\frac{MD^2}{8}$
		*Axis X.* $0.289\sqrt{\frac{2TD^3+bt^3}{2TD+bt}}$	$\frac{1}{12}(2TD^3+bt^3)$
		Axis Y. $0.289\sqrt{\frac{DB^3-2db^3}{DB-2db}}$	$\frac{1}{12}(DB^3-2db^3)$

General formula : For plane figures, the sum of the M.I. about two perpendicular axes through the centre of gravity, in the plane of the figure, is equal to the M.I. about an axis through the C.G., perpendicular to this plane (the polar M.I.).

SOLID BODIES.

(Specific gravity of material = S.)

Body.	Radius of Gyration.	Moment of Inertia
	$\frac{R}{1.414}$	$\frac{\pi l R^4 S}{2}$
Hollow cylinder, inner radius = r	$\sqrt{\frac{R^2+r^2}{2}}$	$\frac{\pi l(R^4-r^4)S}{2}$

SOLID BODIES—*cont.*

(Specific gravity of material = S.)

Body.		Radius of Gyration.	Moment of Inertia.
		$\sqrt{\frac{4l^2+3R^2}{12}}$	$\frac{\pi R^2 l(4l^2+3R^2)}{12}.S$
When R is small (thin rod)		$0{\cdot}5775\,l$	$\frac{\pi R^2 l^3}{3}.S$
		$\sqrt{\frac{l^2+3R^2}{12}}$	$\frac{\pi R^2 l(l^2+3R^2)}{12}.S$
When R is small (thin rod):		$0{\cdot}2887\,l$	$\frac{\pi R^2 l^3}{12}.S$
	Spherical shell	$0{\cdot}8165\,R$	Mass $\times \frac{2R^2}{3}$
	Solid sphere	$0{\cdot}6324\,R$	$\frac{8\pi R^5}{15}.S$
Thick spherical shell Inner radius = r		$0{\cdot}6324\sqrt{\frac{R^5-r^5}{R^3-r^3}}$	$\frac{8}{15}\pi(R^5-r^5).S$
	About axis of cone	$0{\cdot}548\,R$	$\frac{\pi R^4 h}{10}.S$
	About a diameter of base	$\sqrt{\frac{2h^2+3R^2}{20}}$	$\frac{\pi R^2 h(2h^2+3R^2)}{60}.S$
	About an axis through vertex parallel to base	$\sqrt{\frac{12h^2+3R^2}{20}}$	$\frac{\pi R^2 h(12h^2+3R^2)}{60}.S$

SOLID BODIES—*cont.*

(Specific gravity of material = S.)

Body.		Radius of Gyration.	Moment of Inertia.
	About axis of conic frustum	$0\cdot348\sqrt{\frac{R^5-r^5}{R^3-r^3}}$	$\frac{\pi h}{10}\left(\frac{R^5-r^5}{R-r}\right).S$
	About a diameter of base	$k=\sqrt{\frac{h^2}{10}\left(\frac{R^2+3Rr+6r^2}{R^2+Rr+r^2}\right)+\frac{3}{20}\left(\frac{R^5-r^5}{R^3-r^3}\right)}$	$\frac{\pi h}{3}(R^2+r^2+Rr)\times k^2.S$
	Perpendicular axis through centre	$\sqrt{\frac{l^2+b^2}{12}}$	$abl\left(\frac{l^2+b^2}{12}\right).S$
	Perpendicular axis in plane of one end	$\sqrt{\frac{4l^2+b^2}{12}}$	$abl\left(\frac{4l^2+b^2}{12}\right).S$
	Perpendicular axis in plane of large end	$0\cdot204\sqrt{12l^2+B^2+b^2}$	$\frac{al(B+b)(12l^2+B^2+b^2)}{48}.S$

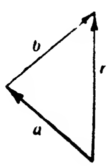
Rotation about an Axis at a Distance.

Moment of inertia = moment of inertia about a parallel axis through the centre of gravity + Mh^2, where M = mass and h = perpendicular distance from C.G. to axis of rotation.

VECTORS.

(*By J. D. W. Ball, A.M.I.C.E.*)

Vector quantities, as distinct from scalar quantities, have direction as well as magnitude, and are represented by straight lines of given length, in given directions, with arrow heads to denote their sense along the respective directions.



ADDITION OF VECTORS.

$$a + b = r$$

SUBTRACTION OF VECTORS.

A vector is said to be subtracted when it is added with its direction reversed.

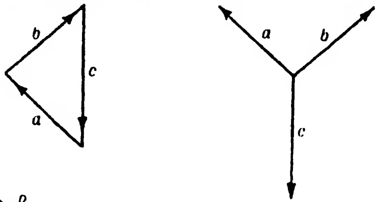
$$\text{If } c = -r$$

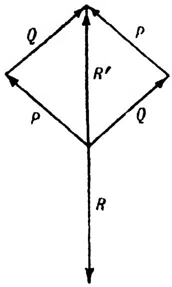
$$a + b - r = 0$$

$$a + b + c = 0$$

Triangle of Forces.

If three forces meeting at a point are in equilibrium, the forces can be represented in magnitude and direction by the sides of a triangle, the sides of which are parallel to the respective forces.



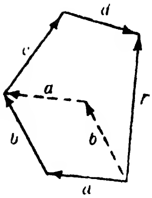


Parallelogram of Forces.

The vectors $P + Q + R = 0$

and $P + Q = - R = R'$

where R' is the resultant of P and Q. R' is the diagonal of the parallelogram of which P and Q are adjacent sides.



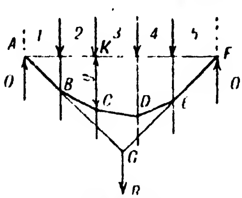
Polygon of Forces.

$$a + b + c + d = r$$

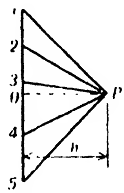
If $e = - r$

$$a + b + c + d + e = 0.$$

If a number of forces, acting at a point, be in equilibrium, the sum of their vectors = 0, or they may be represented in magnitude and direction by the sides of a closed polygon. It is immaterial in which order the vectors are added.



Link Polygon.

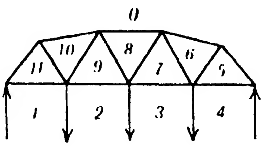


Vector Polygon.

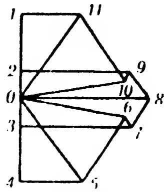
1, 2 ; 2, 3 ; 3, 4 and 4, 5 are a number of parallel forces, such as concentrated loads carried by a beam, the supports of which are 0, 1 and 5, 0.

The forces are represented to a convenient scale in the Vector Polygon, and a pole P selected at a convenient distance from the line of loads, representing, say 10 tons, to the same scale as that used in plotting the vertical loads. Join P1 and in the Link Polygon draw AB parallel to it. Join P2 and across the space marked 2 in the Link Polygon, draw BC parallel to it, and proceed in a similar way with P1, P4, and P5. Join AF and draw P0 parallel to it in the Vector

Polygon. Then 0, 1 and 5, 0 are the reactions at the supports. Produce AB and FE to meet at G, which marks the position of the resultant of the four forces considered. If GK measures *y* feet and the polar distance represents *h* tons, the bending moment at K is *hy* foot-tons.



Truss.



Force Diagram.

The above Force Diagram determines the forces in the members of the truss shown, due to loads applied at the lower chord. Set out the loads as in the previous example, and determine the reactions as there indicated, or by taking moments about one of the bearings. Draw 0, 11 parallel to the corresponding member of the truss, and 1, 11 parallel to the member thus designated in the lower chord. Then 0, 1, 11 is a triangle representing the three forces acting at the left abutment, i.e. the upward reaction 0, 1, the tension in the lower chord 1, 11, and the compression in the raker 11, 0. Draw 11, 10 parallel to the member marked 11, 10 and 0, 10 parallel to the upper chord member 0, 10. Then 0, 11, 10 is a triangle representing the three forces acting at the top of the raker. Draw 10, 9, parallel to the corresponding member, to meet 2, 9, drawn parallel to the lower chord. Then 9, 10, 11, 1, 2, is a polygon, the sides of which represent the four forces acting at the panel point next the abutment on the lower chord. By proceeding in a similar manner the diagram is completed as shown.

The Geometrical and Inertial Properties of Squares, Octagons, Hexagons and Circles.

(By C. L. T. Griffith, late Professor of Civil Engineering, Madras.)

The following tables contain a comprehensive set of factors relating to squares, octagons, hexagons and circles. Octagons and hexagons occur in some cases of engineering practice in steel and wooden shafts, concrete and brick chimneys, and in foundations.

The size of a square, an octagon or of a hexagon may be determined or described in four different ways, as :—

(1) The width across flats, F.
(2) The width across corners, C.
(3) The length of the side or edge, E.
(4) The area of the figure, A.

Table I gives each of these measurements in terms of the other three.

Table II gives the Moments of Inertia about an axis passing through the centre of the figure in terms of F, C, E and A; to which has been added the Moment of Inertia of a circle in terms of its diameter, D, and its area, A. For all these four figures the Moment of Inertia is invariable for any axis passing through the centre, in the plane of the figure.

Table III gives the Radii of Gyration, ρ, and their squares, ρ^2, in terms of the four systems of measurement. Here also the ρ's are invariable, or, in other words, the ellipse of gyration is a circle.

Table IV shows the 'neutral axis distance,' *n* (sometimes written *y*), and the same thing as 'the distance of the extreme fibre,' and is the maximum distance of the boundary of the figure measured perpendicularly from the neutral axis. These dimensions depend on the direction of the neutral axis, and are given for two cases, first, when the neutral axis is parallel to two of the sides of the figure, and second, when the neutral axis is perpendicular to the line joining two corners.

Table V gives certain 'core' or 'kern' distances, *q*. The core of a section is that small area in the centre of the section, hatched in the illustrations, within which the centre of pressure must pass to comply with the condition that no tension exists in any part of the cross section. As regards squares and rectangles this is often loosely referred to as 'the middle third'; but it is not always realised that the middle third is a diamond, and that the 'third' (of the side) is measured across corners. In the case of squares, a deviation of the centre of pressure towards the corner of the square must be 29 per cent. less than the permissible deviation towards the middle of a side if the condition of no tension is to be complied with.

Table VI gives factors for finding the dimensions of octagons and hexagons the areas of which equal the area of a circle of diameter D.

Hollow Squares, Octagons, Hexagons and Circles.

For these hollow figures the areas and moments of inertia are the *differences* between the I's and A's of the external and internal figures, the wall thicknesses being uniform all round.

The *squares* of the radii of gyration are the *sum* of the g^2's of the outer and inner figures. Hence, the radius of gyration of a hollow octagon

$$= 0\cdot257\sqrt{F^2 + f^2},$$

where F is the external, and f the internal, width across flats.

The neutral axis distances are, of course, those of the external figure.

The core distances for hollow figures, like the radii of gyration, are larger than those of solid figures of the same outside size, and can be obtained from the fact that the core distance equals g^2 divided by n, the neutral axis distance. Or we may use the factors given in Table V, and replace F, C, E, D and A by

$$\frac{F^2 + f^2}{F}, \frac{C^2 + c^2}{C}, \frac{E^2 + e^2}{E}, \frac{D^2 + d^2}{D} \text{ and } \frac{A + a}{\sqrt{A}} \text{ respectively}$$

Table I.—The Ratios of F, C, E and A to Each Other.

The following table gives the useful effect of men and animals employed in the horizontal transport of burdens. The second and third columns give the useful effect, viz. the product of the weight in lbs. and the distance in feet. This must not be mistaken for the units of work done by the agent, the agent being employed *not* in raising the weight, but in overcoming the passive resistances, friction, etc., which depend on the weight indeed, but are only a *fraction* of it.

USEFUL EFFECT OF AGENTS EMPLOYED IN THE HORIZONTAL TRANSPORT OF BURDENS.

Agent.	Daily Duration of Work in Hours.	Useful Effect Daily.	Useful Effect per Minute.	Weight transported.*	Velocity. Feet per Min.	Velocity. Miles. per Hr.
Man walking on a horizontal road without burden, i.e. transporting his own weight . .	10·0	25,398,000	42,330	145	292	3·32
Labourer transporting materials in a truck on two wheels, returning with it empty for a new load	10·0	13,025,000	21,710	220	99	1·12
Do. in a wheelbarrow . .	10·0	7,815,000	13,030	130	160	1·14
Labourer walking with a weight on his back	7·0	5,470,000	13,030	90	145	1·64
Labourer transporting materials on his back and returning unburdened for a new load .	6·0	5,087,000	14,110	145	97	1·10
Do. on a handbarrow . .	10·0	4,298,000	7,160	110	65	0·74
Horse transporting materials in a cart, walking, always laden	10·0	200,582,000	334,300	1,500	223	2·53
Do. trotting	4·5	90,262,000	334,300	750	44	5·06
Do. transporting materials in a cart returning with the cart empty for a new load . .	10·0	109,408,000	182,350	1,500	121	1·38
Horse walking with a weight on his back	10·0	34,385,000	57,310	270	212	2·41
Do. trotting	7·0	32,092,000	76,410	180	424	4·82

* Exclusive of the weight of the barrow, truck, cart, etc.

In advocating the employment of mechanical tractors on the farm, *Modern Farming* states that the horse eats annually the product of five acres. According to Edison, the efficiency of the horse is about 2 per cent.

DATA ON MAN-POWER.

The mean effect of the power of a man, unaided by a machine, working to the best practicable advantage, is the raising of 70 lbs. 1 foot in a second, for 10 hours in a day.

Two men, working at a windlass with the handles at right angles to each other, can raise 70 lbs. more easily than one man can 30 lbs.

A man of ordinary strength exerts a force of 30 lbs., for 10 hours in a day, with a velocity o 2½ feet per second = 4,500 lbs. raised 1 foot in a minute = 0·2 of the work of a horse.

A man can travel, without a load, on level ground, during 8½ hours a day, at the rate of 3·7 miles an hour, or 31½ miles a day. He can carry 111 lbs. 11 miles in a day.

A porter going short distances, and returning unloaded, can carry 135 lbs. 7 miles a day. He can transport, in a wheelbarrow, 150 lbs. 10 miles in a day.

WEIGHT OF CROWDS.

Experiments carried out by Professor L. J. Johnson, of Harvard University, show that it is possible for this to reach the high figure of 181·3 lbs. per square foot of floor surface. If the crowd jumps, the apparent load may be 50 per cent. more than the steady load, and running four abreast will show a similar result. A weight of 140 lbs. per square foot is quite possible where there are throngs of people; while a load of 80 lbs. per square foot is quite common in buildings and private houses where social gatherings are frequent, and a maximum of 40 lbs. or 45 lbs. is far short of what actually does prevail.

Some experiments carried out in America show that a crowd of men pushing against a balustrade may exert a horizontal pressure of 168 lbs. per foot run when they are three deep.*

COSTS AND CAPACITIES OF VARIOUS METHODS OF TRANSPORT.

Transport Unit.	Load.	Total Daily Mileage Capacity.	Total Daily Mileage Laden.	Capacity in Ton-Miles a Day.	Charges per Ton-Mile.	Gross Daily Takings.
Porters	60 lb.	15	Assumed always laden	0·4	5*s*. to 1*s*. 6*d*.	2*s*. to 7*d*.
Pack animals	200 to 400 lb.	24	12 to 18	1 to 3	5*s*. to 2*s*.	5*s*. to 6*s*.
Animal-drawn vehicles	1 to 5 tons	16	8 to 12	8 to 60	1*s*. 6*d*. to 9*d*.	12*s*. to 2*l*. 5*s*.
Mechanical pneumatic-tyred wheeled vehicles	½ to 1 ton	80	40 to 60	20 to 60	2*s*. 6*d*. to 1*s*. 6*d*.	2*l*. 10*s*. to 4*l*. 10*s*.
Roadless vehicles	1 to 2 tons	70	35 to 50	35 to 100	1*s*. 6*d*. to 1*s*.	2*l*. 12*s*. 6*d*. to 5*l*.
Roadless vehicles	2 to 5 tons	60	30 to 45	60 to 225	1*s*. to 8*d*.	3*l*. to 7*l*. 10*s*.
Roadless vehicles	5 to 20 tons	60 to 40	30	150 to 600	8*d*. to 4*d*.	5*l*. to 10*l*.
Roadless vehicles	20 to 200 tons	40 to 32	20 to 24	400 to 4,800	4*d*. to 2*d*.	6*l*. 13*s*. 4*d*. to 40*l*.
Arterial railway goods trains	200 to 500 tons	150 to 300	75 to 225	15,000 to 112,500	2*d*. to 1*d*.	125*l*. to 468*l*. 15*s*.

NOTE.—The column of total daily mileage is based on no-return loads as a minimum up to half-return loads as a maximum.

(*Philip Johnson; paper read at a Joint Meeting of Section G (Engineering) and Section F (Economics) at the Southampton Meeting of the British Association, August* 31, 1925.)

DATA ON HORSE-POWER.

A horse can travel 400 yards, at a walk, in 4½ minutes; at a trot, in 2 minutes; and at a gallop, in 1 minute. A draught horse can draw 1,600 lbs. 23 miles a day, weight of carriage included. The ordinary work of a horse may be stated at 32,500 lbs., raised 1 foot in a minute, for 8 hours a day. In a horse-mill a horse moves at the rate of 3 feet in a second; the diameter of the track should not be less than 25 feet. The strength of a horse is equivalent to that of 5 men.

TABLE OF THE AMOUNT OF LABOUR A HORSE OF AVERAGE STRENGTH IS CAPABLE OF PERFORMING, AT DIFFERENT VELOCITIES, ON CANALS, RAILROADS, AND ROADS.

Velocity per Hour.	Duration of Work.	Useful Effect for 1 Day, drawn 1 Mile.			Velocity per Hour.	Duration of Work.	Useful Effect for 1 Day, drawn 1 Mile.		
		On a Canal.	On a Railroad.	On a Road.			On a Canal.	On a Railroad.	Road.
Miles.	Hours.	Tons.	Tons.	Tons.	Miles.	Hours.	Tons.	Tons.	Tons.
2½	11·5	520	115	14·0	6	2·000	30·0	48·0	6·0
3	8·0	243	92	12·0	7	1·500	19·0	41·0	5·1
4	4·5	102	72	9·0	8	1·125	12·8	36·0	4·5
5	2·9	52	57	7·2	10	0·750	6·6	28·8	3·6

A horse in a mill can produce an effect of 106 lbs., at a velocity of 3 feet in a second, for 8 hours in a day. A mule can produce, under a like velocity and time, an effect of 71 lbs.; and an ass, 37 lbs.

An ox, walking at a velocity of 2 feet in a second (1·34 miles per hour), will exert a pull of 154 lbs. for 8 hours in a day.

The draught of man and animals by traces is as follows:

Man, 150 lbs. Horse, 600 lbs. Mule, 500 lbs. Ass, 360 lbs.

* *Engineering News-Record*, Vol. 94, No. 5 (1925), p. 200.

A man rowing a boat 1 mile in 7 minutes performs the labour, while rowing, of 6 fully-worked labourers at ordinary occupations of 10 hours.

Labour upon Embankments.

Single Horse and Cart.—A horse with a loaded dirt-cart, employed in excavation and embankment, will make 100 lineal feet of trip, or 200 feet in distance per minute, while moving. The time lost in loading, dumping, awaiting, etc. = 4 minutes per load.

A medium labourer will load with a cart in 10 hours, the following earths, measured in the bank:

Gravelly Earth, 10; *Loam*, 12; *Sandy Earth*, 14 cubic yards.

Carts are loaded as follows; *Descending Hauling*, ⅓ of a cubic yard in bank; *Level Hauling*, ¼ of a cubic yard in bank; *Ascending Hauling*, ⅕ of a cubic yard in bank.

Loosening, etc.—In *Loam*, a three-horse plough will loosen from 250 to 800 cubic yards per day of 10 hours.

Power Required for Ploughing.

$$\text{Horse-power} = \frac{rwdv}{375}$$

where,

r = soil resistance in lbs. per sq. in.; w = total width in ins. of all furrows ploughed at once d = depth of furrows in ins.; v = speed of travel in miles per hour.

The quantity rwd is the draught of the plough, and at steady speeds it equals the pull exerted at the draw-bar of the tractor of the haulage rope.

The soil resistance r varies according to the type and condition of the soil. It is measured in lbs. per sq. in. of furrow cross-section, and may vary as much as 40 per cent. in one field.

Values of r are as follows :—

Type of Soil.	Sandy.	Sandy Loam.	Light.	Dry Clay Loam.	Heath Land.	Heavy Clay Sod.	Heavy Loam.	Firm Clay.
r	3	3–6	5–7	7–8	8·8	10–11	12	16

The 'angle of hitch' is most important. When the hitch is not correct vertically, either the share digs into the ground too deeply or does not penetrate at all.

A re-pointed and re-sharpened share will show a less draught than a dull one, while a new one may reduce the draught by 36 per cent. over the re-sharpened one.

Experiments carried out at Rothamsted indicated that the speed of ploughing could be considerably increased without proportionately increasing the draught. In fact, an increase of speed of from 1 to 2½ m.p.h., or 150 per cent., increased the draught by 14·5 per cent.

It was found that the draught in heavy clay could be reduced some 15 per cent. by chalking the soil.

(*R. Borlase Matthews.*)

See also 'Electricity in Agriculture' Section XXVI.

2. MECHANICAL POWER.

Mechanical power may be determined by measuring either a *force* or a *torque*, the second being the more common method.

POWER EXPENDED BY A FORCE.

$$\text{Horse-power} = \frac{\text{force (in lbs.)} \times \text{distance travelled per minute (in feet)}}{33{,}000}.$$

POWER EXPENDED BY A TORQUE.

$$\text{Horse power} = \frac{\text{torque (in lb.-feet)} \times 2\pi \times \text{R.P.M.}}{33{,}000}.$$

I. *Dynamometers measuring a Force.* (Traction or drawbar dynamometers.)

(*a*) *Spring Type.*—A coil or laminated spring is incorporated so that its deformation is a measure of the force transmitted by the drawbar. Previous calibration is necessary.

The spring dynamometer has the disadvantage of needing heavy damping. Mechanical multiplication is used to give a more open scale on the indicator. The type is useful when there are no sudden variations of load.

(*b*) *Hydraulic Type.*—The force is transmitted through a piston to fluid in a cylinder and measured as a fluid pressure on a gauge. The force is deduced from the pressure either directly by multiplying it by the piston area, or by a calibration.

Dynamometers of this type include:

(i) The *Hyatt* dynamometer, which uses a rubber bag connected to a recording Bourdon gauge with a radial chart.

(ii) The *Amsler* traction dynamometer, which has a ground and polished piston and cylinder with a coil spring pressure indicator giving a cylindrical chart.

(iii) The *Watson* traction dynamometer, based on an experimental dynamometer designed at the National Physical Laboratory, which uses a steel cylinder and plunger and a remote steam engine type pressure indicator.

(*c*) *Pendulum Type.*—The force to be measured is balanced by the restoring force on a pendulum. This type is often used on dynamometer cars to measure the work done by the locomotive, when it is known as an ergometer. The tangent of the angle made by the pendulum with the vertical is proportional to the algebraic sum of the force of gravity and the force causing acceleration or retardation on the track.

(*d*) *Strain Gauge Type.*—A steel tension bar is fitted with electrical strain gauges, which may be of the induction (moving coil or moving iron) or the resistance type. The gauges are connected either to an indicating milli-ammeter or an oscillograph (Duddell or Cathode Ray). Thus inertia effects due to the dynamometer itself are avoided, since the natural frequency of the deformed element of the dynamometer is high.

Speed-Recording Device.

The ordinary type of centrifugal speedometer is not accurate enough for use with a traction dynamometer. The method used is to record the distance travelled in a known time, by connecting the recording drum to a roadwheel and causing a pen to draw a continuous line with sideways kicks at known time intervals, the pen being worked magnetically or by clockwork.

Rail Dynamometer Cars.

These are used for traction tests on locomotives and resistance tests on rolling stock. They are usually interposed between the locomotive and the train and are fitted with facilities for measuring drawbar pull, buffer thrust, speed, and work done by the prime mover, as well as boiler pressure, flue gas analysis, etc.

The dynamometer is usually of the spring type, but sometimes hydraulic. The recording drum usually integrates the pull with respect to distance, giving a measure of the work done. An 'ergometer' (see above) is also fitted to measure work done in acceleration and deceleration.

II. *Dynamometers measuring a torque.*

These consist of:

(*a*) The *transmission or shaft type*, interposed between the prime mover and the driven apparatus and (*b*) the *absorption type*, where all the power measured is converted to heat or electrical energy.

Transmission or *shaft dynamometers* are chiefly useful where the power to be measured is so large that an absorption dynamometer would be wasteful or inconveniently large. They may be classed either as *torsion meters*, measuring the torque by means of the elastic twist of the shaft, or as direct *torque meters*, measuring the driving force at a given radius from the shaft centre.

(*a*) *Torsion Meters.*—These consist essentially of two sleeves concentric with the shaft and attached to it at opposite ends of the length over which the twist is measured.

(i) The *Föttinger* torsionmeter multiplies the twist by levers and records it on a drum concentric with the shaft. This instrument shows variations in torque during each separate revolution.

(ii) The *Hopkinson-Thring* torsion meter (see fig. 1) uses two mirrors attached to the ends of the test length of shaft, which successively reflect a beam of light on to a fixed scale. The distance between the two spots illuminated on the scale is a measure of the twist. The instrument is callibrated by applying a known twist to the shaft, or by calculation from the elastic constants of the shaft.

(iii) The *Bevis-Gibson* torsionmeter passes a beam of light parallel to the shaft through radial slits in two discs fixed at the ends of the test length. The twist is read off by a 'finder,' consisting of an eye-piece which can be moved circumferentially round the shaft. The finder is rotated until the beam of light, interrupted owing to the twist, is again visible. The movement of the finder measures the twist.

(iv) The *Amsler* torsionmeter has two discs, one attached to each end of the shaft, which are illuminated by a spark synchronised with the rate of revolution, so that reference scales on the discs appear to stand still and can be read off with a telescope.

(v) *Electrical* torsion meters may be of the condenser, induction, or resistance strain gauge type. In the first type, twist of the shaft varies the capacity of a condenser; in the second, the inductance of a pair of coils is changed; the resistance type has resistance elements attached to the shaft so as to indicate torsional strain. The Siemens torquemeter is a good example of the electrical type.

(b) *Direct Torque Meters* work by measuring the driving force at a fixed radius either by means of springs, by hydraulic pressure, by a system of levers connected to a jockey weight or pendulum, or by the difference in tension between the tight and slack sides of a driving belt. A correction is usually needed to allow for the centrifugal force on the mechanism, and it is best to calibrate this type against an absorption dynamometer.

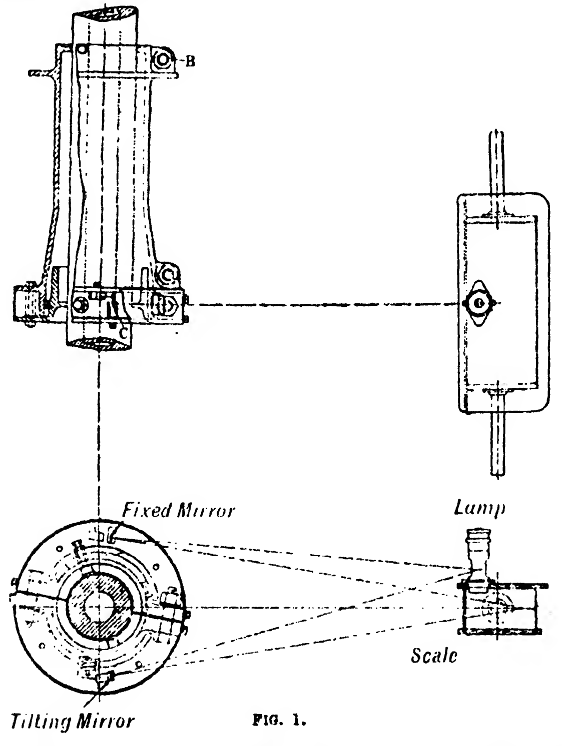

FIG. 1.

(i) The *Ayrton-Perry* torquemeter consists of two parallel discs on the ends of the driving and driven shafts, connected by three tangential coil springs, whose deformation under load causes relative twist between the discs. This is multiplied by a lever system so as to give a radial displacement of a bright bead observed against a graduated dark disc.

(ii) The *Amsler* hydraulic torquemeter works similarly to the above, the coil springs being replaced by oil cylinders connected by an axial hole in the shaft to an indicator of the steam engine type.

(iii) A simple type of torquemeter useful when the driven shaft is parallel to the driver but at a distance from it is one developed at the National Physical Laboratory for use with an abrasion testing machine. Here an idler gear is interposed between gears on the two shafts and the sideways thrust is measured by a weighted lever extension on the idler housing (see fig. 2). The thrust is approximately double the load at the pitch circles of the driving and following gears. (See N.P.L. Annual Report for 1932, p. 181.)

(iv) The *Thornycroft* or *Froude* belt dynamometer uses two pulleys interposed between the driving and driven pulleys and arranged on a swinging frame with a lever arm carrying weights which balance the belt tension.

(v) *Bailey and Bowers'* torquemeter is designed for light loads such as the drives of certain types of textile machinery. It operates by transmitting the torque through two concentric rings, relative motion of which is opposed by a pendulum connected through linkage.

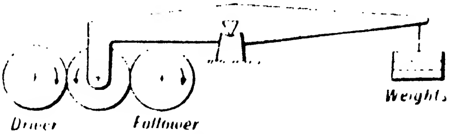

FIG. 2.

III. *Absorption Dynamometers (Brakes).*

Where the power to be measured is not inconveniently large, the absorption dynamometer is the most accurate means of measurement.

The power may be absorbed by solid friction, fluid (water or air) friction, or electrical resistance.

Solid Friction Brakes.

(i) *Hirn's or Kelvin's Rope Brake.* (For small powers.)—A band of rope encircles a pulley on the power shaft. One end of the rope holds a scale pan and the other is attached to a spring balance, as shown.

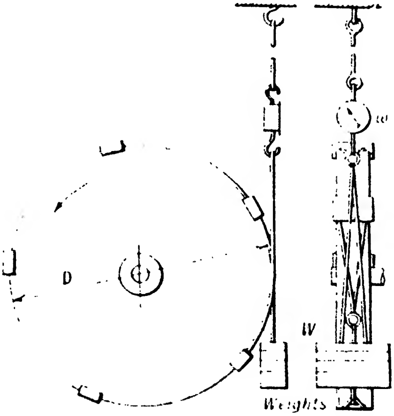

FIG. 3.

$$\text{B.H.P.} = \frac{(W - w) \times \pi DN}{33,000}$$

where W = weight on scale pan; D = diameter to centre of rope;
w = load on spring balance; N = R.P.M.

The arrangement shown has the advantage that an increase in friction tends to slacken the rope, giving stability.

(ii) *The Prony Brake.*—A couple of wooden blocks clipped upon the pulley or shaft transmitting the power to be indicated. The diameter D in the formula for Hirn's brake is, in the case of the Prony brake, double the radius R measured to the point of suspension of the pan.

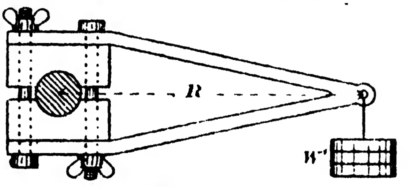

FIG. 4.

The difficulty with the Prony brake is the constant vibration of the weighted arm. The difficulty has been reduced at Purdue University by the addition of a pendulum lever weight, B, fig. 5, the quadrant of which may be divided by actual weight determination.

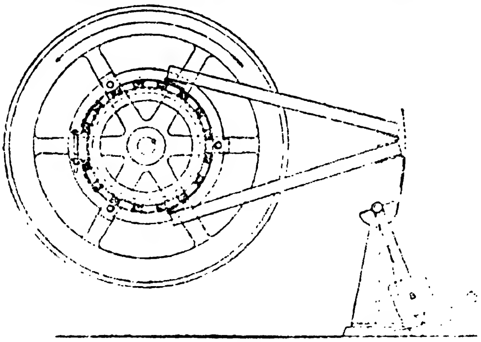

FIG. 5.

FIG. 6.

Fig. 6 shows a form of stabiliser which, it is stated, will damp down the vibrations to a very marked extent. Between the balance and the brake arm are placed in series a heavy weight A and a resilient coil spring B. The pointer of the balance is then set back to offset the initial force, or tare, exerted by the weight. When the motor being tested is in motion, the average torque is transmitted through the spring and suspended weight, and is accurately indicated on the dial of the balance. The momentary vibrations, however, are not of sufficient duration to move the weight, and their motion is dissipated by the auxiliary spring. By employing this type of stabiliser, an oil dashpot may be dispensed with entirely, and readings of a high degree of accuracy may be obtained.

(iii) *The Balk Brake.*—Many methods have been used to compensate for variations in the friction coefficient between the brake blocks and wheel. In the Balk brake (see fig. 7) the tightness of the band is controlled by a compensating lever A with a suspended weight, working between fixed stops X-X. An increase in friction causes the band to carry the lever downwards on to the lower stop; it then rotates clockwise and slackens the band by causing B to move upwards relative to C. A fall in friction causes the opposite effect.

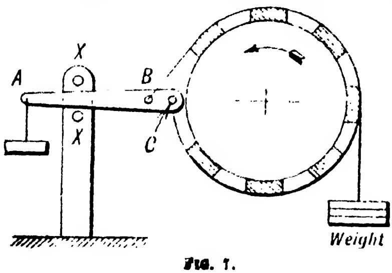

FIG. 7.

Cooling Brake Rims.

In many cases the inside of a brake rim is of trough form (fig. 8), which will hold water when revolving, by virtue of the centrifugal action. The trough being filled with water is kept to (at most) 212° F. by the evaporation of the water, which is kept constantly running into the rim in a small stream.

Another means of cooling is to encircle a sheet-steel brake band with iron wire netting, which holds by capillary action water poured on it; this evaporates and cools the strap. Surplus water runs off at the bottom of the band.

Pullen's brake uses a white-metal brake lining with interior water cooling.

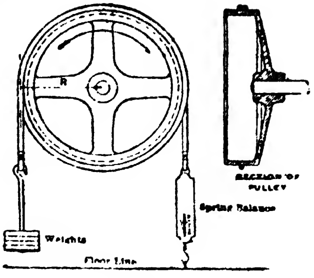

FIG. 8.

FLUID FRICTION BRAKES.

A simple fluid friction brake can be furnished by causing a series of metal discs to rotate in a water bath. The power absorbed at a given speed can be varied by altering the amount of water in the casing. Unsteady action due to splashing can be reduced by radial interior vanes on the casing; the reaction on the latter will then be equal to the resistance to rotation of the vanes, and can be measured by allowing the casing to swing about the shaft axis and balancing the torque by weights on a lever arm. This principle is used in the ' Brotherhood ' absorption dynamometer.

THE FROUDE HYDRAULIC DYNAMOMETER.

In the Froude Water Dynamometer the engine to be tested is directly coupled to the main shaft, transmitting the power to a rotor revolving inside a casing, through which water is circulated to provide hydraulic resistance and simultaneously to carry away the heat developed by absorption of power.

In each face of the rotor are formed pockets of semi-elliptical cross-section divided one from another by means of oblique vanes. The internal faces of the casing are also pocketed in the same way.

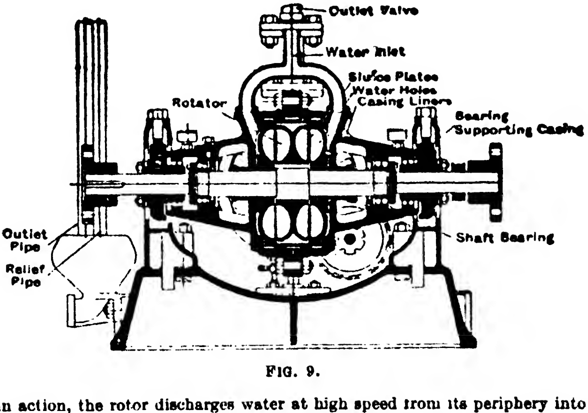

FIG. 9.

When in action, the rotor discharges water at high speed from its periphery into the casing pockets, by which it is then returned at diminished speed into the rotor pockets at a point near the shaft. Thus, the pockets in rotor and casing together form elliptical receptacles round which the water courses at high speed, creating vortices which dissipate the power of the engine as quickly as it is developed.

Hence the rotor causes a reaction on the casing, which endeavours to revolve, but is resisted by a weighing machine calibrated to read the power absorbed. Several types are made.

The Fan Dynamometer.

Owing to the important influence of atmospheric conditions and of environment, the fan brake is more frequently used for applying a load to a rotating shaft than for actually measuring the torque. The power unit is usually mounted on a swinging frame or 'reaction bench' and the torque is measured by a weighted lever on the frame.

The load is adjusted either by altering the radius of the vanes or by fitting vanes of a different size. Where the fan is to be used for measuring torque, the following constants and formulæ may be used:

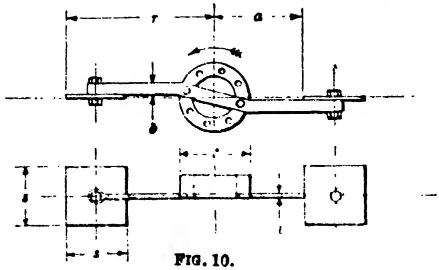

FIG. 10.

If

w = torque driving the fan in inch-lbs.; w_a = resisting torque due to the arms alone; w_b = resisting torque due to the blades alone; N = revs. per min. of the fan;

s = length of side of square blades or diameter of round blades in inches;

r, a, b, t, and c are other dimensions in inches;

W = density of the fluid in which the fan rotates, in lbs. per cubic foot,

$= 62\cdot33$ for water at 50° F. $= \dfrac{1\cdot317 \times \text{barometric pressure in in., for air}}{(460 + \text{temp. in °F.})}$

H.P. = horse-power absorbed by fan;

K = a coefficient depending upon the value of r/s and upon the shape of the blade; see values tabulated below for square and circular blades having square edges.

Values of r/s	2·5	3·0	3·5	4·0	4·5	5·0	5·5	6·0	6·5	9·0	12·0
$K \times 10^{-9}$ for circular blades	1·69	1·69	1·66	1·63	1·60	1·59	1·58	1·575	1·575	1·575	1·575
$K \times 10^{-9}$ for square blades	2·25	2·28	2·24	2·18	2·16	2·12	2·10	2·08	2·04	2·04	2·04

σ = a coefficient depending upon the ration b/t.

Values of b/t	2	3	6
Values of σ	1·3	0·94	0·62

then,

$$w_a = 0\cdot35 + 10^{-8}\sigma N^2 a^4 t W\,;\quad w_b = KN^2 r^3 s^2 W\,;\quad w = w_a + w_b{}^{*}\,;\quad \text{H.P.} = wN/63{,}000.$$

Notes on the Fan Dynamometer.

Care should be taken that the arms and fastenings are amply strong enough to withstand the centrifugal stresses. For reasonably accurate work, with fans rotating in air, one side of the fan should be completely free from obstruction for a distance of at least '3 r' inches from the

* For this relation to hold, t must be less than $s/7$.

plane of rotation, and on the other side 'O' should not exceed '*a*.' Also the floor should be distant at least '*r*' inches. The linear velocity of the centre of the blades must not exceed, say, 350 ft. per second. In order to compute W with accuracy, the barometric pressure, and the temperature of the air at the periphery of the fan should be taken. Fans rotating in water must have at least as much clearance around them as is specified above, and must not be rotated at such a speed as to produce cavitation. To facilitate work in the test-shop the '*H.P., Rev.' curves for each blade used should be plotted on logarithmic paper for some standard value of W. Since the H.P. varies approximately as N^3, N should be observed with great accuracy—a speedometer is usually not sufficiently accurate.

*See also Hodgson, *Proc. Inst. Automobile Engineers*, March 1916.

(*J. L. Hodgson.*)

ELECTRICAL DYNAMOMETERS.

1. *Generator Type.*—An electric generator may be adapted as a dynamometer, but this involves knowing its efficiency and electrical measuring instruments are needed. When high accuracy is not required, the method is sometimes economical, especially when the current generated can be used. Higher accuracy is obtained by mounting the generator field frame to swing freely about the shaft axis and measuring its reaction torque by a weighted lever. The electrical power is then absorbed by resistance mats. A suitable mounting may be obtained either by fitting ball-bearing trunnions to the bearing caps of the frame or by arranging the frame to swing in a cradle in which it rests on its base. The weight of the field frame must be balanced so as to be just stable when the torque is zero.

The range of power and speed available with the electric dynamometer is usually comparatively small, unless complicated auxiliary electrical equipment is provided, but this disadvantage is balanced in that the generator may be used as a motor to determine the power used in driving a machine.

2. *Eddy Current Type.*—A comparatively recent development (at any rate for high powers) is the eddy current or 'dynamatic' dynamometer, in which a magnetic field is set up by the action of a relatively small control current in the stator windings. A special rotor operating in this magnetic field provides the power-absorbing torque through the action of eddy currents, the energy being disposed of partly by air and partly by water cooling. This system has the advantage of providing high torque down to relatively low speeds.

REGENERATIVE OR POWER CIRCULATING SYSTEMS.

For testing gearboxes or transmissions it is economical to measure power losses by connecting output to input by a return circuit (either electrically or mechanically), and supplying only the power loss in the system from an outside source. The test load is varied either by inserting mechanical distortion in the circuit (*e.g.* belt slip or shaft torsion) or by Ward-Leonard control if the return circuit is electrical.

(For further information on power measurement, see Batson and Hyde, 'Mechanical Testing,' vol. ii, chaps. i-ix, also Drysdale, *Journ. Jun. Inst. Engineers.* (London), vol. 48, part ii, p. 499 (August, 1938), 'The Measurement of Mechanical Power.')

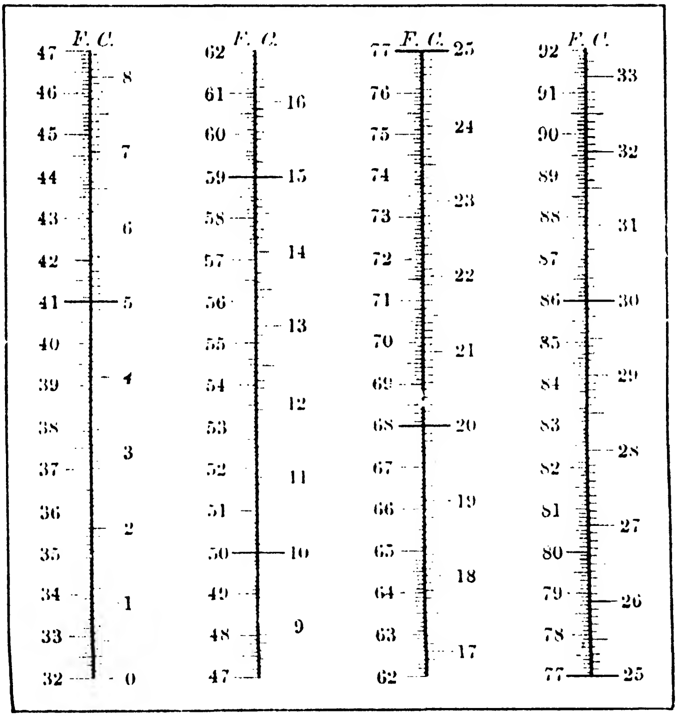
Temperature Scales.

The following three temperature scales are those most commonly in use :—

Scale.	Fahrenheit (F.).	Centigrade (C.).	Réaumur (R.).
Freezing point of water	32°	0°	0°
Boiling point of water.	212°	100°	80°

Thermometer Scale Conversion Chart.



(R. E. Gould American Bureau of Standards.)

Conversion Factors.

°C. contain °F.			°F. contain °C.		
1 = 1·8	4 = 7·2	7 = 12·6	1 = 0·56	4 = 2·22	7 = 3·89
2 = 3·6	5 = 9·0	8 = 14·4	2 = 1·11	5 = 2·78	8 = 4·44
3 = 5·4	6 = 10·8	9 = 16·2	3 = 1·67	6 = 3·33	9 = 5·00

$$°C = \frac{5}{9}(°F - 32°) = \frac{°F - 32°}{1·8} \qquad °F = \frac{9}{5}°C + 32° = 1·8° C + 32°.$$

Absolute Zero of Temperature.

Definition.—The temperature at which the pressure of a given mass of an ideal gas, maintained at constant volume, becomes zero.

Absolute zero is − 460° F. or − 273° C.

Freezing Temperatures.

Sea water, − 2·5° C., 27·5° F.; Mercury, − 38·8° C., − 37·8° F.; Acetone, − 95° C., − 139° F.; No. 1 motor spirit, − 128° C., − 198° F.

Flash Temperatures.

Dr. H. Holm finds that the temperature at which substances in contact with atmospheric air at ordinary pressures will catch fire are, among others:—Lighting gas, 600° C.; benzine, 415° C.; petroleum, 380° C.; gas oil, 350° C.; machine oil, 380° C.; coal tar, 500° C.; tar oil, 580° C.; and benzol, 520° C. These temperatures are greatly influenced by the presence of other substances, which act as catalysers. This is especially the case with hydrogen, methane, and ethane, not ethylene or acetylene. Among solids it is the substances with the biggest molecules which most readily burst into flame. As a broad rule, the nearer a substance is to a gaseous condition, the higher the temperature to which it must be exposed before it will kindle: but this depends also on the chemical constitution.

Freezing Mixtures.

Mixture.	Reduction in Temperature.	Mixture.	Reduction in Temperature.
1 part nitre 1 part sal ammoniac 2 parts water . .	40° F.; 22° C.	5 parts hydrochloric acid 8 parts crystallised sulphate of soda . .	50° F.; 28° C.
Equal parts crystallised nitrate of ammonia and water	46° F.; 25½° C.	2 parts powdered ice or fresh snow . . . . 1 part common salt .	a temperature of −4° F.; −20° C.
Equal parts crystallised nitrate of ammonia (powdered), crystallised carbonate of soda (powdered), and water	57° F.; 32° C.	3 parts crystallised chloride of calcium (cooled to 32°) . . . . 2 parts fresh snow . .	a temperature of −50° F.; −45·6° C.

Anti-freezing Mixtures.

Common Salt (Sodium Chloride).				Commercial Calcium Chloride.			
Lbs. per Gal.	Freezing Point, F.°	Lbs. per Gal.	Freezing Po F.°	Lbs. per Gal.	Freezing Point, F.°	Lbs. per Gal.	Freezing Point, F.°
½	24 above zero	2	6 above zero	½	29 above zero	3½	6 below zero
1	18 ,,	2¼	3 ,,	1	27 ,,	4	17 ,,
1¼	15 ,,	2½	1 ,,	1½	23 ,,	4½	27 ,,
1½	12 ,,	3	3 below zero	2	18 ,,	5	39 ,,
1¾	9 ,,	3½	8 ,,	2½	4 ,,	5½	54 ,,

The salt should be thoroughly dissolved, or the results will not be satisfactory. Calcium chloride is said to be superior to sodium chloride in that it does not corrode steel tanks and barrel hoops. Where calcium chloride is used, the wooden barrels should first be well coated inside with asphaltum, or a mixture of crude paraffin and resin, to prevent the shrinking of the staves and subsequent leakage.

Glycerine is recommended for use in chemical fire extinguishers. It has no effect upon metals, but has a tendency to disintegrate rubber. It has been stated, however, that the continued use of glycerine in water renders it liable to a decomposition that would develop compounds having a corrosive action on metals. The following proportions may be used:—

Glycerine, pounds per gallon . .	3½	5½	(One gall. of glycerine
Temp. solution will withstand . .	+ 10° F.	− 10° F.	weighs 10½ lbs.)

Denatured alcohol has advantages over both glycerine and calcium chloride, in water solutions, as it has no injurious effect on either metal or rubber. A solution of about 50 per cent. is inflammable, but it would rarely be necessary to have a solution of over 30 per cent.

A 20 per cent. solution freezes at	10° F.	A 40 per cent. solution freezes at	− 20° F.
30 " " "	− 5° F.	50 " " "	− 35° F.

Temperature of the Atmosphere

diminishes according to the height above the earth's surface. In the Temperate Zone a diminution of 1° C. corresponds in the mean to an ascent of 180 yards. As the mean of a series of observations made during balloon ascents, a diminution of 1° C. corresponded to an increase in height of 232 yards.

According to Kropotkin, the temperature above the earth's surface decreases 3° to 5° F. for each 1,000 ft. The average temperature at an altitude of 20,000 ft. is 13° below 0° F.; at 25,000 ft. it is 35° below 0° F.; these low temperatures prevail all the year round. The ratio of decrease in temperature, which is 3° F. for each 1,000 ft. at the lower strata, is twice as great at the highest levels, but varies from summer to winter to the extent of about 20° F.

The Mean Daily Temperature is that obtained by adding together twenty-four hourly observations and dividing by 24, the temperature being taken of the air, and not of the ground. The temperature of a month is the mean of those of thirty days, and the temperature of the year is the mean of those of twelve months. The mean temperature of London is 8·28° C., or 46·9° F.; the mean in summer is 62° F., and in winter 40° F.

Temperature of Seas and Lakes.

The temperature of the sea under the Torrid Zone is always about 26° to 27° C. at the surface; it diminishes as the depth increases, and in temperate as well as in tropical regions the temperature of the sea at great depths is between 2·5° and 3·5° C. The average winter temperature of the sea round the coast of England is higher than that of the land. The mean annual temperature of the surface of the sea round England is 49° F.; the mean surface temperature of the Indian Ocean is 89° F., and of the Red Sea 94° F. The temperature of lakes at their surface may be 20° to 25° C. in summer; the temperature of the bottom, 4° C., which is that of the maximum density of water. The Great Geyser, in Iceland, at a depth of 66 feet, has a temperature of 124° C.

Temperature of the Earth.

The average increase in temperature is 1° C. for every 27·4 metres of descent, which is at the rate of 100° F. per mile. Cordier says 1° C. for every 25 metres, or 1° F. in 45 feet.

Another statement is that the increase in temperature of the earth's strata shows a mean average for the entire earth surface of 1° F. for every 56 feet of depth.

Thermal and Other Properties of Gases, &c.

(*W. N. Booth.*)

In the tables, pages 56 to 59, are given many figures relative to the gases chiefly, which are of interest in questions of heat, combustion, and the gas engine. The figures are principally based on Berthelot's thermal determinations of the calorific capacity of the gramme molecule, the figure for which, if divided by the molecular weight, gives the heat generated per gramme of the substance. An attempt is made to give the correct values of the specific heat at high temperatures, with a view to the bearing of this property on the theory of the gas engine, and the possibly erroneous ideas as to the supposed effects of dissociation, which have been much overrated. The thermophysical properties of carbon are more fully tabulated than has hitherto been attempted, with a view to explain the variations due to allotropism.

Heat and Combustion.

There are in practice only two elementary fuels, carbon and hydrogen. They generate heat by union with oxygen, and their compounds are also available as fuels.

Heat is measured in units. The British thermal unit B.Th.U. is the amount of heat necessary to raise 1 pound of water from 60° F. to 61° F., and its mechanical equivalent is J = 778 pounds raised 1 foot in the latitude of Manchester.*

The metrical or French calorie is the amount of heat necessary to raise 1 gramme of water 1° C. This is the 'gramme calorie.' The kilogramme calorie is the heat necessary to raise 1 kilogram of water through 1° C. Its mechanical equivalent is 427 kilograms raised 1 metre at the

* The latitude need not be considered by engineers.

latitude of Paris; this latter refinement being unnecessary in engineering. The following table gives the ratios of English and French units:

1 Calorie = ·001 kilog. calorie.	1 B.Th.U. = 1055 joules = 778 foot-pounds (until recently the accepted value was 772).
1 kilog. calorie = 3·968 B.Th.U.	1 kilog. calorie = 3087·3 foot-pounds.
1 B.Th.U. = 0·252 kilog. calorie.	1 B.Th.U. = 107·6 kilog. metres.
1 kilog. calorie = 127 kilog. metres.	

Chemists use somewhat different terms and state calorific measurements in terms of the molecule. The gramme molecule of hydrogen is the unit employed. One gramme molecule of hydrogen, H_2, taken at 0° C. and 760 mm. of pressure of a mercury column, weighs 2 grammes and has a volume of 22·32 litres. The molecular weight of any other simple or compound gas is the weight which occupies the volume occupied by 2 grammes of hydrogen, that is 22·32 litres. The molecular specific heat of a gas is the heat of this volume in 'petit calories.' Then the molecular heat divided by the molecular weight will give the specific heat per unit weight or gramme; and the molecular heat divided by 22·32 will give the specific heat per unit of volume.

The specific heat of a gas is usually stated at constant pressure and at constant volume. In perfect gas the ratio of these two is about 1·4 at ordinary temperatures. This is an erroneous way of putting it. The difference is really due to work done on the atmosphere in expanding to constant pressure. This work is invariable at 1·91 calories. The true ratio of specific heat at constant pressure or Cp to that at constant volume Cv, is thus properly stated, $Cp = Cv + 1·94$, or usually $= Cv + 2$. Thus, if 22·32 litres of gas are heated 1° C. from 0° C. they will perform work against a column of mercury 760 mm. high to the extent of 1·94 calories at all temperatures. A gas expands when heated 1° C. to an additional bulk = $\frac{1}{273}$ of the bulk occupied at 0° C. Hence the invariable quantity 1·94.

The specific heat of a gas increases with temperature. The number of calories generated by the combustion of a unit weight of a substance if divided by the specific heat of the products of combustion and by the total weight of such products, will give the nominal temperature. The 'theoretical' temperature of combustion is the nominal temperature found by using the specific heat at ordinary temperatures. These nominal temperatures are never attained. The ordinary specific heat of carbon dioxide is quadrupled at 4000° C., and the temperature that might theoretically reach 18000° C., in oxygen in a certain case would not go beyond 4500° C. or thereabouts.

The calorific capacity of fuel may be approximated by calculating the capacity of its constituents of carbon and hydrogen. This is absolutely accurate, subject to allowance for the heat of formation. Thus in the formation of some hydrocarbons, heat is evolved. When these hydrocarbons are burned, the heat which was produced in their original formation cannot be again produced, and the combustion is productive of so much less heat. Others, such, for example, as acetylene, absorb heat when formed, and this substance when burned gives out more heat than corresponds with its carbon and hydrogen. This is one reason for its brilliance, and accounts for its explosive tendency.

VISCOSITY OF GASES.

Sutherland's Formula.

For all gases,
$$\eta_\theta = \eta_{273} \left[\frac{273 + C}{\theta + C}\right] \left(\frac{\theta}{273}\right)^{3/2}$$

Where θ = absolute temperature (°C.).

η_θ = dynamic (not kinematic) viscosity.

c = a constant.

For air, η at 23° C. = 1830×10^{-7} C.G.S. units.

$c = 117$

Temperature coefficient of $\eta = 4\cdot9 \times 10^{-7}$ C.G.S. units per °C.

Kinematic viscosity $= \dfrac{\text{dynamic viscosity}}{\text{density}}$.

[NOTE.—Gases expand by heat to the extent of $\frac{1}{273}$ of their bulk at 0° C. for each degree Centigrade, or $\frac{1}{491 \cdot 4}$ of their bulk at 32° F. for each degree Fahr.

☆ The specific heat of gases varies with the temperature, being more for higher temperatures. At the absolute zero the values of the molecular heat of all gases seem to converge at 6·5 for constant pressure values. Lechatelier therefore gives a formula for specific heat $Cp = 6 \cdot 5 + aT$, where T is the absolute temperature Centigrade and a is a coefficient greater according to the complexity of the molecule. For values of a see table. This has an important bearing on the theory of the gas engine.]

[T = Temperature Centigrade.]

Combustion of Carbon.

Carbon exists only as a solid and is found in three forms or allotropic modifications: (*a*) the diamond; (*b*) graphite; (*c*) amorphous, as charcoal. The heat generated by the perfect combustion of each of these forms is peculiar to that form. Carbon exists in liquid form only in combination with other substances and does not vaporise except at 3600° C. The total heat of combustion of carbon is 11·646 calories per gramme from the state (*a*). Of this amount ·2783 calories disappear in converting the diamond to the amorphous state (*c*); 3·231 calories are absorbed in vaporising the carbon; and 2·4533 calories are set free by its conversion into monoxide CO. 5·684 calories are then produced by the second oxidation of this CO into dioxide = CO_2. In practice the only available heat is that which is set free after vaporising the carbon, *i.e.* 8·137 calories. The following table gives these characteristics in brief, of converting 1 gramme of carbon.

			Calories.
1.	Converting diamond to graphite	=	·041
2.	„ graphite to amorphous	=	·237
3.	„ diamond to amorphous (1) + (2)	=	·278
4.	„ amorphous to monoxide CO	=	2·453
5.	„ monoxide to dioxide	=	5·684
6.	Vaporising amorphous carbon (5) − (4)	=	3·231
7.	Total energy generated converting carbon vapour to dioxide (1) + (2) + (4) + (5) + (6)	=	11·646
8.	Total available heat in practice (7) − (3) − (6)	=	8·137

The difference between (7) and (8) represents expenditure in unlocking the crystal form of the diamond (3) and in converting the carbon to gas (5). The latent heat of vaporisation of carbon is thus 3·231 or about half that of steam.

Hydrogen is known in three states, liquid, solid, and gaseous. The liquid and solid states are those of low temperature. All practical determinations start from the gaseous state. The following figures are found in the combustion of 1 gramme of hydrogen:

		Calories generated.
1.	Converting hydrogen to water gas, H_2O	29·15
2.	„ „ „ liquid	34·50
3.	„ „ „ solid	35·2

The ordinary available heat is that of (1) only; (2) being only partially secured when the products of combustion are cooled considerably below 100° C.

Stated per pound, carbon yields 14,500 British Thermal Units, and hydrogen 52,000 to 62,100 according to the final temperature. The first oxidation of 1 lb of carbon to monoxide yields barely 4,500 heat units, the further oxidation of the resulting carbonic oxide yielding fully 10,000 units.

The difference of the two oxidations is due to the rendering latent of about half the heat of the first oxidation in gasifying the solid carbon. The following equivalent units are useful:

1 Calorie per square metre	=	0·369 B.Th.U. per square foot.
1 B.Th.U. per square foot	=	2·713 calories per square metre.
1 Calorie per kilogram	=	1·800 B.Th.U. per pound.
1 B.Th.U. per pound	=	0·556 calorie per kilogramme.

These calories are kilogramme calories (p. 55).

For thermo-chemical tables of gases see pp. 56-57.

The temperature produced by combustion is largely dependent upon the weight of the resultant product. Thus 1 lb. of hydrogen when burned to water vapour will produce 52,380 heat units, which have to be divided among the 9 lbs. of water. The nominal temperature is 14,375° F., which, however, is based on the suppositious constancy of the specific heat; 1 lb. of carbon, however, which only generates about 14,500 heat units, produces only 3⅔ lbs. of gas, and the nominal resulting temperature is 18·457. These are for combustion in oxygen. With air the additional weight of nitrogen still further reduces the nominal temperatures to about 5,000° in each case.

The percentage of each constituent of a mixed product must be multiplied by the specific heat in order to find the true valency of that product in the calculation of temperature. To find the mean specific heat of a mixture of gases, the weight of each gas is to be multiplied by its specific heat. The products are to be added together and divided by the sum of the weights of all the gases. The result is the mean specific heat. Then the temperature of combustion is found by dividing the total heat of combustion of the combustible gases by the weight of products and by the mean specific heat.

Similarly the calorific value of a mixed gas is found by multiplying the weight of each gas by its calorific value per pound, adding the products together and dividing by the total weight. The result is the thermal value per pound of the mixed gas.

Specific Heat.

Definition.—The amount of heat required per unit mass to cause unit rise of temperature over a small temperature range.

Determination of Specific Heat.

M = weight of body. T = temperature of body. C = specific heat of body.
m = weight of cold water. t = temperature of cold water.
θ = temperature of water after body has been plunged into it.

$$C = \frac{m(\theta - t)}{M(T - \theta)}$$

Latent Heat.

Definition.—The heat absorbed per unit mass in change of state from solid to liquid, or from liquid to gaseous.

Latent heat of fusion of ice at 0° C. = 80 gramme calories.
Latent heat of evaporation of water at 100° C. = 540 gramme calories.

Equal weights of ice and water at 0° C. and 100° C. respectively, have a temperature after mixing of 10·6° C.

The superficial expansion is twice the linear, and the cubical expansion three times the linear. The coefficient of expansion of an alloy is equal to the mean coefficients of expansion of the volumes of the metals composing it.

If a bar is *increased* in length from l to L by an *increase* of temperature of $t°$, then

$$L = l(1 + at°).$$

If a bar is *decreased* in length from L to l by a *decrease* of temperature $t°$, then

$$l = \frac{L}{1 + at°}$$

Thermal Expansion of Air.

Dry air expands or contracts uniformly 0·002039 its volume per degree F. difference under *constant pressure*.

If the *volume is constant* and the pressure varies, then the coefficient per degree F. is 0·002036.

Thermal Conductivity.

Definition.—The quantity of heat per unit area conducted per second through a slab of the substance of unit thickness, per degree of temperature difference.

1 gram calorie per sec. per sq. cm. per degree C. per cm. = 0·0056 pound calories per sec. per sq. inch per degree C. per inch.

OPTICS.

Decomposition of Light in the Spectrum.

Colours.	Maximum Ray.	Combination of Colours.		
		Primary.	*Secondary.*	*Tertiary.*
Violet	Chemical	Blue, Yellow	Green	Dark Green
Indigo		Blue, Red	Purple	Brown
Blue	Electrical	Yellow, Red	Orange	
Green				
Yellow	Light			
Orange				
Red	Heat			

All the colours of the spectrum mixed together make white.

Velocity of Light.

Velocity of light = $3 \cdot 004 \times 10^{10}$ cms. per sec. Mean wave length = $5 \cdot 3 \times 10^{-5}$ cms.

The velocity of light through the atmosphere is 186,330 miles per second (*Newcomb*). The velocity of light through transparent bodies is not known, but probably varies inversely as the square root of the specific gravity of the transparent substance.

Light passes from the sun to the earth ($1 \cdot 487 \times 10^{13}$ cms. = 92,390,000 miles [*Everett*]) in eight minutes, at which velocity light can pass around the earth in one-eighth of a second.

To find the Focal Length of a Convex Mirror.

Use as object an opaque screen, with a hole and pin-point, and painted white, or covered with white paper.

Set up on the bench, in line, say, with the left edge of the hole, the convex mirror and an auxiliary biconvex lens of short focal length (6 ins. or so), and adjust the lens so that the image of the hole and pin-point is formed side by side with the object. The centre of the mirror is now at the point at which the image would be formed by the lens alone; this position may either be calculated or found (after noting the position of the mirror and then removing it) by means of a screen. Thus the radius is easily measured.

If the focal length of the mirror be greater than f, that of the lens, the simplest way of adjusting is to put the lens as close as possible to the mirror, put the object at principal focus of lens, and move the object back until the image is formed as above.

If, however, the focal length be less, we can be sure of finding the position by putting the mirror at a distance of $4f$ from the object, and the lens at $2f$ and moving the lens back until the desired position is reached.

To find the Focal Length of a Concave Lens.

Use an object like the one mentioned above, an auxiliary convex lens (say, 6 ins. focal length) to produce a convergent beam, and an auxiliary plane mirror, placed beyond the concave lens.

Adjust until the image is formed side by side with the object, as before; then the rays must be emerging parallel to one another from the concave lens, and hence the convergent beam from the convex lens will (when the concave lens and mirror are removed) form an image at the principal focus of the concave lens. A direct measure can thus be made of the focal length.

(*E. Budden.*)

Relation between Positions of Object and Image.

Distance of object from lens or mirror = u.
" " image " " " " = v.
Focal length of lens or mirror = f.
Radius of curvature of mirror = r
∴ $2f$.

Distances measured on the same side of the lens or mirror as the object are taken as positive and those on the opposite side as negative.

Spherical mirror.— $$\frac{1}{v} + \frac{1}{u} = \frac{2}{r}$$

(For concave mirror, r is positive. For convex mirror, r is negative.)

Lens.— $$\frac{1}{v} = \frac{1}{u} + \frac{1}{f}$$

(For concave or divergent lens, f is positive. For convex or convergent lens, f is negative.)

Photographic Lens Apertures.

Stops or apertures are openings in the lens diaphragms which determine the amount of light admitted to the sensitive plate in a camera. They are usually expressed as fractions of the lens focus, *i.e.* with an 8-in. focus lens a stop or aperture 1 in. in diameter would be known as *f*8—*viz.* it would divide into the focal length eight times; *f*16 would be ½-in. diameter, and so on.

The exposure required varies inversely as the area of the opening. The apertures mostly in use are *f*5·6, *f*8, *f*11, *f*16, *f*22, *f*32, *f*45 and *f*64, and each will be half the area and require twice the exposure of the next larger aperture. *E.g.*, if *f*11 requires 1 second *f*16 would require 2 seconds and *f*8 only half a second.

If the diameter of any one aperture be known the remainder can be ascertained by the method shown in fig. 1.

Say the diameter of *f*11 is ¾ in., set off *f*11 as one side of a right-angled triangle ABC; then BD, at right angles to the hypotenuse, would give the diameter of *f*16, DE would give *f*22 FA the diameter of *f*8, and so on as indicated.

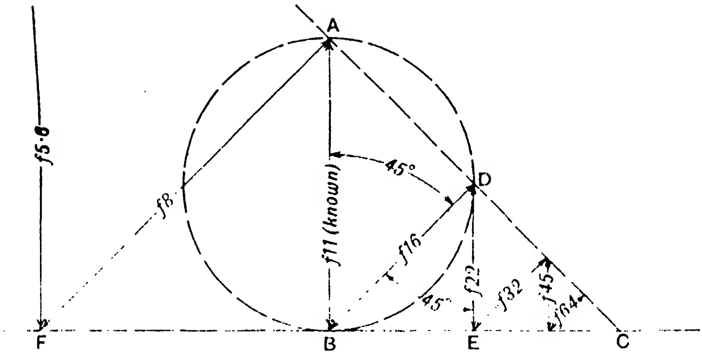

FIG. 1.

Theoretically *f*8 in one lens should be of the same exposure value as *f*8 in any other lens of whatever make or focus, but loss due to refraction, etc., must vary according to the number of component parts, and a compound lens containing many surfaces would obviously be slightly slower than one of the simplest form.

SECTION IV

ACOUSTICS, VIBRATION AND NOISE (Pp. 69-81)

(By C. W. Glover, M.I.C.E., M.I.Struct.E., Member Acoustical Society.)

SECTION IV

ACOUSTICS, VIBRATION AND NOISE.

(By C. W. Glover, M.I.C.E., M.I.Strupt.E., Member Acoustical Society.)

SCOPE.

The scope of the subject is set out diagrammatically below :-

The Science of Sound.

- Atmospheric acoustics.
  - Listening equipment.
    - National defence.
      - Design of high-speed machinery.
  - Navigation by sound.
    - Sound ranging.
      - Subaqueous sound ranging and signalling.
  - Mirage and weather.
- Physiological acoustics.
  - Speech.
  - Hearing.
    - Aids to the deaf.
      - Sound measurement.
        - Sound recording.
        - Sound reproducing.
        - Filtration of sound.
          - Design of equipment.
- Architectural acoustics.
  - Absorption and dissipation of noise.
    - Exterior noise.
    - Interior noise.
      - Provision of proper acoustica conditions in auditoria.
        - Problems demanding acoustical study in design.
        - Acoustical correction of auditoria after construction.
  - Sound Insulation.
    - Contact noises
      - Structural vibration.
    - Air borne sound.

SOUND.

Sound is a form of energy which finds its origin in the vibration of matter.

For the propagation of sound energy matter is necessary.

Sound is propagated radially outwards from the source on spherical wave fronts with a velocity which depends upon the elastic properties and density of the vibrating medium.

Velocities of Sound at 0° C.

Air	1,090 ft. per second.	*Note.*—The velocity is independent of both the frequency and amplitude of vibration.
Coal gas	1,600 " " "	
Water	4,700 " " "	
Pinewood	10,900 " " "	
Brick	11,980 " " "	
Iron	16,000 " " "	
Steel	16 360 " " "	

Sound Waves.

Sound waves are of the compression or longitudinal type. The distance from 'peak to 'peak' of pressures is called the *wave-length* and this depends upon the *frequency* or the number of complete waves passing in one second.

Limits of Audibility.

The slowest vibration producing audible sound is 20 cycles per second, the corresponding wave-length being 56 ft.

The highest audible frequency is 20,000 cycles per second (10 octaves higher), corresponding to a wave-length of 0·056 ft.

The maximum particle displacement from the normal is called the amplitude and this is only 0·004 ins. for the loudest sound and 0·00000005 ins. for a sound barely audible.

The velocity can be calculated from the formula $V = \sqrt{\frac{E}{p}}$

where E is the modulus of elasticity of the medium
in solids E is Young's Modulus;
in liquids E is the bulk modulus;
in gases E is the pressure modulus.
the adiabatic elasticity must be used and

$$V = \sqrt{\frac{1 \cdot 4\, p_1}{p}}$$ where p_1 is the pressure.

is the density of the medium.

If the temperature of the medium is raised, in air the velocity becomes $V = 332 + 0 \cdot 6t$ metres/sec., where t is the temperature in degree C.

There are three principal characteristics of audible sound : pitch, loudness and tone quality.

Pitch.

The pitch of a sound is the frequency of vibration measured as the number of complete vibrations passing in one second. It is independent of the amplitude.

Loudness.

The loudness of sound is described as a comparative statement of the strength of the sensation received through the ear.

Its measurement in physical values is not simple, loudness being largely a physiological effect which depends upon the ear. It corresponds to brightness in optics and depends upon the amount of energy in the sound waves entering the ear.

The amount of energy in ergs which passes in one second through an area of 1 sq. cm. is called the intensity of the sound.

The loudness of a sound varies as the square of the amplitude and inversely as the square of the distance from the source. This latter does not apply to sound in a closed space like an auditorium or to sound propagated from a source of dimensions comparable with its distance.

The ear perceives generally on a logarithmic basis, but loudness sensation also varies with the pitch. Fechner's law states that $S = c \log_{10} p + a$;

where p is the excess pressure (dynes per sq. cm. and c and a are parameters depending upon the frequency.

This law is considerably in error for loud sounds. The fundamental relationship between the loudness of a sound and the acoustic energy producing it is still much in dispute, but as a fundamental basis for the measurement of loudness, *aural comparison with a standard scale* is adopted internationally.

The equivalent loudness of a sound is then measured in 'phons' by the intensity of a standard reference and pure tone in d.b. considered by the observer to be as loud as the sound being assessed.

Units.

A 'bel' is the decimal logarithm of the ratio of two powers.

Two powers *differ* by $\log_{10} \frac{W_1}{W_2}$ bels, or a 'bel' is a 10-fold increase in power or energy.

A 'decibel' is a tenth of a 'bel' and equals a transmission unit.

The number of T.U.'s or d.b. = 10 $\log_{10}$ ratio of powers in watts,
or 20 $\log_{10}$ ratio of voltages,
or 20 $\log_{10}$ ratio of current intensity.

Twenty times the change in photographic density in sound films equals the change in electric power in d.b.

The ultimate standard of reference is an acoustical pressure of 0·0002 dynes per sq. cm. for a 1,000 cycles pure note. This is the adopted arbitrary zero for the d.b. scale at 1,000 cycles

THE DECIBEL SCALE.

Ratio of Sound Power to that at Threshold.	Decibels above Threshold.	Sound pressure at 1,000 ∼ in dynes per sq. cm.	Ratio of Sound Pressure to that at Threshold.
Threshold of feeling, 10^{13}	130	$2 \times 10^{2.5}$	$10^{6.5}$
" " " 10^{12}	120	2×10^{2}	10^{6}
" " " 10^{11}	110	2×10^{1}	$10^{5.5}$
" " " 10^{10}	100	2×10^{1}	10^{5}
" " " 10^{9}	90	2×10	$10^{4.5}$
" " " 10^{8}	80	$2 \times 10 = 2$	10^{4}
" " " 10^{7}	70	$2 \times 10^{-0.5}$	$10^{3.5}$
" " " 10^{6}	60	2×10^{-1}	10^{3}
" " " 10^{5}	50	$2 \times 10^{-1.5}$	$10^{2.5}$
" " " 10^{4}	40	2×10^{-2}	10^{2}
" " " 10^{3}	30	$2 \times 10^{-2.5}$	$10^{1.5}$
" " " 10^{2}	20	2×10^{-3}	10^{1}
" " " 10^{1}	10	$2 \times 10^{-3.5}$	$10^{0.5}$
Threshold of audibility, $10^{0} = 1$	0	$2 \times 10^{-4} = 0{\cdot}0002$	$10^{0} = 1$

The loudness of a tone is given in 'phons.'

An *equivalent loudness* of '*n* phons' is equal to that of the standard tone when operating at '*n* decibels' above its zero.

APPROXIMATE LOUDNESS SCALE OF 'PHONS.

130 phons	Threshold of feeling.
120 "	Heavy gun-fire.
110 "	Near aeroplane engine.
100 "	Near express train.
90 "	Pneumatic drill at 4 ft.
80 "	In tube train (windows open).
70 "	In express overland train (windows open).
60 "	Loud conversation.
50 "	Average conversation.
40 "	Suburban house.
30 "	Very quiet room.
20 "	Whispering.
10 "	Rustling of leaves in quiet garden.
0 "	Threshold of audibility.

Measurement of Loudness is effected by the use of—

(*a*) *Objective noise meters*, in which the sound received by a calibrated microphone is converted into electric energy, amplified and rectified and measured on a micro-ammeter.

(*b*) *Subjective noise meters*, in which the sound to be measured is matched with a pure reference tone produced by the instrument or alternatively masked by the latter. The degree of adjustment required affords the means of measurement.

Churcher suggests a *scale of loudness* such that the magnitude of a sound in phons is given by the d.b. above threshold pressure of 0·0002 dynes per sq. cm. of the tone of 1,000 cycles per sec., which, heard in free space with both ears, sounds as loud as the noise when the two are heard alternately.

$$\text{Loudness} = (\text{phons})^3 \times 10^{-3}.$$

Tone Quality.

The tone quality of a sound is that characteristic which distinguishes it from another sound of the same loudness and pitch. Nearly all sounds are composite and can be analysed into their separate component tones called partials. Those partials which have the lowest frequency are called fundamentals, the others being the overtones. Those overtones, having a frequency which is an exact multiple of that of the fundamental, are called harmonics.

The higher frequencies are essential to intelligibility in speech and to brilliance in music, whilst the lower frequencies contribute timbre or volume.

Reflection of Sound.

The laws of sound generally conform with those of light, but owing to the greatly increased wave-length of sound diffraction results. The higher frequencies are more directional in effect and the lower are not so subject to sound shadows.

Reflection and inter-reflection of sound within an auditorium introduces reverberation, which is desirable except when excessive.

Optimum reverberation times for auditoriums of the volumes tabulated are given below.

When the sound is reproduced or amplified, deduct 15 per cent. from the times given.

Volume of Auditorium. Cub. Ft.	Optimum Reverberation in Seconds with Auditorium Two-thirds Full. (512 Cycles.)			
	Music and Speech.	Choral Music.	Music.	Speech.
50,000	1·20	1·68	1·38	1·00
100,000	1·45	2·00	1·67	1·23
200,000	1·80	2·50	2·10	1·55
300,000	2·00	2·80	2·30	1·70
400,000	2·10	2·94	2·40	1·80
500,000	2·20	3·10	2·50	1·87
600,000	2·30	3·20	2·65	1·95
700,000	2·35	3·30	2·70	2·00
800,000	2·40	3·36	2·76	2·05
900,000	2·45	3·44	2·84	2·10
1,000,000	2·50	3·50	2·88	2·13

Special auditoria require reverberation times as below :—

Radio Studios.—0 to 10 secs. to suit the broadcast. Studios of various sizes, others with adjustable absorbents and others with echo rooms attached, provide the scope required.

Sound Film Studios.—About half the period given in the ' speech ' column above.

Gramophone Studios.—Speech *0·5 secs.* graduated to bands at *4 secs.*

The optimum reverberation time is not the same at all frequencies but having ascertained optimum at 512 ∼ as above, that at the other frequencies can be calculated by using the appropriate multiplier tabulated below.

Frequency in Cycles per Sec.	Multiplier Speech.	Multiplier Music.	Multiplier Speech and Music.
64	1·75	2·30	2·03
128	1·38	1·55	1·47
256	1·15	1·20	1·18
512	1·00	1·00	1·00
1,024	1·00	1·00	1·00
2,048	1·00	1·00	1·00
4,096	1·14	1·04	1·09
8,192	1·35	1·15	1·25
16,384	1·60	1·35	1·47

Reverberation varies directly as the volume and inversely as the acoustic absorption present.

When the average coefficient of acoustic absorption is less than 0·2, the W. C. Sabine formula may be used.

$$t = \frac{V}{20\,(s_1a_1 + s_2a_2 + s_3a_3 \ldots)}$$

where t is the time in seconds.

V is the volume in cubic feet.

a_1, a_2, a_3, etc., are the respective sound absorbing coefficients of the various materials having surfaces s_1, s_2, s_3, etc.

For ' dead ' conditions the Eyring formula is more correct.

$$= \frac{V}{20\,s_T\,(-\log_e(1-a))}$$

where s_T is the total interior surface and a is the total absorption $\div\ s_T$.

When a standard strength of source is used rather than an initial loudness, the P. E. Sabine formula is the more applicable.

$$= \frac{0{\cdot}0083\,V}{A}\,(9{\cdot}1 - \log_{10} A$$

where A is the total absorption present.

Absorption.

The absorption coefficients at 512 ∼ are now available for most materials and range from marble at 0·01 to fibre boards at 0·35 and the open window at 1·00.

The coefficient is not the same at all frequencies.

Draped and porous materials absorbing principally in the upper register.
Resilient materials like carpet—in the middle register.
Stretched membranes and resonating panels in the lower register.

Optimum absorption at all frequencies can only be secured by a judicious selection of acoustic materials.

It is desirable to dispose reflecting surfaces about the origin and to incline them in such a way that the acoustic images of the source of sound are as near as possible to the origin. Absorbent surfaces should be remote from the source.

The general requirements for good acoustics in buildings may be briefly stated as below :—

(1 Uniform distribution of sound throughout the room without distortion

(2) Proper reverberation time.

(3) Adequate loudness of sound throughout the room.

(4) Absence of disturbing extraneous noise.

A summary of acoustical defects, their causes, recommendations for their avoidance in design and the remedy to be applied in existing buildings, is given below.

SUMMARY OF ACOUSTICAL DEFECTS.

Defect.	Causes.	Avoidance in Design.	Remedy for Existing Buildings.
Excessive Reverberation.	A. Excessive volume.	Keep volume down to 100–150 cub. ft. per seat.	Increase seating, reduce volume or increase interior surface by bold decoration.
	B. Insufficient absorption.	Add absorbents.	Add absorbents.
Echoes	A. Unsuitable shape.	Avoid curves in design.	Alter shape or use absorbents on offending surfaces.
	B. Distant Reflecting surfaces.	Make distant surfaces highly absorbent.	Ditto.
Sound Foci	Concave reflecting interior surfaces.	Avoid curvilinear interiors.	Alter shape or use absorbents on focussing areas.
Dead Spots	A. Positions denuded by sound foci.	Avoid curvilinear interiors.	Alter shape, make focussing area absorbent, use parabolic sounding boards, or directional speakers.
	B. Screens.	Reflect sound into screened areas.	
Interference	Undiffused reflections of sustained note.	Design bold breaks in walls and ceilings. Use resonating wall covering.	Add bold decorative and/ or resonating interior eatment.
Insufficient Sound Volume.	A. Too voluminous a building.	Use orchestra of appriate size.	
	B. Lack of reflection close to origin.	Use electrical amplification. Dispose hard reflecting surfaces about origin.	
	C. Excessive absorption.	Adjust absorption to give optimum reverberation.	
Distortion	A. Selective absorption.	Use of collection of absorbents to obtain desired reverberation characteristic.	
	B. Screening of higher frequencies.	Avoid obstructions.	Reflect higher frequencies into sound shadows.
	C. Uncontrolled resonance.	Select board absorbents which resonate over wide range and fix on battens at irregular intervals.	
Resonance	Flimsy partitions and linings	Adopt rigid construction with studs, etc., at irregular spacings.	
Masking Noise	Insufficient sound insulation, bad fitting doors and windows or badly designed vents.	Select construction having least overall insulation value of 50 d.b.	

Sound Insulation.

Air-borne sounds may be transmitted to an adjoining room in three ways :—

(a) By direct passage of air waves through openings in the wall, through ventilators, etc.
(b) By vibration of the dividing medium itself as a diaphragm which by its motion re-creates sound waves on the farther side ; and
(c) By direct transmission of elastic-wave motion through the dividing medium which imparts to the air at the farther side a wave motion exactly timed to that of the origin.

Air-borne sounds are most effectively stopped by rigid walls that do not have openings for pipes or ventilators, though the construction of the wall itself, apart from the question of rigidity, has an important bearing upon the degree of insulation.

For the transmitted sound to be a minimum—*i.e.* for the greatest sound insulation—the sound energy dissipated in other ways must be a maximum.

(a) The reflected sound will be large in proportion to the incident sound if the reflecting surface is ' hard.'
(b) The sound absorbed by conversion to heat energy will be increased by using ' laminated ' construction with the inner layer very absorbent of sound.
(c) The sound energy absorbed as mechanical energy will be increased by using heavy ' massive ' construction.
(d) The diaphragm-like vibration can be minimised by the adoption of ' rigid ' construction.

Rigidity.

A partition may be bulged by pressure of sound, and if the periodicity of the sound waves corresponds with the natural period of vibration of the partition, the transmitted sound will be ' increased ' in loudness by resonance.

Measurement of Sound Insulation.

There is no simple formula for the calculation of sound insulation of composite construction, but the insulation of homogeneous partitions is proportional to the log. of the weight per square foot.

The insulaton in d.b. $= 14 \cdot 3 \log_{10}$ wt. per sq. ft. $+ 22 \cdot 7$ d.b. and the following values are of interest :—

Mass per sq. ft. of wall area.	Insulation in d.b. at 512 ~
1 lb. wt.	22·7
5 "	32
10 "	37
20 "	41
40 "	45
60 "	48
100 "	51·3
400 "	60

In porous-flexible materials the sound insulation in d.b. is proportional to the thickness of the material.

Thus a 10-fold increase in the thickness of a flexible porous material like hair felt will bring about a 10-fold increase in the sound insulation, whereas a 10-fold increase in the thickness of a rigid non-porous partition, say from 10 to 100 lb. wt. per sq. ft., will only bring about an increase of insulation from 37 to 51·3 d.b., *i.e.* less than a 2-fold increase.

Note that to provide an insulation of 60 d.b. by means of a solid non-porous wall, a mass of 400 lb. per sq. ft. would be necessary—say a 40-in. brick wall.

Owing to the slow rate of increase of insulation with weight of partition, it is generally uneconomic in practice to provide for insulation greater than 45 d.b. solely by mass and rigidity.

In panels of homogeneous nature, mass and rigidity are the determining factors, but when the construction departs from homogeneity, structure becomes of predominating importance.

Tests on construction of various kinds appear to show quite definitely that in practice refraction effects may be ignored, and that it is necessary only to consider the diaphragm-like vibrations.

An increase in stiffness and/or mass will therefore improve the sound insulation of a wall.

Cross connections are very detrimental to the sound-insulating value of lath and plaster or similar partitions. The one side should be constructed entirely independent of the other by the use of staggered studding.

An air space is generally better than a filling material, unless the filling material is quilted (to prevent its settlement and tight packing) and fixed to one side only.

CONCLUSIONS.

Undoubtedly the important points for the prevention of sound transmission in walls and partitions are :—

(a) A hard reflecting surface on the outside of the wall.
(b) A non-homogeneous structure containing inert air cells.
(c) An air gap to prevent continuity.
(d) A layer of insulating material.
(e) A sound-absorbent surface facing the other room.
(f) A massive and rigid construction.

It is quite certain that the important points for the prevention of sound transmission through floors are :—

(1) A floating floor isolated from the walls.
(2) An isolating material of non-homogeneous nature between the floor covering and the floor proper.
(3) The floor proper (of massive and rigid construction) ; and
(4) A suspended ceiling.

For the adequate insulation of structure borne sound or 'contact noise' in floors, the 'floating' surface must have sufficient inertia.

To isolate the noise of footfalls the 'floating' surface should weigh not less than 15 lb. per sq. ft.

INSULATION AGAINST VIBRATION

Structural Vibrations.

The full effect of sound transmission through the members of a structure are but imperfectly realised. Vibration in one part of the structure is conveyed easily through the continuity of solid material and by setting up resonant vibrations recreates sound waves in a position often very remote from the original source of sound.

If the design of the structure precludes any possibility of breaking continuity of structural contact, very special endeavours must be made to prevent linings of all rooms coming in structural contact with the framework of the buildings.

An effective method of control lies in the interposition of an elastic discontinuity in the path of the vibrations.

Sound Insulation in a Steel-framed Building.

Isolation of structural vibration in the various members of a steel-framed building may be effected by the use of lead and asbestos cloth sheets.

Note that in isolated connections, bolts sheathed in asbestos and bitumen must be used in place of rivets which would provide structural contact.

The use of isolator pads on every principal joint in a steel-framed building would reduce the general rigidity of the whole and so permit greater freedom in vibration.

It will usually be sufficient to isolate only the member shaken in the case of localised vibration, but to use pads under all foundations when earth vibrations have to be dealt with.

Sound Insulation of Reinforced Concrete Buildings.

The use of resilient pads under the bearing of pre-cast reinforced concrete units of a structure offers a solution in this type of construction, and the reinforced concrete floors in brick buildings can be similarly dealt with.

On the other hand, *in situ* constructed monolithic reinforced concrete buildings, from the mere nature of their design, are admirably suited to the effective transmission of vibration, and loaded reinforced concrete floors may act as very effective sounding boards in a framed reinforced concrete structure.

The effects of mass and rigidity have, however, a damping influence and it is not easy to determine in any particular design just the degree of discontinuity of structure, effecting as it does the overall rigidity, which would be productive of the greatest resistance to the transmission of noise and vibration.

The concensus of opinion inclines to the view that structures of reinforced concrete give less cause for complaint than those of steel-framed construction.

There is no doubt that, for the minimisation of vibration and noise in reinforced concrete buildings, the following points need careful attention :—

(1) Foundations should be built upon a resilient layer having the requisite elastic strength and 'compliance,' and particular care should be taken to prevent the arrangement becoming waterlogged, as water transmits vibration with the greatest facility.
(2) The various members of the structure should be isolated from each other by resilient pads of lead and asbestos, where such an arrangement would not result in serious loss in structural rigidity.
(3) The interior surface of all rooms should be carefully isolated from the structural elements.

Machinery Vibration.

In rotating parts eccentricities give rise to vibrations at frequencies equal to the speed of rotation, and at the 'critical' speed the frequency of the vibration corresponds to the natural period of the machine on its support—a coincidence which is marked by an alarming increase in the amplitude of vibration.

There are as many 'critical speeds' as there are modes of vibration.

Quiet machinery is usually secured by close attention to the following points

(1) The vibromotive forces should be kept down to the minimum by
- (a) carefully balancing reciprocating parts,
- (b) keeping reciprocating parts as light as possible,
- (c) dynamically balancing all rotating elements to eliminate unbalanced centrifugal forces and whipping effects, and/or
- (d) by the provision of a dynamic absorber tuned to neutralise the unbalanced vibration.

(2) Heavy, rigid frames should be provided.

(3) Loose and worn parts should be replaced.

(4) Smooth-meshed gearing and quiet, well-lubricated bearings should be used.

Human Susceptibility.

Susceptibility to vibration is dependent upon the velocity of motion, the amplitude of vibration, the acceleration of movement, or the total impulse of the vibrating mass.

The intensity of vibration is the product of the amplitude in m.m. and the frequency in cycles per second.

An intensity of one or more constitutes a nuisance.

In practice it is best to ascertain the dominant vibration of a machine at normal operating speeds and to design the mounting accordingly, since haphazard installation may aggravate the vibration.

Isolators.

The most important properties of good isolators are elasticity and deflection, and the degree of success in isolation of vibration will depend upon the manner in which the relative magnitudes of these properties are adjusted.

It is usually found that a reduction in area of supporting pads will result in an improvement in isolation of vibration.

The Design of Damping Devices.

If a machine of mass m be supported on a resilient pad, the natural frequency of the mass m on its elastic supports must be low compared with the frequency of the vibration to be isolated, otherwise the pad may be worthless.

The amount of vibration transmitted to the floor or foundation is determined by the elastic or viscous properties of the pad, and the 'transmissibility' of the support is given by the ratio of the vibratory force communicated with and without the isolating pad.

$$\frac{\text{Transmitted vibration with pad}}{\text{Transmitted vibration without pad}} = \tau = \sqrt{\frac{r^2 + \dfrac{1}{4\pi^2 n^2 c^2}}{r^2 + \left(2\pi nm - \dfrac{1}{2\pi nc}\right)^2}}$$

where c is the 'compliance' of the pad (*i.e.* the reciprocal of the force constant or of the modulus of elasticity).

(Rubber has low elasticity but considerable compliance. Steel has high elasticity but little compliance.)

r is the internal mechanical resistance owing to the viscous forces within the pad, and

n is the frequency of the vibration to be isolated.

The compliance c is calculated by observing the elastic deflection of a specimen loaded in compression for each additional unit of compressive force.

The compliance c for any elastic material will be directly proportional to the thickness and inversely proportional to the area of cross-section.

The internal resistance r can be ascertained from the 'decay' curve by observing the successive amplitudes of the free vibrations of a known mass on a measured specimen of the resilient material, or by measurements of the rate of return of the displaced mass.

The internal resistance is directly proportional to the area of cross-section of the flexible support and inversely proportional to its thickness.

The resistance factor r is not so important as the compliance factor, and in approximate calculations may be regarded as zero.

The relation between the transmissibility τ and the ratio of the frequency of the forced vibration to that of the natural vibration of the machine on its elastic support is given in the table below:

Ratio of Forced to Natural Frequencies.	Transmissibility.	Remarks.
0	1·0	..
0·5	2·2	Amplification
1·0	3·1	„
1·5	1·7	„
2·0	0·8	Damping
2·5	0·3	„
3·0	0·1	„
3·5	0·05	„
4·0	0·005	„

Examination of these figures will show that when the ratio of forced to natural vibrations is 1, *i.e.* when the natural frequency of the machine on its elastic support corresponds with that of the vibration to be isolated, a condition of resonance obtains and the vibration submitted will be three times that of the machine direct upon the floor without an isolator.

It will also be seen that when the ratio is 3 or more, there will be very little of the forced vibration transmitted to the floor or foundation.

In general, the elastic support should be sufficiently compliant and the mass supported should be sufficiently heavy to make the natural frequency of the arrangement low in comparison with the vibration to be isolated.

The isolator should have a relatively large compliance, should be loaded to its safe maximum within the elastic limit, and should have as large an internal resistance as is consistent with the above conditions.

The elastic support transmits all frequencies below about twice the natural frequency of the machine on its support, but isolates all frequencies above about

$$\frac{1}{\pi\sqrt{mc}}$$

In the design of spring damping devices the following data will be useful.

Coiled Springs.

D = mean diameter in inches.
d = diameter of round material or side of square material.
H = free height as made and unloaded.
h = height when pressed down solid.
R = range of deflection (H—h).
W = Load in tons (test load for deflection R).
N = Number of free coils.
δ = deflection per ton in inches.

Round Sections.

$$R = \frac{N.D^2}{36d}$$

$$\delta = \frac{N.D^3}{700d^4}$$

$$W = \frac{20d^3}{D}$$

Square Sections

$$R = \frac{N.D^2}{48d.}$$

$$\delta = \frac{N.D^3}{1000d^4}$$

$$W = \frac{21d^3}{D}$$

The natural frequency of a loaded spring is a function of the deflection per ton ( ).

Natural frequency $f_0 = \frac{1}{2\pi}\sqrt{\frac{S}{m}}$ where S = Spring factor (Force in absolute units causing unit deflection of spring).
and m = mass in absolute units.

$$\text{or } f_0 = 3 \cdot 13 \sqrt{\frac{\text{Load per spring}}{\text{Load per spring} \times \text{deflection.}}}$$

$$\text{Deflection under load} = \frac{10}{\text{Square of Frequency required}} \text{ (approx.).}$$

Building Vibrations.

These take place in the three planes due to machinery, traffic and other causes.

The frequencies are between 1 and 10 per sec., the full amplitudes being from 0·0014" to 0·00004". Vibrations at audio frequency may be induced in wall panels.

A vibrating telephone membrane produces audible sound when vibrating with full amplitudes between 0·000006" and 0·04".

NOISE.

Noise is a ubiquitous accessory of the age and may be defined as any unwanted sound.

Noise is usually of very complex nature, the acoustic spectrum being devoid of harmonic relationship.

Sounds are unpleasant on account of their pitch, their persistence and/or their loudness.

High-pitched tones are more annoying than low-pitched tones of the same equivalent loudness.

The effect of masking noise on the intelligibility of speech is shown in the table below.

Background of Noise in Phons.	Percentage Syllable Articulation.	Remarks.
0 to 15	95 to 85	Good hearing.
15 ,, 35	85 ,, 65	Satisfactory with attentive listening.
35 ,, 70	65 ,, 25	Unsatisfactory hearing conditions.

TRAFFIC NOISE.

A comprehensive noise survey of London shows daylight noise levels to be from 60 to 85 d.b.; day averages being as high as 78 d.b. in some places and the night average only 11 d.b. lower.

Isolated peaks, averaging 7 d.b. high, occur at the rate of 2 to 8 per minute.

Very roughly, up to 60 vehicles per second, twice the number of vehicles passing per minute equals the noise level in d.b.

Between 60 and 130 vehicles per minute the increase is only some 25 d.b.

If the number of commercial vehicles increase the traffic noise increases in proportion.

For a given total number of vehicles, if the percentage of commercial vehicles to total vehicles increase from zero to 100 per cent., the traffic noise increases proportionately by an amount up to 20 d.b. maximum.

The construction of lofty buildings, by the introduction of reverberation within street spaces, tends to maintain the sound level until the height of the surrounding buildings is passed.

Confined sites are more noisy than open ones, and tramway crossings and traffic starting places are the most noisy.

The greatest energy in average traffic noise occurs between 600 and 2,000 ~, though the higher frequencies (up to 15,000 ~) are the most annoying.

NOISE ABATEMENT.

Suppression of noise at its source is always more efficacious than abatement by acoustical methods.

In an enclosed space, increasing the absorption reduces the noise.

$$\text{Noise reduction in d.b.} = 10 \log_{10} \frac{a_2}{a_1}$$

where $\frac{a_2}{a_1}$ is the absorption ratio; doubling the absorption only reduces the noise 3 d.b. Ten times the absorption would be required for a 10 d.b. drop in equivalent loudness, though this would usually represent an annoyance reduction of over 60 per cent.

Absorption of the higher frequencies renders the noise more acceptable.

The effect of the absorption is greater the more remote from the source.

The absorption has a localising effect and reduces the 'fear reaction.'

The use of sound absorbing ceilings in noise abatement in buildings can be shown in extreme cases to effect a 5 per cent. increase in efficiency and to pay for itself in 6 months.

TRAIN NOISES.

Train noises are due to wheel rumble and joint impacts and increase largely with speed. Between 60 and 80 m.p.h. the noise level in a carriage with windows open is 74 d.b., and in the corridor 84 d.b. Closing the windows reduces the noise some 5 d.b. In tunnels the noise level increases by about 10 d.b.

The use of rubber treads on the wheels, offers the most effective remedy.

In the London tubes the noise levels average 87 d.b., with peaks up to 100 d.b. when running at 30 m.p.h. At points and crossings these values are up 7 d.b.

Acoustic treatment in the lower sections of the tube reduces the noise level some 8 d.b. The use of rubber pads under chairs on the sleepers and well-packed ballast, has quietened the track to some extent, though reverberation of air-borne sound seems to be the principal difficulty.

For the principles of insulation for the vehicles, see notes on aeroplane noise.

Aeroplane Noise.

Aircraft noise originates in engine clatter, exhausts, air-screw noise and 'flutter' of parts of the aircraft caused by air-speed eddies.

The frequency range is from 100 to 2,000 cycles per sec., the minimum energy occurring on a band between 200 and 800 cycles per sec.

About a third of the total noise is attributable to engine clatter, one-third to the airscrew and the balance to exhausts and 'flutter.'

Aircraft.

The modern all-steel monoplane is more rigid and produces less noise than the older type of biplane, with its multifarious struts and ties, which, despite careful streamlining, set up 'flutter.'

The engine nacelle fitted directly into the wing structure of a monoplane having tractor propellers, with the thrust axis in line with the centre line of the wing, gives the least interference, the greatest propulsive efficiency and the least noise from flutter.

Engine exhausts should preferably be located over the wings and over the cabin. If engines are kept well forward the noise level in the cabins from this source may be reduced by from 5 to 10 d.b.

Silencers.

The general principles involve the provision of sound absorbing baffles and a capacity effect for removing the explosive pulsation of the exhaust gases without introducing excessive back pressures.

Silencers of the long perforated tube type may be relied upon for no more than a 10 d.b. reduction in loudness level, but a special type of silencer, weighing 75 lbs., reduces the exhaust noise of a 500-h.p. engine by 25 d.b., the back pressure at full throttle not exceeding 2½ lbs. per sq. inch.

Propellers.

For some time air-screws were thought to be the principal source of aircraft noise, especially as high-speed thick propellers produce such a loud and irritating note.

Tests carried out by the National Physical Laboratory in conjunction with the Royal Aircraft Establishment show that air-screw noise is generally consistent with the following rough rules :—

Noise reductions in propeller design.
10 d.b. per 100 ft./sec. reduction in tip speed.
1 d.b. per degree decrease in pitch setting.
10 d.b. for change from thick to thin section.
5 d.b. per foot increase in diameter.
10 d.b. for change from 2 blades to 4 blades of the same diameter.

Capon reports that in a cruising flight at a distance of 15 ft. from a two-bladed propeller, the noise level was approximately $20 + 0 \cdot 1$ V. d.b., where V was the tip speed in feet per sec.

It is desirable to keep the tip speed down to 600 ft. per sec., reducing the noise level to 80 d.b. from this source.

Cabin Insulation in Aircraft.

(a) *Isolation of Structure-borne Noise in Aeroplanes.*

The noise vibrations arise from engine torque recoil or from flutter.

The former can only be dealt with by the mounting of the power unit in vibration damping devices and the latter by the provision of the most rigid design of structure.

The interior of the cabin can, however, be isolated from the structure if the lining is fixed to it through cork or sorbo-rubber pads or gaskets.

(b) *Insulation against Air-borne Sound.*

The cabin is a box in an atmosphere of noise and unless the interior is absorbent of sound the noise level inside will eventually build up to that outside.

In fact, equilibrium is reached only when the rate of sound admission into the cabin is equalled by the rate of sound absorption inside.

For the best results, therefore, the cabin walls must be *insulating* and the interior *absorbent*.

The exterior intensity × area × t = the interior intensity × area × a;

where t is the coefficient of transmission and a is the coefficient of absorption, whence

$$10\log_{10}\frac{\text{absorption}}{\text{transmittance}} = \text{d.b. reduction.}$$

By the adoption of laminated construction :—

(Corrugated duralumin exterior skin on 3-in. duralumin channel framing, loose filling of kapok. Inner duralumin lining in sorbo rubber packing on frame. Lined with fireproofed upholstering fabric on $\frac{3}{32}$-in. cork sheets.)

On a 12-seater plane, an all-in reduction of 25 d.b. can be obtained at 37 lb. weight of treatment per passenger.

This allows for transmittance through windows and doors.

Lighter treatment, not exceeding 10 lb. per passenger, results in an insulation of some 12 d.b.

Exhaust Silencers for Internal Combustion Engines.

The impulses in the exhausts from internal combustion engines may have a frequency of from 10 to 200 per second.

The noise created may cover the entire audible range, the lower frequency-band being attributable to the exhaust impulses and the upper to the vortex effects and the vibration of metallic parts.

The pressure in an exhaust system may rise momentarily to 50 lb. per sq. in., thus causing expansions in the casings of silencers timed to the impulses and causing low frequency sounds and their concomitant overtones.

Silencing is best affected by the use of a sound absorbent for the higher frequencies coupled with a capacity type silencer or expansion chamber with perforated baffle for damping out the low frequency components of the noise.

Motor cycle engine silencers using perforated tubes, surrounded with glass silk, through which the exhaust gases pass to expansion chambers before discharge to the atmosphere, have been found to reduce the noise some 20 d.b. without impairment of engine performance.

In large stationary installations the ' capacity ' exhaust silencer can conveniently be provided by a large pit filled with rubble, through which the exhaust gases are discharged after passing through the ordinary engine silencers.

A low velocity of discharge to atmosphere is desirable if air pulsations are to be removed.

Silencing Exhausts from Ventilating Fans.

In exhausting a noisy atmosphere into a quiet zone it is desirable to keep the velocity of discharge from the fans down to 1,000 ft. per min. and to use an expansion chamber arranged to discharge to atmosphere through weathered louvres at a velocity not exceeding 300 ft. per minute.

The expansion chamber should be packed with sound absorbing tubes (of, say, Seapak on perforated zinc) carefully aligned to the flow of air so as to prevent air turbulence and to divide the flow into passages such that the mean dimension of the passage is not greater than one-tenth the mean travel of the air through it.

Noise Due to Electrical Machinery.

In transformers the laminations are attracted to each other twice each electrical cycle and therefore give a note of double the supply frequency.

A 100 k.v.a. outdoor distribution transformer, designed for quiet operation, gave the following results :—

Frequency. Cycles per Second.	Loudness Value. Phons.
100	18
200	7
300	6
600	14

Note the comparatively high equivalent loudness of the upper harmonics.

The cases must be stiffened to prevent amplification of the noise by vibration.

Analysis of the frequency components of noise from electrical machinery enable the causes to be traced with certainty.

B. G. Churcher quotes test results on an induction motor as below :—

Frequency of Component.	Frequency. Revs. per Sec.	Corresponding to
225	9	9 blades on fan.
675	27	Third harmonic of fan note.
1,120	45	45 rotor slots.
100	---	Vibration of stator punchings at twice supply frequency.

Care should be taken to distinguish the difference between Stubs' Iron Wire Gauge and Stubs' Steel Wire Gauge. The former is commonly known as the Birmingham Wire Gauge, and designates the Stubs' *Soft* wire sizes.

The Stubs' Steel Wire Gauge is the one employed in measuring drawn steel wire or drill rod, of Stubs' Make, and is also used by some makers of American drill rods.

(*Brown and Sharpe.*)

(b) SCREW THREADS AND SCREWS.

Forms of Screw Threads.

Figs. 1, 2, 3, and 4 show four usual forms of thread, each of 1 inch pitch.

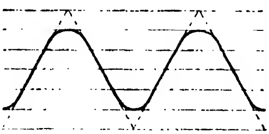

FIG. 1.—Whitworth Thread-form.

Fig. 2.—American Thread-form.

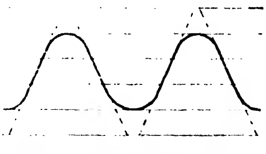

FIG. 3.—Swiss Thread-form.

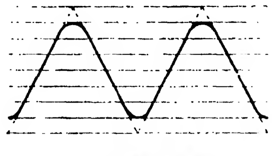

FIG. 4.—Steinlen Thread-form.

In the *Whitworth* or *English Standard* thread (fig. 1) the angle made by the two sides of the thread is 55° for all sizes of thread. One-sixth of the depth of the triangle is rounded off the top and bottom, so that the angle of 55° gives for the actual depth rather more than three-fifths and less than two-thirds of the pitch.

In the *American* (*Sellers'*) thread (fig. 2) the angle made by the two sides of the triangle is 60°, and one-eighth of the depth is cut off the top and bottom of the triangle, leaving a flat one-eighth of the pitch in width.

In the *Swiss* or *Thury* thread (fig. 3) the angle made by the two sides of the thread is $47\frac{1}{2}°$ and one-fifth of the depth is rounded off the top and bottom of the triangle.

For screw-plate Swiss threads the depth of the thread is three-fifths the length of the pitch.

The top of the ridge is formed by a circular arc, the radius of which equals one-sixth of the pitch. The space between two consecutive ridges is formed at the side next the core by a circular arc, the radius of which equals one-fifth of the pitch.

The Swiss thread for screws made in the lathe is the *Steinlen* thread (fig. 4). The angle made by the two sides of the thread is 58° 8′, and the radius of the connecting arcs is ·1011 of the pitch. The generating figure is an isosceles triangle, of which the base and the height are equal to the pitch. One-eighth of the depth is rounded off the top and bottom of the triangle.

The *British Association* thread is similar to that of Thury, except that the top and bottom of the threads are both rounded to the same radius, namely, two-elevenths of the pitch.

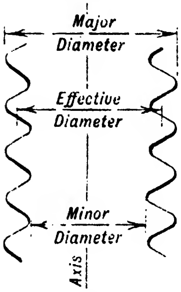

FIG. 5.

BRITISH STANDARD SCREW THREADS.

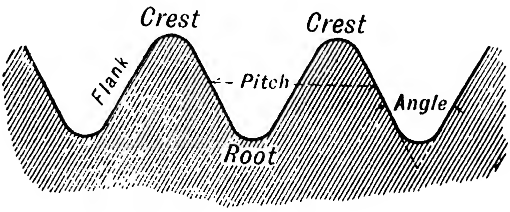

FIG. 6.

DEFINITIONS.*

The Effective Diameter of a parallel thread is the diameter of the imaginary co-axial cylinder which intersects the surface of the thread in such a manner that the intercept on a generator of the cylinder, between the points where it meets the opposite flanks of a thread groove, is equal to half the nominal pitch of the thread (fig. 5).

The *Major Diameter* of a thread is the diameter of the imaginary co-axial cylinder which just touches the crest of an external thread or the root of an internal thread (fig. 5).

The *Minor Diameter* is the diameter of the cylinder which just touches the root of an external thread or the crest of an internal thread (fig. 5).

The *Crest* of a thread is the prominent part of a thread, whether external or internal (fig. 6).

The *Root* is the bottom of the groove between the two flanking surfaces of the thread, whether external or internal (fig. 6).

The *Flanks* of a thread are the straight sides which connect the crest and the root (fig. 6).

The *Angle* of a thread is the angle between the flanks, measured in an axial plane section (fig. 6).

The *Pitch* of a thread is the distance, measured parallel to its axis, between corresponding points on adjacent thread forms, in the same axial plane (fig. 6).

Definition of Whitworth Form of Thread.

The British Standard Whitworth form of thread is a symmetrical V-thread in which the angle between the flanks, measured in the axial plane, is 55°; one-sixth of the sharp vee is truncated at top and bottom, the thread being rounded equally at crests and roots by circular arcs blending tangentially with the flanks, the theoretical depth of thread being thus 0·640327 times the nominal pitch.

The basic thread depths calculated from the above definition are rounded off to the nearest 0·0001 inch.

Tolerances.

British Standard Specification No. 84—1940 gives dimensions for standard Whitworth threads of 'close,' 'medium,' and 'free' fit respectively. The tolerance on effective diameter for 'medium' fit is calculated from the formula:

$$\text{Tolerance in inches} = 0\cdot002\sqrt[3]{D} + 0\cdot003\sqrt{L} + 0\cdot005\sqrt{P}.$$

where D = major diameter of thread,
L = length of engagement,
P = pitch. (All in inches.)

* By permission of the British Standards Institution.

Tolerances for 'close' fit are two-thirds of those for 'medium' fit, and for 'free fit,' 1½ times those for 'medium' fit.

When the above formula is applied to B.S. Whitworth threads from ¼ in. to 3 in. and to B.S. Fine threads from ¼ in. to 1½ in. diameter (taking the length of engagement as equal to the diameter of the thread), it gives tolerances in agreement with the 'standard' effective diameter tolerances in B.S. Specifications 92—1919 and 84—1918 (now superseded by B.S.S. 84—1940).

Note.—In introducing B.S.S. No. 84—1940, it was made clear by the British Standards Institution that caution should be exercised in changing over to the new standard if, during the present emergency, such a change might hamper production in any way. If its adoption is likely to introduce any difficulty in production or in gauging, arrangements can be made, by discussion between the manufacturer and the Government inspector, for production to continue to B.S.S. 84—1918 and 92—1919 or to other authorised specifications operative at the time of the introduction of B.S.S. 84—1940. (See also Amendment Slip, 1942.)

Acme Screw Threads.

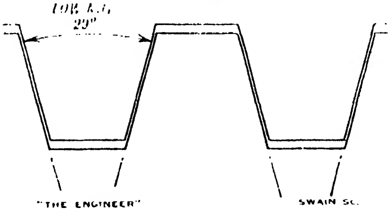

Fig. 7.

The contour of the Acme thread is given in fig. 7. It is the subject of the B.S.I. Standard 1104—1943. (Now withdrawn, but to be re-issued.) The angle is 29° and the depth of the thread one-half the pitch. The standard series goes from $\frac{1}{2}$-in. up to 5 ins. and from 10 threads per inch down to 2 per inch.

Screw Heads.

British Standard Heads for Small Screws.

(No. 450—1932.) (*Abstract.*)

For all classes of heads except cheese, the diameter to be 1·75 times the full diameter of the thread ; for cheeseheads, 1·5.

The width of saw-cuts to be according to the formula,

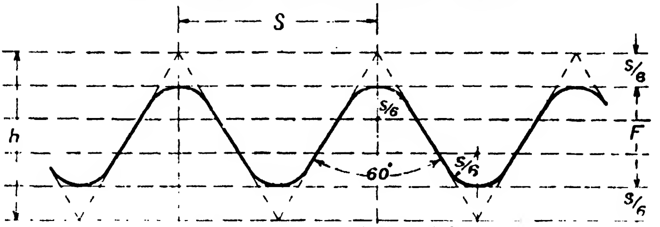
$$S = \cdot 2\,D + \cdot 1 \text{ mm.},$$

where

S = width of saw-cut, and D = full diameter of the thread in millimetres.

The standard depth of saw-cut to equal one-half the total depth of the head in all cases, such depth being measured at the centre of the head.

Cycle Engineers' Institute Standard Threads.



$h = 0{\cdot}866$ S. F = 0·5327 S.

Fig. 8.

The dimensions given below are for right-hand threads except those marked ** which are for left-hand threads only, and that marked * (i.e. $\frac{9}{16}$ in.) is for right or left hand threads.

Comparison of U.S. Standard and Whitworth Screw Threads.

The difference in form that exists between the Whitworth and the U.S. standard screw thread is shown in fig. 10. The comparison is based upon a screw with 1 thread per inch. Clearances and interferences for the two forms of threads having any other pitch may therefore be obtained by dividing the respective values given in the diagram by the number of threads per inch under consideration.

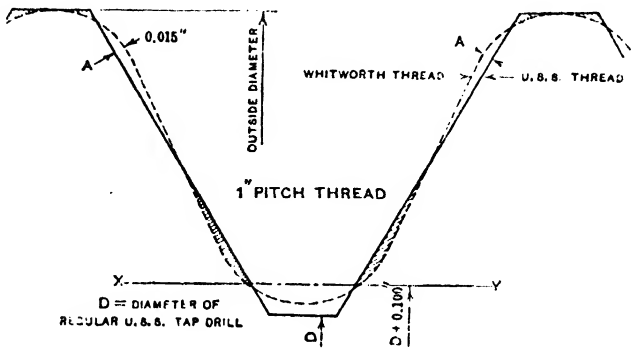

FIG. 10.

A new series of Unified Screw Threads has now been agreed on for common use as an alternativ to the existing Whitworth and U.S. Standards.

PIPE THREADS.

NOTE.—*Tubes 7 in. and upwards*: The ends shall be specially sized prior to screwing, in order to ensure ample thickness below the root of the thread. This condition shall be complied with for the screwing of cut tube at site.

BOLTS AND NUTS.

According to the Whitworth system of standard sizes of bolts and nuts, the thickness of the bolt-head is seven-eighths of the diameter, and that of the nut is equal to the diameter.

In the Sellers' (American) system the heads and nuts are hexagonal, the thickness of the heads and of the nuts being equal to 1 diameter minus one-sixteenth inch. The breadth across the flats is equal to 1½ diameters plus one-sixteenth inch.

Dimensions of B.S. Black Bolts, Nuts and Lock Nuts (Hexagon and Square).

Shank and Core Diameters are given in decimals of an inch.
Fractions in Drill sizes are fractions of an inch.
Mean Core Diameter, is the mean of the variations which the Makers give as possible, but these variations are only in the third place of decimals.

Bolt Spacing.

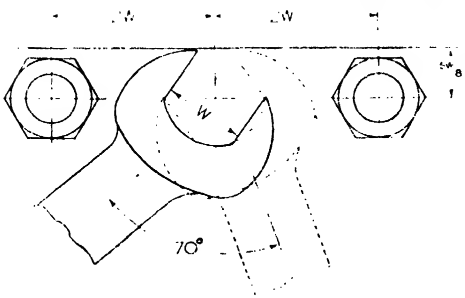

Fig. 20.

Fig. 20 shows minimum spacings and pitches for Whitworth studs, bolts, and nuts. which will give sufficient space to enable a standard spanner to be used. Being for use with hexagonal nuts a movement of 70° full is allowed for the spanner.

Pipe Flanges.

Flanges and Bolts of Cast-iron Pipes.

Hydraulic Test Pressure for B.S. Steel Tubes.

The test pressure for tubes of all classes is 700 lb. per sq. in.

British Standard Specification for Cast-Iron Pipes and Special Castings for Water, Gas, and Sewage*

(No. 78—1938.) (*Abstract.*)

3. The metal used for casting the pipes shall be a suitable mixture of pig iron and scrap, and shall be melted in the cupola or air-furnace, or may, if approved by the purchaser, be refined in a molten condition in a mixer of an active type. The pig iron shall be best tough grey foundry pig iron, and the scrap shall be clean, unburnt, and of good quality. There shall be no admixture of cinder iron or any material calculated to render the metal inferior in quality, and the resulting casting shall not be white or vitreous on fracture.

10. The tensile breaking strength of the metal shall be not less than 10 tons per sq. in. for a test piece of 0·875 in. diameter or less, or 9 tons per sq. in. for a test piece between 0·875 in. and 2·1 in. in diameter.

12. Straight pipes shall be cast vertically, in dry sand moulds formed from turned iron patterns and in accurately faced and truly jointed boxes, and without the use of core nails, chaplets, or thickness pieces or any substitute therefor. They shall be cast with a sufficient head of metal to ensure soundness, which head shall be afterwards cut off in a lathe and the finished pipe left the length and shape required. Straight spigot and socket pipes shall be cast socket downwards.

25. The straight pipes shall, before being coated, respectively withstand the following hydraulic test pressures without showing any leakage, sweating, or other defect:—

—	Gas.	Water & Sewage.		
	Class A.	Class B.	Class C.	Class D.
Test pressure in feet head . .	200	400	600	800

While under the test pressure each pipe shall be smartly struck with a suitable hand hammer weighing not less than one and a half pounds.

Standard Diameters, Thicknesses, and Test Pressures for Steel Pipes to be Interchangeable with Cast-Iron Pipes.

Notes.—(i) This table applies only to spigot and socket pipes which are required to be interchangeable with cast-iron pipes in accordance with B.S.S. No. 78—1938, Cast-Iron Pipes for Water, Gas and Sewage.

(ii) Where weldless pipes are ordered to be made of steel of from 35–41 tons/sq. in. tensile strength the test pressures set out in the table may, if desired by the purchaser, be increased by 40 per cent. with a maximum of 2,300 ft. head.

British Standard Steel Spigot and Socket Pipes for Water, Gas and Sewage.

(B.S.S. No. 534—1934.)

Standard Diameters, Thicknesses and Test Pressures.

Notes.—Weldless pipes of the type dealt with in this Specification are not at present manufactured larger than 15 ins. nominal size.

When weldless pipes are ordered to be made of steel of from 35–41 tons sq. in. tensile strength, the test pressures set out in the table may, if desired by the purchaser, be increased by 40 per cent., with a maximum of 2,300 ft. head.

Reference should be made to the Table on p. 114 for pipes which are required to be interchangeable with cast-iron pipes in accordance with B.S.S. No. 78—1938, Cast-Iron Pipes for Water, Gas and Sewage.

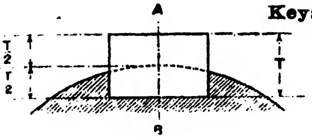

FIG. 21.

Keys and Keyways.

BRITISH STANDARD KEYS.

(No. 46—Part I—1929.) (*Abstract.*)

The depth of immersion of the key on the centre line (A–B) is calculated so as to give approximately half and half immersion at the sides.

In 1929 the British Standards Institution issued a revised specification, No. 46, Part I, for keys and keyways. The Specification includes exhaustive tables for Rectangular Parallel, Square Parallel, Rectangular and Square Taper Keys, Gib-headed Keys, Woodruff Keys, etc. The tables are far too long to reprint and users are advised to consult them. It is, however, to be noted particularly that the depth of immersion of a rectangular key is no longer half and half at the tangent of the shaft as was the old practice, shown in the sketch, but as near as possible half and half at the edge of the keyway. A few typical dimensions are tabulated below.

RECTANGULAR PARALLEL KEYS.

Designation.	Shaft Diam.		Key.		Keyway.		
						Depth.	
B.S.K.B.	Over	Up to	Width.	Thickness.	Width.	Shaft.	Hub.
$\frac{5}{16}$	1	$1\frac{1}{4}$	0·3125	0·2187	0·3125	0·1325	0·0883
$\frac{7}{16}$	$1\frac{1}{2}$	$1\frac{3}{4}$	0·4375	0·28125	0·4375	0·1721	0·1122
$\frac{9}{16}$	2	$2\frac{1}{4}$	0·5625	0·375	0·5625	0·2269	0·1511
$\frac{11}{16}$	$2\frac{1}{2}$	$2\frac{3}{4}$	0·6875	0·46875	0·6875	0·2822	0·1906
$\frac{7}{8}$	3	$3\frac{1}{4}$	0·875	0·625	0·875	0·3746	0·2544
$1\frac{3}{8}$	5	$5\frac{1}{2}$	1·375	0·9375	1·375	0·5629	0·3796
$1\frac{7}{8}$	7	$7\frac{1}{2}$	1·875	1·25	1·875	0·7513	0·5047
3	11	12	3	2	3	1·2031	0·8049

FOUR AND SIX SPLINES.

Shafts with four and six splines are covered by tables in Specification No. 46, Part 2—1929. These tables begin at $\frac{1}{2}$-in. diameter over splines and go up to 6 in. diameter. The fit is on the minor diameter, but throughout the entire range of sizes the whole dimensions and the limits on the shaft diameters for the various fits are in accordance with British Standard Limits and Fits for Engineering (*B.S. Report*, No. 164—1924), whereas the splines standardised for the automobile industry are based on the standards of the American Society of Automotive Engineers.

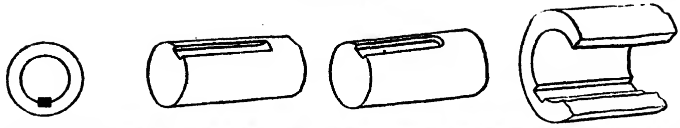
In another Table in No. 46, Part 2, tentative standards for multiple spline shafts and for serrated shafts are given. (See also B.S. Aircraft Standard A20—1946.)

CONED AND KEYED SHAFTS.

The standard taper of the cone is 1 in 10. The key is parallel to the side of the cone, and its size corresponds with the diameter at the larger end of the cone. The length of the key should not be less than one and a half times the larger diameter of the cone.

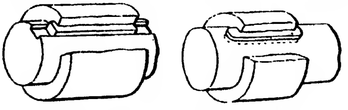
TAPER PINS. No. 46, Part 3.—1935.

The taper is 1 in 48 or $\frac{1}{4}$ in. per ft. In split taper pins the split should be one-fifth of the length.

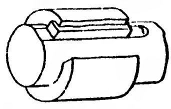


1 AND 2—*Key.*—A key is a piece inserted between the joint of two parts to prevent relative movement. For the purpose of this specification a key is defined as a piece inserted in an axial direction between a shaft and a hub to prevent relative rotation. *Keyway.*—A recess in a shaft or hub to accommodate a key.

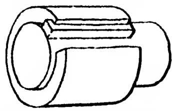
3 TO 7—*Plain Parallel Key.*—A key of rectangular or square section; uniform in thickness and width and with squared ends. *Round-ended Parallel Key.*—A plain parallel key with ends rounded as to width. *Plain Taper Key.*—A key of rectangular or square section uniform in width; tapered in thickness and with squared ends. *Round-ended Taper Key.*—A plain taper key as defined above, but with ends rounded as to width. *Gib-head Key.*—A key provided with a head to facilitate withdrawal.



8—*Sunk Keys.*—A key partly in the shaft and partly in the hub.

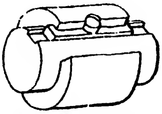


9—*Flat Saddle Key.*—A taper key fitting a keyway in the hub and a flat on the shaft.

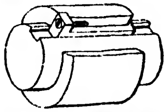


10—*Hollow Saddle Key.*—A taper key fitting a keyway in the hub, the bottom of the key being formed to fit the cylindrical surface of the shaft.

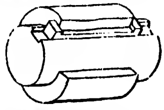
11—*Feather Key.*—A key attached to one member of a pair and permitting relative axial movement.



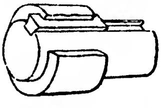
12—*Peg Feather Key.*—A feather key with a peg to prevent its relative movement in the part to which it is attached.



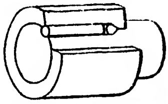
13—*Single Head Feather Key.*—A feather key with a projection at the end to prevent its axial movement in hub.



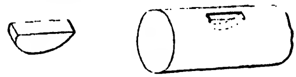
14—*Double Head Feather Key.*—A feather key with a projection at each end to prevent its axial movement in hub.



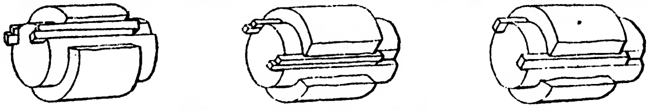
15—*Dovetail Key.*—A key having one portion of its cross section of dovetail form.



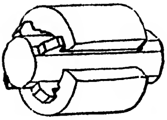
16—*Round Key.*—A key of circular section fitted in a hole drilled partly in the shaft and partly in the hub.



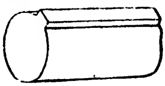
17 AND 18—*Woodruff Key and Keyway.*—A key in the form of a segment of a parallel-sided circular disc and a segmental recess in a shaft to accommodate a Woodruff key.



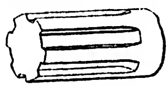
19—*Tangential Keying.*—The use of keys acting tangentially in opposite directions.



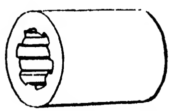
20—*Stake Keying.*—The use of taper keys for centralising the hub on the shaft and for preventing relative movement. They may be hollow or flat saddle keys.



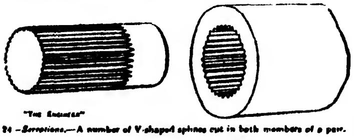
21—*Spline.*—A key-like projection integral with a member of a pair.



22—*Spline Shaft.*—A shaft having one or more splines. Spline shafts are designated by the number of splines, e.g., six-spline shaft.

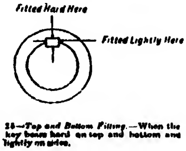


23—*Spline Hub.*—A hub having one or more splines.

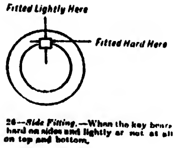


"The Engineer"

24—*Serrations.*—A number of V-shaped splines cut in both members of a pair.



25—*Top and Bottom Fitting.*—When the key bears hard on top and bottom and lightly on sides.



26—*Side Fitting.*—When the key bears hard on sides and lightly or not at all on top and bottom.

SECTION V

PART II

WEIGHT OF MATERIALS.

(Revised by S. A. Wood, M.Sc., M.I.Mech.E.)

A.—DENSITY AND SPECIFIC GRAVITY.

Definitions.—Density is mass per unit volume. In the C.G.S. system this is expressed in grammes per millilitre, and the F.P.S. system, in lb. per cub. foot.

Specific gravity is the ratio of the mass of a given volume to the mass of the same volume of some reference substance (usually water or air) at a fixed reference temperature and pressure. The reference conditions for water are 62° F. and 30 inches of mercury.

RELATION BETWEEN VOLUME AND WEIGHT OF WATER.

Detail.	Fresh.	Sea.
Greatest density at	39·2° F.	Freezing-point
1 cubic foot at 62° F. weighs . . .	62·288 lbs.	64 lbs.
1 cubic inch „ „	0·036047 lb.	0·037037 lb.
1 cubic foot „ equals	6·2288 gals.	
1 gallon 62° at F. weighs	10 lbs.	10·3 lbs.
1 ton equals	35·962 cub. ft.	35 cub. ft.
1 ton contains	224 gals.	217 gals.
Freezes at	32° F.	27·4° F.

From 4° C. water expands regularly as the temperature rises; so that 1,000 parts at 0° C. become at 0° = 1,000·00, at 4° = 999·88, at 10° = 1,000·14, at 20° = 1,001·67, at 30° = 1,004·21, at 40° = 1,007·61, at 50° = 1,011·93, at 60° = 1,016·86, at 70° = 1,022·43, at 80° = 1,028·73, at 90° = 1,035·58, at 100° = 1,043·03.

DENSITY OF ATMOSPHERIC AIR.

1 cubic foot of dry atmospheric air at 62° F. and 30 inches of mercury weighs 532·5 grains (7,000 grains = 1 lb. avoir.).

To find Specific Gravity.

Solids.

W = weight of a body in the air,
S = specific gravity of the body,
W = weight of the body (heavier than water) immersed in water;

then,

$$S = \frac{W}{W - \mathit{W}};$$

When the body is lighter than water, annex to it a heavier body that is able to sink the lighter one.

S = specific gravity of the heavier annexed body;
s = specific gravity of the lighter body;
W = weight of the two bodies in air;
W = weight of the two bodies in water;
w = weight of the heavier body in air;
w = weight of the lighter body in air;

then,

$$s = \frac{w}{W - \mathit{W} - \frac{w}{S}}$$

A simple way to obtain the specific gravity of a wood is to form it into a parallel rod, and place it vertically in water; then, when in equilibrium, the immersed end is to the whole rod as the specific gravity is to 1.

Liquids.

Measure the weight of a stoppered-glass bottle; then fill the same with distilled water and weigh it again; the difference between the two measurements gives the weight of the distilled water. Then completely empty out the water and refill the bottle with the liquid whose specific gravity is required and again weigh; this weight less the weight of the bottle gives the weight of the liquid; this weight divided by the weight of the water gives the specific gravity of the liquid.

In practice it is convenient to employ a bottle (called a specific gravity bottle) that holds exactly 10 grammes of distilled water at 4° C., because, when such a bottle is filled with the liquid under trial the weight in centigrammes of the liquid taken at 0° C. represents the specific gravity at once, without calculation. For convenience a counterpoise of brass is adjusted to the weight of the bottle.

Gases.

Measure in the same way as liquids, taking Air as the standard. A large and very light, *i.e.* thin, glass vessel must be used for the purpose, otherwise the weight of the glass will swamp, as it were, the weight of the enclosed gas, and accurate results cannot be obtained. Certain corrections have to be made in practice, for great accuracy.

To Discover the Adulteration in Metals, or to find the Proportions of Two Ingredients in a Compound.

$$w = \frac{W - s(W - W')}{1 - \frac{s}{S}}.$$

EXAMPLE.—A metal compounded of silver and gold weighs, $W=6$ pounds in the air, and in water, $W'=5{\cdot}636$ pounds. Required the proportions of silver and gold.

$S=19{\cdot}36$ specific gravity of gold. $s=10{\cdot}51$ specific gravity of silver.

$$\text{Weight } w = \frac{6 - 10{\cdot}51(6 - 5{\cdot}636)}{1 - \frac{10{\cdot}51}{19{\cdot}36}} = 4{\cdot}755 \text{ pounds of gold.}$$

and 1·245 pounds of silver.

NOTE ON SPECIFIC GRAVITIES OF WOODS.

The specific gravity or weight per cubic foot of wood varies with the amount of water it contains. In the preceding list the figures refer to timber at a moisture content of 15 per cent. of the oven-dry weight, which represents a condition intermediate between kiln-seasoned and air-seasoned. A short list showing the change in weight which takes place when green timber is seasoned is given on page 283. Reference may also be made to the number of cubic feet in 1 ton of timber in the green and seasoned conditions on p. 283.

In any particular timber there is a considerable range of weight owing to the natural variation which occurs in different trees and in different parts of the same tree. It must be emphasised that the figures given are averages only.

(*Forest Products Research Laboratory.*)

SPECIFIC GRAVITIES OF GRANULAR MATERIALS.

The values given in the table on p. 122 for granular materials, such as cement, are those of the solid material, and should be distinguished from the density of the material in bulk, which is affected by the voids between the particles.

Bulk Densities of Granular Materials.

Material.	Bulk Density Lbs. per Cub. Ft.	Material.	Bulk Density Lbs. per Cub. Ft.
Cement, Portland	90	Gunpowder	60
,, Roman	97	Gravel	109
Earth, loose	93	Sand, coarse	112
,, rammed	100	,, damp, loose	87
,, with moist sand	128	,, dried, loose	97
		,, siliceous	106

Hydrometer Scales.

Liquids lighter than Water.

The Tagliabue formula, adopted by the American Petroleum Institution and in fairly general use, is

$$\text{Degrees A.P.I.} = \frac{141\cdot5}{\text{Sp. Gr.}} - 131\cdot5$$

The Bureau of Standards formula, less generally used, is

$$\text{Degrees Baumé} = \frac{144}{\text{Sp. Gr.}} - 144$$

(See page 126 for liquids heavier than water.)

Weight of Wrought Iron and Steel.

(The Table gives the weights for wrought iron, 1 cubic foot of wrought iron being taken to weigh 485 lbs. For steel an addition of about 1 lb. in 100 lbs. must be made to the tabular amounts.)

Thickness or Diameter in Inches.	Thickness or Diameter in Decimals of a Foot.	Weight of a *Square Foot* in Pounds.	Weight of a *Square* Bar, 1 Foot long, in Pounds.	Weight of a *Round* Bar, 1 Foot long, in Pounds.	Weight of *Balls* in Pounds.	Thickness or Diameter in Inches.	Thickness or Diameter in Decimals of a Foot.	Weight of a *Square Foot* in Pounds.	Weight of a *Square* Bar, 1 Foot long, in Pounds.	Weight of a *Round* Bar, 1 Foot long, in Pounds.	Weight of *Balls* in Pounds.

Weight of Steel Wire Ropes.

The weight per fathom (6 ft.) in lbs. of the usual engineering wire rope is approximately the square of the circumference, *i.e.*, for example, a 3-in. rope would weigh 9 lbs. per fathom, approximately.

Weight of Hexagon Rod Metal.

Weight of hexagon rod metal, measured across sides = weight of square metal × 0·86602.

Weight of Octagon Rod Metal.

Weight of octagon rod metal, measured across sides = weight of square metal × 0·82843.

Weight of Rolled Lead, Copper, and Brass: Sheets and Bars.

Thickness or Diameter, or Side.	Lead. Sheets, per Square Foot.	Lead. Square Bars, 1 Foot long.	Lead. Round Bars, 1 Foot long.	Copper. Sheets, per Square Foot.	Copper. Square Bars, 1 Foot long.	Copper. Round Bars, 1 Foot long.	Brass. Sheets, per Square Foot.	Brass. Square Bars, 1 Foot long.	Brass. Round Bars, 1 Foot long.	Thickness or Diameter, or Side.

Specification of Sheet Metals.

When specifying for sheet metals, care should be taken that the nature of the gauge is stated, *i.e.* whether it is S.W.G., B.G., or Trade Gauge. In the case of 'Sheet Zinc,' for example, the Trade Gauge No. 20 is 0·063 in. (see above, and Index, 'Sheet Zinc Trade Gauge'), but this if expressed in S.W.G. is 0·36 in. (see Index, 'Imperial Standard Wire Gauge').

(Siemens Bros. & Co.)

Weight of Pipes and Tubes.

D = outer diameter; b = bore; t = thickness; W = weight of 1 ft. length; k = ·02182 × weight of 1 cubic foot of metal.

$$W = t(D - t)k = t(b + t)k.$$

Approximate Weights of Cold Drawn Weldless Steel Tubes in Lb. per Foot. Plain at Ends.

If the external diameter is given, subtract figure **in** *black type at bottom of column; for example, the weight per lineal foot of a copper tube 2 inches external diameter, 12 S.W.G., is 2·65 — 0·26 = 2·39 lbs.* The weights are calculated from 12 samples of tubes made from tough copper (specific gravity at 60° F. 8·8917, or ·3299 lb. per cubic inch). **Brazed copper tubes weigh more than seamless; but an exact multiple cannot be given. Mandril-drawn brazed tubes weigh the same as seamless tubes. In practice a slight deviation from the above theoretical weights must be expected. To ascertain the weight of a seamless tube of other metal, multiply the weight of a similar copper tube by ·96 for brass (70 and 30 alloy), by ·86 for wrought iron, by ·81 for cast iron, or by 1·28 for lead.** *(The Broughton Copper Co., Ltd.)*

WEIGHT OF SEAMLESS BRASS TUBES.

(Containing 70 % of copper.)

The figures in italics show the difference in percentage of weight of brass tubes made to the B.W.G. and the S.W.G., the latter being taken at 100.

The above weights, multiplied by ·994, give the weight of a brass tube 2 and 1 alloy.

These weights are calculated from the specific gravity of 16 samples of tubes, from various makers, each of the samples being 1 foot long × 1 3/8 inch external diameter × 14 B.W.G., which was found to be 8·558, or ·3089 lb. per cubic inch, for the alloy of 70 and 30, and 8·508 specific gravity, or ·3071 lb. per cubic inch, for the alloy of 2 and 1 at a temperature of 60° F.

To ascertain the weight of a seamless tube of copper, multiply the weight of a similar brass tube by 1·0388.

SIZES AND WEIGHTS OF ALUMINIUM TUBES.

SECTION V

PART III

STRENGTH OF MATERIALS.

(Revised by S. A. Wood, M.Sc., M.I.Mech.E.)

A. STRENGTH AND ELASTICITY OF METALS.

MODULI OF ELASTICITY IN TENSION (YOUNG'S MODULUS) AND SHEAR FOR METALS.
(Lbs. per sq. in. × 10^6.)

Metal.	Modulus in Tension (E).	Modulus in Shear (C).
Steel (0·14% Carbon)	29·6	12·0
„ (1·7% „)	30·2	11·0
„ (Nickel)	28·5	11·2
Iron (wrought)	30·3	10·9–11·8
„ (cast)	14·2–18·6	5·0–7·5
Invar	20·0	—
Aluminium	10·1	3·7
Duralumin	10·4	4·0
'Y' Alloy (Cu-Ni-Mg-Al)	10·6	—
Brass (66–34)	13·8–14·5	5·0
Bronze	11·4	4·9
Phosphor bronze	14·8	6·1
Copper (drawn)	18·0	5·6
„ (electrolytic)	17·3	6·5
Lead (pure cast)	2·3	0·7
Nickel	29·9	10·6
Silver	11·2	4·1
Tin	7·7	2·4
Zinc	10·5–14·9	5·5

TRANSVERSE STRENGTH OF MATERIALS.

If a beam is tested to destruction in bending, the maximum fibre stress f is calculated from the formula

$$= \frac{My}{I}$$

M = bending moment.
y = distance from neutral axis of beam to extreme fibre.
I = moment of inertia of cross-section.

This is not usually the same as the ultimate strength found by direct loading.

Definition.—f is known as the Modulus of Rupture, and is generally understood as applying to rectangular sections.

Strength Data on Metals at Normal Temperatures.

STRESS UNITS: TONS PER SQUARE INCH.

BRITISH STANDARD SPECIFICATION FOR STRUCTURAL STEEL FOR BRIDGES AND GENERAL BUILDING CONSTRUCTION.*

(No. 15—1948.) (*Abstract.*)

(See also No. 449—1937. Amended 1938–1946.)

No. 1 quality Steel shall be made by the Open Hearth Process (Acid or Basic) or Acid Bessemer Process unless one of these processes is specially required or specified, and shall not show on analysis more than 0·06 per cent. of sulphur or of phosphorus.

No. 2 quality (Copper Bearing) Steel shall conform to the above specification for No. 1 quality Steel but shall in addition contain copper within the following limiting values, as may be specified :

(*a*) 0·20 to 0·35 per cent., or (*b*) over 0·35 to 0·50 per cent.

The quality of the steel required shall be stated in the enquiry or order.

Plates, sections, and flat bars must show a tensile breaking strength of 28 to 33 tons per sq. in., with an elongation of not less than 20 per cent. for steel of ·375 in. thickness and upwards, and not less than 16 per cent. for steel below ·375 in. thickness

Round and square bars (other than rivet bars) must show a tensile breaking strength of 28 to 33 tons per sq. in.; the elongation must be not less than 20 or 24 per cent. (according to the form standard test piece used for making the test).

Rivet Bars, 25 to 30 tons per sq. in. breaking strength, and not less than 26 or 30 per cent. elongation (according to the test piece used).

The minimum yield stress is also specified for each shape.

BRITISH STANDARD SPECIFICATION FOR STRUCTURAL STEEL FOR MARINE BOILERS.*

(No. 14—1942.) (*Abstract.*)

***Plates.*—The tensile breaking strength of steel plates for shells, butt straps, and girders shall be between the limits of 26 and 35 tons per square inch. For plates intended for flanging or welding, and for combustion chambers and furnaces, the tensile breaking strength shall be between the limits of 26 and 30 tons per square inch. The elongation, measured on a Standard test piece having a gauge length of 8 ins., shall be not less than 20 per cent. for material of 0·375 in. in thickness and upwards required to have a tensile breaking strength of 28 to 35 tons per sq. in.; and not less than 23 per cent. for material of 0·375 in. in thickness and upwards required to have a tensile breaking strength of 26 to 30 tons per sq. in.**

***Angle and Tee Bars and Stays.*—The tensile breaking strength of angle and tee bars shall be between the limits of 28 and 32 tons per sq. in., with an elongation of not less than 20 per cent. measured on the Standard test piece. For bars for longitudinal stays the tensile breaking**

* By permission of the British Standards Institution.

strength shall be between 28 and 35 tons per sq. in., with an elongation of not less than 20 per cent. measured on the Standard test piece.

For material under 0·375 in. in thickness the elongation may be not more than 3 per cent. below the above-named elongations.

***Rivet Bars.*—The tensile breaking strength of rivet bars shall be between the limits of 26 and 30 tons per sq. in. of section, with an elongation of not less than 25 or 30 per cent. (according to the test piece used). The bars may be tested the full size as rolled.**

BRITISH STANDARD SPECIFICATION FOR STRUCTURAL STEEL FOR SHIPBUILDING.*

(No. 13—1942.) (*Abstract.*)

***Plates.*—The tensile breaking strength of steel plates, determined from Standard test pieces, shall be between the limits of 28 and 33 tons per sq. in. or 26 and 32 tons per sq. in. For plates specially intended for cold flanging the tensile breaking strength shall be between the limits of 26 and 30 tons per sq. in. The elongation, measured on a Standard test piece having a gauge length of 8 ins., shall be not less than 20 per cent. for material of ·375 in. in thickness and upwards, and not less than 16 per cent. for material below ·375 in. in thickness.**

***Angles, Bulb Angles, Channels, etc.*—The tensile breaking strength of sectional material, such as angles, bulb angles, channels, etc., shall be between the limits of 28 and 33 tons per sq. in. The elongation, measured on a Standard test piece having a gauge length of 8 ins., shall be not less than 20 per cent. for material of ·375 in. in thickness and upwards, and not less than 16 per cent. for material below ·375 in. in thickness.**

***Rivet Bars.*—The tensile breaking strength of rivet bars shall be between the limits of 25 and 30 tons per sq. in. of section, with an elongation of not less than 25 or 30 per cent.** (according to the test piece used).

BRITISH STANDARD TENSILE AND IMPACT TESTS.

For details, see British Standard Specifications No. 18—1938 (Tensile Tests), No. 131—1933 (Notched Bar Tests) and No. 1349—1947 (Impact Test for Cast Iron.)

ADMIRALTY TESTS FOR STEEL AND IRON.

(1925.)

TESTS FOR STEEL.

TESTS FOR STEEL ANGLES, ANGLE BULBS, TEES, TEE BULBS, ZED BARS, SHIP PLATES, AND SHIP SHEETS.

(*Abstract.*)

Strips cut lengthwise or crosswise to have an ultimate tensile strength of not less than 26 and not more than 30 tons per sq. in. of section, with an elongation of 20 per cent. in a length of 8 ins. For plates of 10 lbs. and sheets elongation may be not less than 18 per cent.

One bar, plate, or sheet is to be selected from every charge, provided the number of bars, plates, or sheets does not exceed 50. If above that number, one for every additional 50 or portion of 50. A sample may be selected from every section of bar, or every thickness of plate or sheet, from each charge, but bars may be received or rejected without a trial of every section, and plates or sheets without a trial of every thickness, on the invoice.

Strips cut crosswise or lengthwise 1¼ in. wide must stand bending cold in a press to a curve of which the inner radius is one and a half times the thickness of the steel tested.

The steel shall stand such forge tests (hot and cold for bars and hot for plates and sheets), and other general usage tests as may be considered necessary to prove the soundness of the material and its fitness to stand such treatment and bending as it may be subjected to in the shipyard.

The strips may all be cut in a planing machine, and have the sharp edges taken off.

The ductility of every bar or plate is to be ascertained by the application of such of the above tests as may be considered necessary.

The steel to be free from lamination and injurious surface defects.

* By permission of the British Standards Institution.

TESTS FOR STEEL RIVETS.

One tensile test shall be taken from each charge, but when the weight of the bars, as rolled from one charge exceeds 5 tons, an additional test shall be made for each further 5 tons or portion thereof.

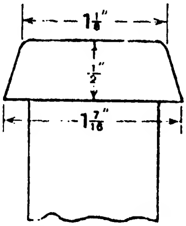

FIG. 1.—Pan Heads, Straight Necks.

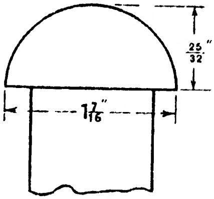

FIG. 2.—Snap Heads, Straight Necks.

SHIP RIVETS. ACID, BASIC, OR ELECTRIC FURNACE.

The rivets are to be made from British 'acid open-hearth' steel bars having an ultimate tensile strength, for 'ordinary and screw' rivets of not less than 26 and not more than 30 tons per square inch, with a minimum elongation of 25 per cent. in a length of 8 diameters of the test piece.

Rivets selected as considered necessary to stand the following tests:—

(a) Bending double when cold, and hammered till the two parts of the shank touch, in the manner shown in fig. 6, without fracture.

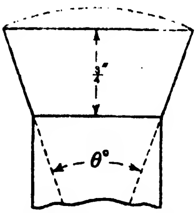

FIG. 3.—Countersunk Heads.

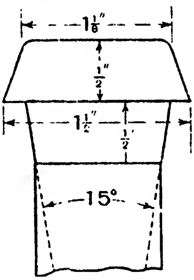

FIG. 4.—Pan Heads, Conical Necks.

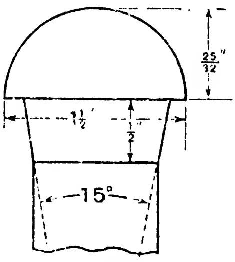

FIG. 5.—Snap Heads, Conical Necks.

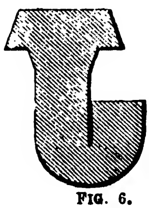

FIG. 6.

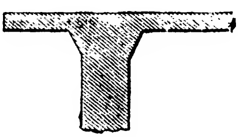

FIG. 7.

(b) Flattening of the rivet head, while hot, in the manner shown in fig. 7, without cracking at the edges. The head to be flattened until its diameter is twice the diameter of the shank.

(c) The shank of the rivet to be nicked on one side, and bent cold to show the quality of the material.

TESTS FOR STEEL BARS, FLAT, SEGMENTAL, ROUND, SQUARE, AND HEXAGONAL.

Test pieces are to have an ultimate strength of not less than 28 and not exceeding 32 tons per square inch of section, with an elongation of 20 per cent. in a length of 8 ins. The steel to stand such forge tests, both hot and cold, as may be sufficient to prove soundness of material and fitness for service.

Strips not less than 1 in. square or of the full thickness of section of the bar as rolled, must stand bending double in a press to a curve of which the inner radius is one and a half times the thickness of the steel tested. To be tested cold.

Hot and Cold Forge Test.

The steel shall stand such forge tests, both hot and cold, as may be sufficient in the opinion of the Overseer to prove the soundness of the material and fitness for the service for which it is intended.

Welding Test.

Whenever the Overseer may deem it necessary, sample pieces are to be taken for testing the welding qualities of the steel by welding two pieces together, and bending the resulting piece in way of the weld when cold. The result is to be satisfactory to the Overseer.

INSTRUCTIONS FOR TREATMENT OF MILD STEEL.

All plates or bars which can be bent *cold* are to be so treated, and if the whole length cannot be bent cold, the portion to be bent hot must be of a uniform temperature throughout; the varying temperature from hot to cold portion is to be extended so as to avoid an abrupt termination of the heat.

If plates or bars have been so severely cold worked as to raise any doubts as to their suitability for the service intended, subsequent normalising may be required at the discretion of the Overseer.

In cases where plates or bars have to be heated, the greatest care should be taken to prevent any work being done upon the material after it has fallen to the dangerous limit of temperature known as a 'blue heat'—say from 600° to 400° F. Should this limit be reached during working, the plates or bars should be reheated.

Where plates or bars have been heated throughout for bending, flanging, &c., and the work has been completed at one heat, subsequent normalising is unnecessary.

Where simple forge-work has been done, such as the formation of joggles, corners, and easy curves or bends, on portions of plates or bars, and the material has not been much distressed, subsequent normalising may be dispensed with.

Every care is to be taken, however, to allow the material to cool slowly and uniformly throughout the part which has been heated.

Plates or bars which have had a large amount of work put upon them while hot, and have had to be reheated, should be subsequently normalised. It is preferred that this normalising should be done simultaneously over the whole of each plate or bar when this can be done conveniently.

If it is inconvenient to perform the operation of normalising at one time for the whole of a plate or bar, portions may be normalised separately, proper care being taken to prevent an abrupt termination of the line of heat. If the severe working has been limited to a comparatively small part of a plate or bar, normalising may be limited to the parts which have been heated, the same care being taken to prevent an abrupt termination of the line of heat.

Normalising Mild Steel.

The material is to be evenly and gradually heated until it reaches a temperature of about 870° C. It is to soak at that temperature for about 30 minutes. It is then to be removed from the furnace and allowed to cool in air free from draughts.

In important cases where any bar or plate shows signs of failure or fracture in working, the details should be forwarded to the Admiralty, in order that instructions may be given as to the disposal of the bar or plate. Failure need not be reported in every case.

It is not generally necessary to anneal plates or bars after punching as a means of making good damage done in punching. For mild steel plating which forms an important feature in the general structural strength, such as the inner and outer bottom plating, deck plating, deck stringers, &c., the butt straps should have the holes drilled or punched $\frac{1}{8}$-in. small and rimed. In such plating the countersunk holes should be punched about $\frac{1}{8}$ in. less in diameter than the rivets which are used, the enlargement of the holes being made in the countersinking. All countersinking to be carefully done.

All steel and iron work is to be carefully scaled, scraped, and cleaned before being painted, and each portion of it as it is turned out of hand is to have a coat of linseed oil, thin red lead, or other substance, as may be required, as soon as it is sufficiently completed to receive it, in order to prevent as far as possible the work from becoming in any degree injuriously oxidised during the building of the ship. The plates of outer and inner bottom and sides, vertical keel and longitudinals, the lower plates of bulkheads, including those above the inner bottom, all the plates of oil fuel, water ballast and fresh water compartments, and the lower plates of frames, are to be treated as follows, with a view to removing the black oxide or scale:—The plates previous to their being taken in hand for working are to stand a few hours in a liquid consisting of 19 parts of water and one of hydrochloric acid. The plates should be pickled on edge and not laid flat. When plates are removed from the dilute acid bath both the surfaces are to be well brushed and washed to remove any scale which may still adhere to them. They should then be placed in another similar bath filled and kept well supplied with fresh water, or be thoroughly washed with a hose, as may be found necessary; the plates on removal from the fresh water should be placed on edge to dry.

TESTS FOR IRON.

TESTS FOR BAR IRON.

The whole of the iron supplied is to be of the description known as 'puddled' wrought iron.

The whole of the samples of every description of iron when tested with the grain are to realise a tensile strength of 22 tons to the square inch. Elongation 20 per cent. test piece 'B' for squares or rounds, and 20 per cent. test piece 'A' for flats.

Forge Test, Hot.

Bars are to be punched with a punch one-third the diameter of the bar, at distances of one and a half and three diameters from the end of the bar, the holes being at right angles to one

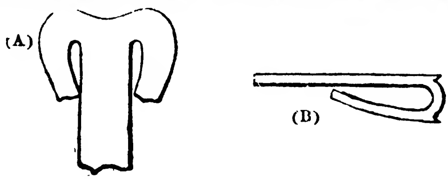

FIG. 8.

another. The holes are then to be drifted out to one and a quarter times the diameter of the bar. The sides of the holes are then to be split, and the ends must admit of turning back without fracture, as shown by (A).

Broad thick flats may be flattened on the edge to admit of being punched.

Thin flats $\frac{3}{8}$ in. thick and below are to be bent to a radius of two and a half times their thickness with the grain, without fracture.

Forge Tests, Cold.

Samples should be notched and bent, as shown by (B), to show the quality of the iron.

Bar Iron.

Ductility Test.

Test pieces as selected by the Overseer must withstand being bent cold through an angle of 90° by pressure, or by a succession of light blows, the inner radius of the bend to be not greater than three-fourths the diameter or thickness of the test piece, measured radially through the bend, without showing signs of cracking on the outside of the bent portion.

In all cases the samples are to be bent with that portion in tension that is nearest to the outside of the bar.

Welding Test.

Two pieces from each quantity of iron samples are to be scarphed and welded and subsequently bent whilst hot across the weld in order that the Overseer may be satisfied with the welding qualities of the iron.

Fire-Bars.

The bars are to be free from flaws and surface defects, and are to be subjected to such bending and other usage tests as may be considered necessary.

The standard weight of the bar iron is to be taken at 40 lb. per sq. ft. for bars of 1 in. thick, and in proportion for bars of all other thicknesses. No bar iron should exceed this prescribed weight, but a latitude of 5 per cent. below this weight will be allowed for thicknesses of ¼ an inch and upwards, and of 10 per cent. for less thicknesses. The weight of the iron ordered will be ascertained by weighing the parcel when its weight does not exceed 5 tons, and in ots of 5 tons when its weight exceeds 5 tons.

Strength of Tubes.

Let,

p = pressure in lb. per sq. in. inside tube;
D = outside diameter of tube in inches;
d = inside " " "
f = maximum hoop tensile stress in tube.

Then, up to the elastic limit,

$$p = \frac{D^2 - d^2}{D^2 + d^2} f.$$

If

t = thickness of tube, and $n = \frac{d}{t}$,

then,

$$p = \frac{2}{n + 1 + \frac{1}{n+1}} f$$

If

t is small compared with d,

then

$$p = \frac{2t}{d} f.$$

For a value of $\frac{D}{d} = 1 \cdot 1$, this 'thin cylinder' formula gives a value of p about 5 per cent. high.

Strength of Thick Hollow Cylinders.

For mild steel,

if p = pressure causing yield, in lb. per sq. in.
f = tensile stress at yield in lb. per sq. in.;
k = ratio of external to internal diameter;

then

$$p = 0 \cdot 6 f \frac{k^2 - 1}{k^2}$$

For cast iron,

if p = bursting pressure
and f = ultimate strength in tension

$$p = f \frac{k^2 - 1}{k^2 + 1}$$

Collapsing Strength of Steel Tubes.

Researches by Prof. R. T. Stewart (Amer. Soc. Mech.E., 1906) led to the following principal results:

1. The length of tube, between transverse joints tending to hold it to a circular form, has no practical influence upon the collapsing pressure of a commercial lap-welded steel tube so long as this length is not less than about six diameters of tube.

2. The formulæ, as based upon the present research, for the collapsing pressure of modern lap-welded Bessemer steel tubes are as follows:—

$$P = 1{,}000\left(1 - \sqrt{1 - 1{,}600\frac{t^2}{d^2}}\right) \quad . \quad . \quad (A) \qquad P = 86{,}670\frac{t}{d} - 1{,}386 \quad . \quad . \quad (B)$$

P = collapsing pressure, in pounds per square inch; d = outside diameter of tube in inches; t = thickness of wall in inches.

Formula (A) is for values of P less than 580 lbs., or for values of $\frac{t}{d}$ less than 0·023, while formula (B) is for values greater than these.

These formulæ, while strictly correct for tubes that are 20 ft. in length between transverse joints tending to hold them to a circular form, are at the same time substantially correct for all lengths greater than about six diameters. They have been tested for seven diameters, ranging from 3 ins. to 10 ins., in all obtainable commercial thicknesses of wall, and are known to be correct for this range.

3. For the most favourable practical conditions—viz. when the tube is subjected only to stress due to fluid pressure, and only the most trivial loss could result from its failure—a factor of safety of 3 would appear sufficient.

4. When only a moderate amount of loss could result from failure, use a factor of 4.

5. When considerable damage to property and loss of life might result from a failure of the tube, then use a factor of safety of 6.

6. When the conditions of service are such as to cause the tube to become less capable of resisting collapsing pressure, such as the thinning of wall due to corrosion, the weakening of the material due to overheating, the creating of internal stress in the wall of the tube due to unequal heating, vibration, etc., the above factors of safety should be increased in proportion to the severity of these actions.

Strength of Iron Chains.

(*Abstract, Safety Pamphlet No. 3; 'The use of Chains and other Lifting Gear.' Issued by the Home Office*, 1930.)*

Chains, hooks and other similar appliances for lifting purposes are generally manufactured from wrought iron or mild steel. The selection of a suitable quality of material is of the utmost importance. Material which is ductile and sufficiently elastic to recover from the strain produced by shocks should always be used. (See B.S. specification for 'Short Link Wrought Iron Crane Chain,' No. 394—1944.)

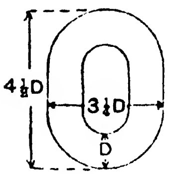

FIG. 9.—Straight-Sided Link.

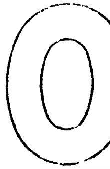

FIG. 10.—Oval Link.

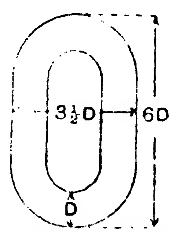

FIG. 11.—Long Link.

Ordinary short-link or close-link chains usually have links (fig. 9) with an overall length of four and a half times, and a breadth of three and a quarter times the diameter of the bar. For chains designed to stand severe shocks, links with slightly oval sides, as in fig. 10, instead of with straight sides, as in fig. 9, should be adopted; they give the chain greater elasticity.

* **His Majesty's Stationery Office, York House, Kingsway, London, W.C. 2.**

A cheaper but weaker form of link (fig. 11) is sometimes used for packing chains and for light foundry chains in cases where it is required to hitch a hook in any link. The links of such chains have an outside length of six times and an outside breadth of three and a half times the diameter of the bar.

The Ultimate Strength of Chain Iron.

The ultimate strength of chain iron varies from 21 to 25 tons per sq. in., but a reduction in strength results from welding and bending action in a link, so that the breaking stress in actual tests is about 15·5 tons per sq. in. for close-link crane chain. Based on this, the breaking strength of this class of chain is obtained by the formula $W = \frac{15 \cdot 5}{2} \pi d^2 = 24d^2$ tons (approximately).

This corresponds very closely with the standard adopted by the Admiralty, War Office, railway and dock companies, and with that specified in the Anchors and Chain Cables Act, 1899, for short-link chain cables, but most authorities agree that *short-link or close-link lifting chains of good quality should have a minimum strength of approximately $27d^2$ tons*, for chains up to 1½ in. diameter, but slightly less for chains exceeding this diameter (*see* Table A, below).

Safe Working Loads for Chains.

The tensile test loads, generally known as the Admiralty Proof Loads, are approximately equal to $12d^2$ tons for short-link cable where, d is the diameter in inches of the iron of the chain.

The safe working load generally adopted for close-link welded chains is one-half the proof load, i.e. *the safe working load* $S.L. = 6d^2$ *tons*. With chain having a breaking strength of $27d^2$ tons this allows a factor of safety * of 4·5, which may be regarded as satisfactory if the chain is not subjected to shock or any abnormal use.

1 5/16	47 7/10	20 5/8	10 3/10				

* As a result of experiments on chains carried out at Illinois University, the National Safety Council of the United States of America has recommended that the safe working load for chains should not exceed $0 \cdot 4fd^2$ where f is the safe tensile stress of the material; for good wrought iron this may be taken as 7 tons per sq. in., hence the safe working load would be $2 \cdot 8d^2$ tons, which allows a factor of safety o fover 9, i.e. about twice the factor of safety generally adopted in this country.

Where there is any special risk to life or limb a maximum safe working load of $5d^2$ tons should be adopted, and where chains are subjected to shock or heavy wear, or work over pulleys, or are used for lifting vessels containing molten metal or heated liquids, the safe working load should not exceed $3 \cdot 5d^2$ tons.

The maximum safe working load for a long-link chain (fig. 11) *should not exceed two-thirds of that for a short-link chain of the same diameter.*

RINGS.

(1.)

The opening of a ring is determined, to some extent, by the size of the hook or shackle upon which it is to be placed, as this should be sufficient to allow the ring to hang freely and without jamming the end links of any attached chains.

Rings attached to sling chains are usually made with a mean diameter of four to five times the diameter of the iron forming the ring.

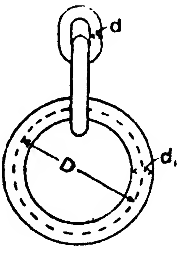

FIG. 12 —Ring

A ring must be sufficiently strong to carry safely a load equal to the sum of the safe loads of all the attached chains, and, moreover, must be capable of standing the total proof loads of these chains without deformation. When a proof load is applied to a chain, it causes a slight elongation, but this is not objectionable, because in use the load on the links is always applied in the same direction, but a ring is liable to be turned round, and hence deformation must be avoided.

If the safe working load for a ring (fig. 12) is regarded as one-half the proof load; then if D = mean diameter of ring and d_1 = diameter of the iron of the ring, the *maximum safe load can be calculated* by the formula S.L. $= 10 \dfrac{d_1^3}{D}$ tons. This should also be equal to the maximum safe load of the attached chain, i.e. $6d^2$ where d is the diameter of iron in the chain links.

EYEBOLTS.

Eyebolts should be used only for loads applied in the axial direction unless given adequate side support. The length of thread engaged with the article to be lifted should not be less than the diameter of the screwed portion. In a collared eyebolt, a neck equal in diameter to the core diameter of the screw and with a fillet under the collar should be provided. This is to prevent weakness due to cutting the thread right up to the collar.

If D is the diameter of the shank in inches, the safe load (direct) is $W = 1 \cdot 78\ D^2$ tons for wrought iron, or $W = 2 \cdot 2\ D^2$ tons for mild steel. The diameter C of the metal of the ring is usually $0 \cdot 9$ D, and the mean diameter of the ring 3 C.

SWIVELS.

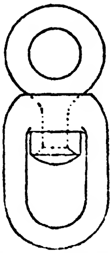

FIG. 13.—Swivel.

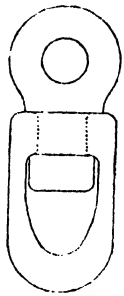

FIG. 14.—Weldless Swive..

The Board of Trade Regulations * for testing chain cables, etc., require that the various parts of a swivel shall be of the following proportions: 'The diameter of the iron in the common link being regarded as unity, the diameter of the iron in the eye of the swivel must be at least 1¼; the diameter of the iron in the pin at the bottom of the thread must be 1⅜; the diameter of the iron in the crown of the bow piece must be 1¼; the depth of the bow piece where bearing on the swivel nut must be 1¼; the diameter of the nut of the swivel pin must be 1⅜. The swivel pin should be screwed to the Whitworth standard and the nut secured thereto by welding it to the end of the pin or by fitting a tapered locking pin.'

The nut or collar on the shank of a swivel must be rigidly secured so that it cannot work loose, and if the shank is riveted at the end, an ample countersink must be allowed in the collar so that the metal cannot be sheared and the shank pulled through.

SLINGS.

The values of T for different values of W from ¼ to 20 tons, calculated for different angles between the legs, and the size of chain necessary to lift these loads safely, without the tension exceeding a safe working load of $6d^2$ tons, is given in Table B. Table C shows the actual loads calculated from the formula $W = 12d^2 \times \frac{AC}{AB}$ which can be safely lifted by slings of different sizes when used with two legs at various angles.

Thus it will be seen from Table B that a load of 5 tons can be safely lifted with a two-legged sling of $\frac{11}{16}$ in. chain if the angle between the legs does not exceed 30°, but when the angle is increased to 90° a $\frac{13}{16}$ in. chain is required, whilst with an angle of 150°, i.e. the sling nearly flat, a $1\frac{5}{16}$ in. chain is required if the tension in the chain is not to exceed the safe

* The Anchors and Chain Cables Act, 1899, with Regulations as to Testing, Scale of Maximum Charges, etc., issued by Board of Trade—to be obtained from H.M. Stationery Office, York House, Kingsway, London, W.C. 2.

oad $6d^2$ tons. Again, Table C shows that, whereas a two-legged sling made from good quality 1 in. chain can safely lift a load of 12 tons if the sling legs are vertical, the load should not exceed 10·35 tons if the legs are at an angle of 60°, nor more than 6 tons with an angle of 120°.

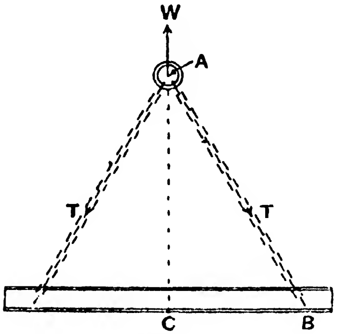

FIG. 15.

TABLE B.

SHOWING SIZES OF CHAIN REQUIRED IN TWO-LEGGED SLINGS WHEN TENSION DOES NOT EXCEED SAFE LOADS.

6	3/4	3/4	13/16	7/8	1	1 7/16
8	7/8	7/8	15/16	1	1 3/16	1 5/8
10	15/16	15/16	1	1 1/8	1 5/16	1 13/16
12	1	1 1/16	1 1/8	1 1/4	1 7/16	2
14	1 1/8	1 1/8	1 3/16	1 5/16	1 9/16	2 1/8
16	1 3/16	1 3/16	1 1/4	1 3/8	1 11/16	2 5/16
18	1 1/4	1 1/4	1 3/8	1 1/2	1 3/4	2 7/16
20	1 5/16	1 5/16	1 7/16	1 9/16	1 7/8	2 5/8

Many large users of chains issue to their employees printed rules containing instructions as to the use of multiple slings and the loads which can safely be lifted at various angles of the legs. In some cases a rule is adopted that the horizontal distance between the points of attachment of the load shall not exceed the length of sling leg; this means, in effect, that the angle between the legs must not exceed 60°.

This is a simple rule which can be readily followed by the slinger, but it makes it necessary always to provide chains which can safely lift any particular load at this opening of the sling legs. Thus, to lift a load of 12 tons, 1¼ in. chains should be used.

TABLE C.

SAFE WORKING LOADS FOR TWO-LEGGED SLINGS.

A few firms allow double slings to be used for the normal working load, provided the angle between the legs does not exceed 90°. This is an unsafe practice, as at this angle the tension in each leg is 0·7 times the total load, and unless the normal working load for the sling is taken with a very ample factor of safety the chains may be overstrained.

Shortening Slings.—Chain slings should never be shortened by tying the chain into a knot, a method frequently adopted, but one which causes excessive bending stresses in some of the links, and may result in permanent injury or fracture. If it is necessary to shorten a chain a suitable adjuster should be used, and the links bearing the load will then be subjected only to their normal stresses.

TESTING.

TABLE D.

ORDER BY THE BOARD OF TRADE.

Tests for Short-Link Chain Cables.

Order of the Board of Trade dated June 26, 1900, under s. 8 of the Anchors and Chain Cables Act, 1899.

Short-Link Chain Cables.

Breaking and Tensile Strains.

Diameter of Iron Common Links. (1)	Breaking strain which 3 links in each 15 fathoms must withstand previous to the tensile strain being applied. (2)	Tensile strain to be applied to every 15 fathoms separately. (3)	Diameter of Iron Common Links. NOTES.

Wood or other suitable packing should be provided to prevent the links coming in contact with corners of loads of hard material.

All chains and other lifting appliances should—(*a*) If used for lifting in connection with molten metal or molten slag, be examined at least once in every month and be annealed at least once in every six months; or (*b*) if used in connection with lifting machinery or plant operated mechanically or electrically, or used for lifting in metal foundries other than that mentioned in paragraph (*a*) above, be examined at least once in every three months and be annealed at least once in every twelve months; or (*c*) if used for classes of lifts other than those mentioned in (*a*) and (*b*) above, e.g., in connection with hand cranes, be examined at least once in every six months and be annealed at least once in every two years; or (*d*) if used for holding down any crane or other lifting machinery upon a stage or platform should be examined as far as reasonably practicable, *in situ*, at least once in every three months, and be fully examined and annealed at least once in every twelve months, unless the nature of the operations preclude such examinations and annealing.

A chain or other appliance should not be used for lifting its maximum working load if the wear at any part exceeds 10 per cent. of the nominal dimension of that part, or for lifting any load if it has been subjected to a severe shock or is deformed or otherwise injured.

A chain or other appliance which has been altered or repaired should be re-tested before use.

Sling chains and other lifting appliances, when not in use, should be stored under cover and kept on suitable racks or pegs.

A record with full particulars should be kept of every chain.

ANNEALING AND NORMALISING WROUGHT IRON CHAINS.

The surface metal of chain links becomes brittle as a result of repeated local impacts. When a link section is subjected to bending strains, the hardened skin cracks. Either annealing at a dull red heat (1200° F.) or normalising at 1830° F. will effectively restore the chain to a condition of great ductility.

The best method is 'close annealing.' The chain is placed in a gas- or oil-fired muffle furnace, heated to redness out of contact with the air, and then allowed to cool slowly, either in the furnace or by covering it with dry sand or ashes after removal. Close annealing prevents oxidation and subsequent scaling, and the chain is heated uniformly. Coal or coke may also be used for a close annealing furnace, and a fireclay gas retort makes a good muffle.

Chains are sometimes softened merely by heating them on a smith's fire and allowing them to cool on the hearth for about 36 hours. This method is faulty; chains so treated cannot be considered to have been effectually annealed.

After annealing, the chain should be cleaned by brushing, and each link examined for faulty welds, cracks, etc.

CHAINS AT LOW TEMPERATURES.

Grave danger of brittle failure may be incurred at 'frost' temperatures in chains with links which have received surface injuries. (See below.)

Brittleness of Chains at Low Temperatures.

Gough (*Proc. Inst. Mech. Engineers*, 1930), as a result of investigations on new wrought iron chains at low temperatures, arrived at conclusions, of which the general trend is as follows:

(1) Best quality chain iron does not develop brittleness in absence of notches at temperatures 170° C. to −78° C.

(2) The 'notched-bar' value of best chain iron decreases slightly from 200° C. to air temperature. Notch brittleness becomes increasingly evident as temperature is further reduced.

(3) Brittleness of wrought iron at moderately low temperatures disappears when normal temperatures are again attained.

WIRE ROPE SLINGS AND LIFTING TACKLE.

For general information, see British Standard Specification, No. 1290—1946 and British Standard Handbook, No. 4 (1946).

Strength of Ropes.*

The following rules are useful for very roughly estimating the safe working loads for ropes:

Steel Ropes.

C = Circumference of rope in inches; S = Safe working load in tons.

$$S = C^2 \div 2.$$

The strength naturally depends on the quality of the steel, and the factor of safety upon the service of the rope.

See Section XXI, Part III, for haulage and mining ropes.

Hemp and Manila Ropes.

For hemp and Manila ropes the strength depends greatly on the age and condition of the rope, also on the number of strands and lay of the rope. The ultimate strength, in lb., of new Manila ropes for slings, etc., is approximately $C^2 \times 700$ to $C^2 \times 1000$. (C = circumference in inches.)

See British Standard Specification No. 451—1946. (Amended 1946–1947.)

The factor of safety for lifting ropes should be at least 6, and in adverse conditions 7 to 8.

*** See paper read by Mr. Daniel Adamson, M.I.Mech.E., before the Inst. of Mech. Engrs. 1912.**

C = Circumference of rope in inches: S = Safe working load in cwts. (very roughly).

$$S = C^2.$$

From a series of 368 tests of Manila rope in sizes from ½ in. to 4½ in. diameter carried out at the United States Bureau of Standards it was found that the average breaking strength of a three-strand regular lay rope is very closely represented by the formula

$$L = 5000\, d\, (d + 1).$$

where L is in lb., d in inches.

Testing Manila Rope.

This test has been adopted by the United States Bureau of Standards: Free the rope from oil, soak it for 20 seconds in a solution of bleaching powder acidulated with acetic acid, rinse in water and then in alcohol, and finally expose the fibres of the rope for a minute to the fumes of ammonia. Manila fibre turns russet brown, while all other rope fibres turn a cherry red.

Preservation of Manila and Wire Ropes.

Manila ropes and slings and wire cables through neglect do not last as long as they should because they are allowed to decay and rust, and apart from the waste of not preserving them they are a source of accidents. Ordinary ropes should be painted over with beeswax and resin, about equal parts of each, melted together, and applied with a paint brush. The rusting of wire cables and ropes is arrested by treating them with a mixture of tallow and oil, seven or eight pounds of melted tallow to a gallon of oil, lime being added, when the mixture is cold, until it is thick. The composition is then applied with a brush.

Hemp ropes may be preserved by being dipped when dry into a solution of 1 oz. of sulphate of copper dissolved in 2½ pints of water, and kept in this solution for four days, afterwards being dried; the rope should then be soaked in a solution of 5 ozs. of soap dissolved in 2½ pints of water, and again dried.

Sisal Ropes.

For corresponding details on sisal ropes, see British Standard Specification 208—1946 (amended 1946–17).

Strength of Soldered Joints.

It is generally recognised that the strength of soft-soldered joints is increased if the film of solder between the surfaces of the join is kept as thin as possible. Some experiments carried out by T. B. Crow and described in *The Journal of the Society of Chemical Industry*, No. 13, vol. xliii, showed that by keeping the film as thin as possible a tensile strength 2½ times as strong as the original solder is obtainable in a joint between copper pieces, although in no case was the strength up to the yield point of the copper. It was demonstrated that the tin of the solder diffuses into the copper. With solder films 0·1 to 0·15 mm. in thickness the strongest joints, in tension, were those made at 265° C., while those made at a temperature above 280° C. were noticeably weak and brittle.

Effect of High Temperature on the Strength of Metals.

For data relating to the strength of metals at high temperatures, see Section XXIII, Part I.

Stress due to Temperature.

If change of temperature occurs when change of dimensions is prevented, stress is induced in the material, of amount $f = E\, a\, t$

where E = Young's modulus, a = coefficient of linear expansion, t = change of temperature.

Temperature Change in ° Fahrenheit Corresponding to Stress of 1 Ton per Square Inch.

Weight of bar after $6\frac{1}{2}$ months . . .	0·6393	0·6614	1·2633
Loss in $6\frac{1}{2}$ months	46·3 per cent.	45·45 per cent.	1·2 per cent.

CORROSION OF IRON ROPES.

Experience has shown that wire ropes of compound construction, subjected to corrosion influences, are likely to deceive engineers as to the strength remaining in them. Where reduction of diameter or circumference of the rope has taken place, not accounted for by the evidence of wear, the part of the rope under examination should first be fully loaded and then relieved of the load. Any noticeable difference in circumference in these circumstances, and the slackening of the outside wires when the load is off, will indicate that internal corrosion has taken place. The extent of corrosion inside the strand can only be estimated by the slackness of the outside wires. The corrosion between the strands can be further examined by untwisting the rope or displaying the strands sufficiently with a marlin-spike.

Poisson's Ratio.

Definition.—The ratio of lateral to longitudinal strain under load, usually denoted by $\frac{1}{m}$ (Strains are measured relative to breadth and length respectively.) The value of $\frac{1}{m}$ for a range of engineering materials is given in the following table.

VALUE OF POISSON'S RATIO $\left(\frac{1}{m}\right)$.

Material.	$\frac{1}{m}$	Material.	$\frac{1}{m}$

B.—STRENGTH AND ELASTICITY OF TIMBER.

The strength of timber varies greatly according to the condition and specific gravity. The following table gives approximate relations between the specific gravity and some mechanical properties in green and dry conditions. (Specific gravity = d.)

Condition.	Modulus of Rupture.	Compressive Strength across Grain.	Shear Strength parallel to Grain.	Modulus of Elasticity (E).
Green . .	$17 \cdot 6d^{\frac{5}{4}}$	$3d^{\frac{9}{4}}$	$2 \cdot 7d^{\frac{4}{3}}$	$2{,}360d$
Air-dry . .	$25 \cdot 7d^{\frac{5}{4}}$	$4 \cdot 6d^{\frac{9}{4}}$	$4d^{\frac{4}{3}}$	$2{,}800d$

Unit = 1,000 lb. per sq. in.

The table of strength data below gives typical values of approximate ranges. It should be noted that in the case of timber, increased rate of loading usually gives an increase in apparent strength.

Stresses in thousands of lbs. per sq. in.
Moduli E and C in millions of lbs. per sq. in.

Resistance of Wood to Reversals of Stress.

The limiting resistance of spruce (used for aeroplane wing spars) to alternate tension and compression was proved by experiment to be above 1,600 lbs. per sq. inch, and below 1,970 lbs. per sq. inch. For spruce of this quality the safe range of stress under reversals of bending would be approximately ± 1,800 lbs. per sq. inch, or one-quarter of the ultimate stress, which was found to be 6,800 lbs. per sq. inch. In this respect spruce appears to be at a slight disadvantage compared with mild steel, in which the safe limit of stress under similar circumstances is generally about one-third of the ultimate stress. (*The National Physical Laboratory.*)

Holding Power of Spikes and Nails in Wood.

The holding power of spikes varies roughly in proportion to the depth to which they are driven. Six-inch S.W.G. No. 1 smooth wire nails were found by Warren to require approximately 1,000 lbs. per inch of depth for withdrawal, in Australian hardwoods.

Screwed spikes exert 30–80 per cent. more resistance than smooth. The resistance is also higher with unseasoned than with seasoned timber.

Holding Power of Glue.

FATIGUE IN METALS.*

(By F. W. Thorne, B.Sc., A.M.I.C.E., A.M.I.Mech.E.)

It is well known that metal parts, that may be tough and ductile and able to withstand severe test loads, commonly break in a brittle manner after smaller loads have been applied or reversed large numbers of times. This mode of fracture, by which a ductile metal breaks in a brittle manner after repeated changes of a moderate load, is known as fatigue.

Fatigue fractures may be recognised by the shell-like markings that radiate from the origin of the crack, and by the absence of ductile yield near the origin. Before actual fracture, the fatigue crack may often be observed as a hair crack which grows slowly. In laboratory tests fatigue cracks often extend so rapidly that they are not observed on the surface before fracture.

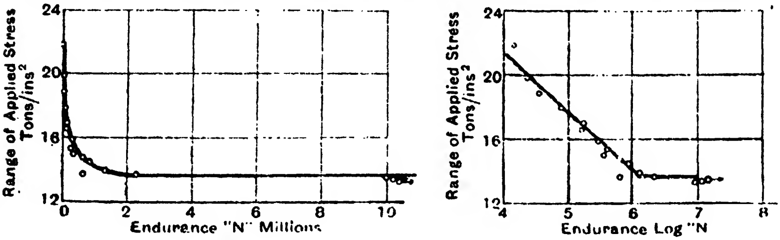
* For further information on this subject the reader is referred to *The Fatigue of Metals*, H. J. Gough, O.B.E. (Scott, Greenwood); *The Fatigue of Metals*, Moore and Kommers (McGraw-Hill Book Co.). Bibliographies in the above text-books contain respectively 183 and 448 individual references to original papers.

Fatigue fracture is liable to occur when the stress acting at any point in the part or test-piece varies, in magnitude or in direction, beyond certain ascertainable limits. The object of fatigue testing is to ascertain these limits of stress, or the corresponding limits of variation of load that can be permitted without liability to fracture.

Fatigue testing practice comprises two distinct fields of experiment with different objects: (1) the testing of different metals, in test-pieces of the simplest possible shape such that the stresses are reliably calculable; and (2) the testing of parts of complex shape, for which the intensities of stress are only nominally calculable. The second field has attained great importance in recent years, and is employed as a method of design in lieu of calculation. Fatigue-testing machines differ widely in size and design according to their applications, for testing small test-pieces or larger models of complex parts.

Methods of Testing.

To ascertain the safe conditions of loading for a given metal or a given design of part, a number of identical samples are tested under different conditions, *e.g.* with different ranges of alternating load combined with one and the same steady load. The 'endurance' is defined as the number of cycles of loading imposed before fracture terminates the test. After carrying out a number of such tests on identical pieces, the ranges of stress or load and the endurance are plotted as in fig. 16, A and B. A logarithmic base for endurance, as first adopted by Sir Thomas Stanton



A FIG. 16. B

and shown in diagram B, is usually preferred for its convenience, although both diagrams give the same data.

The form of the diagram usually reveals the 'fatigue limit,' defined as the semi-range of stress (or load in the case of a complex model) that can be applied continually without resulting in fracture. In different cases tests have to be continued to different numbers of millions of cycles to ascertain any such limit, and in some few cases no such limit has yet been established to exist even at 100 million cycles. In most cases the knee of the fatigue graph is already evident when the endurance reaches about 2 million cycles in a Haigh machine or 10 million cycles in a Wöhler rotating-beam or cantilever.*

Testing Machines.

Fatigue-testing machines may be roughly classified as follows:

(*a*) Wöhler machine for rotating-beam or cantilever test-piece. The rotating test-piece is gripped at one end in a chuck and loaded at the other through a ball bearing. The profile may be

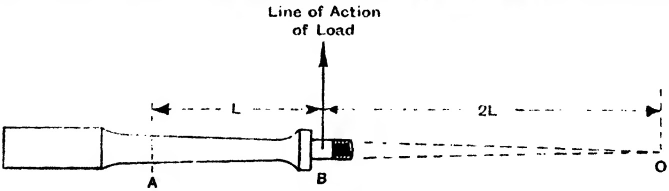


FIG. 17.

varied at will, but is preferably of the form shown in fig. 17, in which case fracture occurs at the section A, remote from sudden changes of section, so that the stress is more reliably calculable.

* R. D. Francis (Bureau of Standards, Washington, A.S.T.M., 1931).

(*b*) Reversed plane bending machines, with adjustable angle of flexure. These have been used in the U.S.A., and also at the National Physical Laboratory, for testing flat springs. The range of stress is deduced by calculation from the observed deflection.

(*c*) Haigh machine for direct push and pull, with adjustable range of load and adjustable mean or 'steady' load. The alternating load is applied and measured electro-magnetically, and the steady load is applied and measured by means of a heavy spring, which is adjusted in stiffness to compensate the force required to accelerate the moving parts.

Although the machine operates on the 'load principle' in respect that it repeats the same measured loads during each successive cycle, it operates on the 'strain principle' as regards the distribution of that load on the test-piece. As the ends of the test-piece are moved in parallel motion, all parts are equally strained when the piece is of uniform section. The machine is of large size, suitable for testing models or even full-sized parts.

(*d*) Stromeyer or other direct torsion machines, with or without bending, are made in a variety of forms for special investigations.

(*e*) Rotating strut machine for wires (Haigh & Robertson Patent No. 33113, Nov. 23, 1932). To eliminate the difficulty that wires, being of uniform section, usually break at the grips in other fatigue tests, the test-piece in this case is flexed as a strut so that maximum bending moment occurs at mid-span remote from the ends. The machine works at a very high speed of rotation, usually about 15 millions per day.

Fatigue Limit.

It has been shown conclusively that the fatigue limit bears no relation to the tensile elastic limit, and in annealed metals may be higher than the yield point.

As a result of great numbers of tests it appears that the ultimate tensile strength affords the most consistent basis of comparison for different metals. The following table gives values for the ratios between the fatigue limit and the ultimate tensile strength for stresses that reverse between equal values of push and pull.

Metal.	Fatigue limit as percentage of Ultimate tensile strength.	Metal.	Fatigue limit as percentage of Ultimate tensile strength.
Softest annealed iron, of high quality	up to 60%	Alloyed steels, 40 to 70 tons/inch² ult. quenched and tempered	35–50%
Low carbon steels, annealed	up to 60%	Alloyed steels, 70 to 100 tons/inch² ult. quenched and tempered	35–45%
Ditto. As rolled, or quenched and drawn	about 50%	Aluminium alloys of good quality	20–45%
Ditto. Poor qualities	down to 35%	Duralumin, heat-treated	25–40%
Moderate carbon steels, annealed	up to 45%	Rolled brasses, 70–30, 65–35	30–50%
Ditto. As rolled	down to 35%	Monel metal, as rolled or annealed	about 40%
Cast steel and iron	45–35%	Nickel, as rolled or annealed	about 40%
Alloyed steels, 30 to 50 tons/inch² ult. normalised	40–55%	Copper, ,, ,,	30–40%

At the frequencies usually adopted in fatigue-testing machines the fatigue limit appears to be sensibly independent of the frequency of test. Professor Jenkin found an increase in the fatigue limit of 15 per cent. when working up to 2,000 cycles per second and a further rise of 60 per cent. was recorded when working up to 20,000 cycles per second.

The form of the specimen and the method of testing have a marked influence on the fatigue limit in some metals. Different investigators have found ratios as follows in steels:

$$\frac{\text{Fatigue limit in rotating beams}}{\text{Fatigue limit in reversed plane bending}} = 1{\cdot}07 \text{ to } 1{\cdot}31$$

$$\frac{\text{Fatigue limit in reversed plane bending}}{\text{Fatigue limit in direct push and pull}} = 1{\cdot}00 \text{ to } 1{\cdot}26$$

$$\frac{\text{Fatigue limit in rotating beam}}{\text{Fatigue limit in direct pull and push}} = 1{\cdot}00 \text{ to } 1{\cdot}35$$

Thus the rotating beam appears consistently higher and the direct pull and push consistently lower when differences are observed.

S—a DIAGRAMS.

When a stress varies in magnitude between unequal extreme values it may be described as a combination of a steady stress (S) equal to the mean between the extremes, and an alternating stress (a) equal to half the difference, see fig. 18.

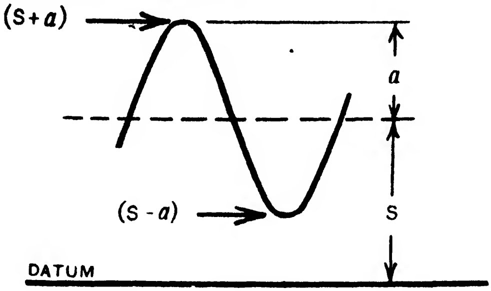

FIG. 18.

The two extreme values are then described as $(S + a)$ and $(S - a)$.

It is found that the limiting safe alternating stress value depends on the value of the steady stress; and that the value can be expressed as follows:

$$a_s = a_0 \left\{1 - K_1\left(\frac{S}{U}\right) - K_2\left(\frac{S}{U}\right)^2\right\}$$

where a_s = fatigue limit when the steady stress is acting, and a_0 = usual fatigue limit found when there is no steady stress.

The coefficients K_1, K_2, etc., can be ascertained only by direct experiment, and their sum is found to be usually greater than unity. Values are given in the following table for a series of metals.

Material.	Tensile ultimate U. Ton per sq. in.	Tensile yield point Y. Ton per sq. in.	Ordinary fatigue limit a_0 Ton per sq. in.	Coefficients. K_1	Coefficients. K_2

* Limit of proportionality or elastic limit.
† Proof stress.
‡ Reduction of area in drawing.

S — *a* AND YIELD.

The relative values of the yield stress and the fatigue strength of a metal have an important bearing on the choice of a material for a given problem. Fig. 19 shows the S — *a* diagram for a high tensile steel, together with lines representing the yield (*yy*) and ultimate tensile strength (*uu*).

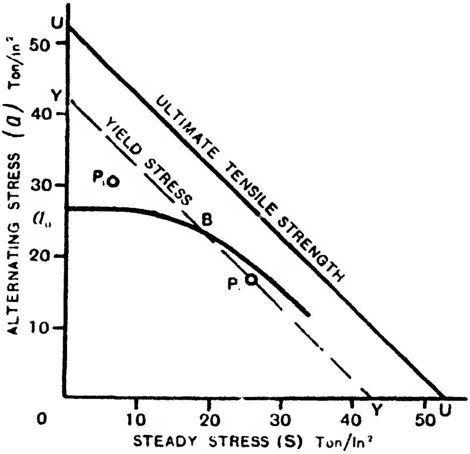

FIG. 19.

Fatigue occurs without yield if or when the state of stress is represented by a point, *e.g.* P_1 in the area a_0YB, and yield occurs immediately if or when the state of stress is changed so that it is represented by a point, *e.g.* P_2 on the line *yy*.

Effect of Temperature.

The fatigue limit does not appear to be greatly affected by rise of temperature, and as the yield point falls rapidly it follows that fatigue failure is unusual at high temperatures in practice. At still higher temperatures creep occurs slowly, and is liable to cause fracture after considerable elongation, or embrittlement without elongation.

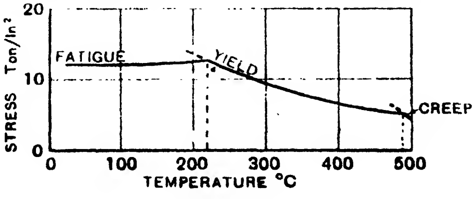

FIG. 20.

Fig. 20 shows how the safe stress is bounded by the fatigue-yield-creep graph for a 0·17 per cent. C steel.

Chemical Action and Fatigue.

Although it was long believed that fatigue was wholly mechanical in nature, experiments published in 1917 showed: (1) that fatigue fracture is accelerated in many metals, although not in all, when water or other reagents act on the surface of the metal during the test; (2) that corrosion prior to the test has much less effect, although the surface may be more severely pitted; (3) that the atmosphere appears in some cases to act as a chemical reagent. Such conjoint chemical and mechanical actions are now known as 'corrosion fatigue.'

Among other features demonstrated in more recent research the following are outstanding: (4) the acceleration of fatigue is reduced when the reagents are heated, (5) the action is markedly influenced by gases in solution, (6) high-tensile carbon steels are affected more than milder in such degree that the corrosion fatigue limit in carbon steels does not vary widely with ultimate tensile strength, (7) in stainless steels the value of the corrosion fatigue limit is higher, particularly in fresh water, (8) in lead fatigue can be delayed by using oil or grease to exclude atmospheric air, (9) in lead fatigue can be eliminated by appropriate chemical action, although this is associated with violent pitting and evolution of gas, (10) in vacuo, the fatigue limit in many instances is higher than in air, (11) in hard-drawn wire, the reduction of the fatigue limit can be almost wholly eliminated by 'galvanising' the wire with zinc.

A series of round figures have been taken from experiments performed by Dr. McAdam and are given in the following table:

Material.	Ultimate tensile strength. Ton/in.^{2}	Corrosion fatigue limit. Ton/in.^{2}	
		Fresh water.	Salt water.
Carbon steels 0·03 per cent.–0·49 per cent. C	19–50	6·7–11·2	—
Nickel-chromium steels	47–66	12·1–12·9	—
3½ per cent. nickel steels	41–56	11·2–12·9	—
5 " "	54–59	8·5–12·0	—
Stainless irons	27–48	13·4–17·8	6·3– 8·0
High chromium steel	49·5	21·4	—
Stainless steels (chromium nickel steels)	38–56	14·3–22·8	6·7–15·2
Nickel	34–59	10·7–11·2	9·8–10·7
Monel metal	37–57	11·2	12·3
Nickel-copper alloys	21–38	9·1– 9·8	8·1–11·2
Electrolytic copper	20·8	7·6	7·6
Aluminium	6–9	2·0	0·9–1·3
Duralumin	15–31	3·5	2·9

Fatigue Strength of Wires and Springs.

The fatigue strength of wires depends to a large extent on the surface finish and strict attention should be paid to this point, especially in such cases as trolley wires, overhead cables and wire ropes which are subjected to alternating stress.

The spiral spring presents a further difficulty in so far that the spring must usually be heat-treated after it is formed.

The wide discrepancy between the fatigue limit of prepared specimens under torsional loads and the fatigue limit of the same steel when coiled into springs was noticed by Lea and Heywood in 1927 (I.Mech.E., April 1927). As a result of their investigations, Lea and Heywood came to the following conclusions amongst others: (*a*) the range of repeated stress (A_s) for a given mean stress (S) is given by $A_s = A_0 - B\,S$. where A_0 is the range of stress at zero mean stress; (*b*) in springs that have been quenched and tempered if the limiting safe range of stress is exceeded, a comparatively small number of repetitions causes failure; (*c*) defects of the wire not brought to light by the tensile test have a considerable effect on the life of the spring. Grinding of the wire preparatory to coiling seems desirable, but does not preclude the possibility of cracks forming due to subsequent heat-treatment.

Experiments on spring plates at the National Physical Laboratory by Batson and Bradley (I.Mech.E., 1931) were performed to determine the effect of grinding away the outer skin of the plate, and also to ascertain if the 'surface effect' of heat-treated spring plates was due to heat-treatment. As a result of these investigations it was found that the condition of the surface layer of the spring steel plates was the principal factor in causing the fatigue limit of the spring to be considerably lower than that deduced from the properties of the metal. The thickness of the layer was small, and when a thin surface layer was removed by grinding, after heat-treatment, the fatigue limiting stress was raised in ratios ranging from 4·75 to 1·75 in different cases. Only slight improvement was observed if the spring plates were heat-treated after grinding.

An interesting paper by Swan, Sutton and Douglas (I.Mech.E., 1931) on valve springs confirms the results of Lea and Heywood in that the removal of the surface layer increases the safe range of stress and reduces the variability. It was found that longitudinal cracks caused premature fatigue failure. The results of torsional fatigue tests on wire at full diameter and on samples which had been reduced in diameter by grinding are given below.

Reduction of diameter. Per cent.	Maximum Values of Limiting Stress Range. Ton/in.^{2}	
	Heat-treated in full diameter.	Heat-treated in final diameter.
0	35	—
10	52 (?)	42
20	58	45
40	64	47

Stress Concentrations.

In practice fatigue cracks almost always start from corners of keyways, sharp fillets, holes, or other discontinuities of section where stresses are concentrated locally. Such stress concentrations being seldom calculable are commonly covered in design by allowing higher 'factors of safety' when dealing with 'live' loads.

The ratios in which different discontinuities and surface finishes reduce the apparent fatigue limit are indicated in the table below, in which the strength of a polished cylindrical test-piece is used as a basis of comparison.

Finish or Discontinuity.	Fatigue limit as percentage of Fatigue limit of Polished specimen.
Emery finish, different grades	90% upwards
Filed finish, different roughnesses	80% „
Scratches produced by use of needle	84%
Sharp changes of section in shafts	50–75%
Changes of section with fillet	70–90%
Small round holes in flanges	40–60%

(Based on results given by Eden Rose and Cunningham (I.Mech.E., 1911), and W. N. Thomas, *Engineering*, 1923).)

Owing to the lower a_e/Y ratio (and the high K_1 value), the weakening effects in high tensile steels of small holes and the like are more evident than in milder qualities. In mild steel in alternating pull and push, the difference in fatigue limit between polished and rough-turned pieces has been found to be less than 5 per cent., but even in mild steel, an unduly sharp radius of curvature on a fillet will reduce the fatigue strength to one-third or less.

Fatigue of Welds.

Structural butt welds, made under practical conditions such as found in the shipyard or in general structural practice, can be relied on to give a fatigue strength of $\pm$ 6 Ton/in.^{2}, provided the usual precautions are taken. Welds in boiler plates, machine-made under ideal shop conditions, will give a consistent strength of $\pm$ 10½ Ton/in.^{2}.

The shape of lap welds so common in ship construction has considerable influence on the strength of the weld due to the bending stresses introduced by eccentricity of loading. If the joint is of the shallow double joggle type the fatigue strength is only $\pm$ 4 Ton/in.^{2}. The single joggled joint often used in the outer bottom plating of ships has a fatigue strength of only $\pm$ 3 Ton/in.^{2}. In this case the fatigue cracks start from the edges of the deposited metal where the bending stresses are greatest and spread through the parent metal.

These figures may be exceeded in special cases, but they afford a sound basis for design in structural work.

Fatigue of Riveted Joints.

When riveted joints crack and fail by fatigue in laboratory conditions, the forms of fracture approximate closely to those of riveted joints cracked in service. Riveted joints rarely if ever fail in the manner observed in tensile tests.

If the plates do not slip fracture occurs in the plate at 0 $\pm$ 3 Ton/in.^{2} reckoned on the gross cross-sectional area of the plate, or 0 $\pm$ 4 Ton/in.^{2} reckoned on the nett cross section between rivets. When slipping occurs, even slightly, under reversing loads failure is due to fatigue in the rivet caused by bending. In this case the rivets are bound to crack at mid-length and also under the heads and points, these often falling off in service. A half-inch diameter rivet under these conditions is found to fail at a load of $\pm$ 5,000 lb.

Hysteresis in Fatigue.

Mechanical hysteresis is readily observed in many metals in a tensile test by means of a sensitive extensometer in conjunction with a suitable testing machine. When the load is applied and removed a hysteresis loop is formed, the area of which is a measure of the quantity of work absorbed. In some metals in the annealed condition this 'primary' hysteresis is considerable. In most cases the area of successive loops frequently becomes smaller with successive stress cycles and after about 250,000 cycles settles down to a much smaller value. Conclusions drawn from 'static' loops or from tests in which the endurance is below 250,000 cycles might be, and often are, misleading when applied to engine vibration. Hysteresis plays an important part in damping forced oscillations such as are met with in crankshafts of engines and propeller shafts. It has been found that hysteresis can be represented very closely by the empirical formula

$$H = Cf^n$$

where H is the hysteresis heat and f the semi-range of applied stress. In steel n lies between 3 and 4. In brasses the values of n vary widely with composition and previous history, and may vary between 6 and 12.

METERING APPLIANCES

(pp. 191–207)

(Revised by S. A. Wood, M.Sc., M.I.Mech.E.)

SECTION VI

METERING APPLIANCES.

(Revised by S. A. Wood, M.Sc., M.I.Mech.E.)

METERING OF WATER, AIR, GAS, STEAM, AND COAL.

The metering of fluids is undertaken to enable running costs to be apportioned, sales to be effected on an equitable basis, the mixing of reagents in various chemical processes to be controlled, wasteful or inefficient use to be detected so that working costs may be reduced and unnecessary additions to plant obviated, etc.

Various efficient and accurate types of water and gas meters have been in use for many years. It is only recently, however, that accurate and reliable air, steam and oil meters have been developed. The first large installation of air meters was made on the Rand in 1911, where now more than 400 million h.p. hours per annum are metered, at an ascertained annual aggregate money saving of over £130,000.*

The following is a brief summary of the principal classes of fluid and gaseous meters, with notes as to their application.

1. Meters Based on Volume or Weight Measurement.

(*a*) Tanks or weighing. [For liquids, condensed steam.]
(*b*) Receivers of known capacity discharging between known pressures and temperatures. [For air and gas.]
(*c*) Piston displacement meters. [For water and oil.]
(*d*) Water-sealed drum meters. [For gas.]
(*e*) Bellows meters. [For gas.]
(*f*) Overbalancing bucket meters. [For water or oil.]
(*g*) Conveyor weight meters. [Measure granular material in terms of the weight carried per unit length of the conveyor.]
(*h*) Conveyor volume meters. [Measure granular material in terms of the height of material on the conveyor.]

2. Meters which Measure the Velocity at a Point or Points in the Cross-Section of the Stream.

(*a*) Pitot tube meters. [For gases and non-viscous liquids.]
(*b*) Hot wire, or hot wire plus thermocouple, velocity indicator. [For air and gas.]
(*c*) Impact meters. [For measuring air velocity in mine tunnels.]
(*d*) Anemometer meters. [For water in open channels, or air in conduits and passages.]
(*e*) Floats. [For measuring the velocity of water in open channels. Balloons, smoke, heated air particles can be similarly used for measuring air velocities.]
(*f*) Chain meters. [For coal, etc.]

3. Meters which Depend on the Drop of Pressure due to an Obstruction Placed in the Stream.

(*a*) Weirs. [For liquids in open channels where sufficient 'head' is available.]
(*b*) Venturi flumes. [For liquids in open channels where the available 'head' is small.]
(*c*) Venturi tubes. [For water, air, steam and gas in pipes.]
(*d*) Nozzles. [For gas, water, air, or steam.]
(*e*) Circular, chord, or tongue orifices. [For water, air, gas, or steam.]
(*f*) Variable orifices. [For water, air, gas, or steam.]

* See Hodgson, *Proc. Inst. C.E.*, Vol. CCIV, Part 2, and Mayor, *Trans. Inst. Mining Engineers*, Vol. L, Part 4.

4. Rotary or Turbine Meters.

(a) Which measure the whole of the flow passing. [For water, air, steam or gas.]

(b) Which are placed in a shunt circuit. [For water, air, steam, and gas.]

5. Meters Based on the Movement of a Spring or Weight Controlled Obstruction Placed in the Pipe Line.

(a) In which a disc moves axially in a circular chamber with conical or perforated walls. [For water, gas, steam or air.]

(b) In which a shaped plug opens up an orifice. [For steam, water, gas or air.]

(c) In which a weighted hinged gate is opened by the flow. [For water, gas, steam or air.]

6. Meters Based on the Drop of Pressure caused by Frictional Losses.

(a) In which two pressure connections are arranged at the ends of a length of channel or pipeline. [For measuring irrigation water.]

(b) In which the fluid is caused to pass through a large number of narrow passages arranged in parallel, so that the flow is viscous.

7. Meters Based on the Introduction of a Measured Amount of (a) Heat, or (b) Chemical Reagent, and the Consequent Rise of Temperature of the Fluid or Dilution of the Reagent at some point further downstream.

(a) [For air and gas.]

(b) A method used for measuring the discharge of rivers and canals, recently further developed for the measurement of air and steam flows. Salt solution is usually introduced when measuring water-discharges, and ammonia or carbon dioxide gas when measuring steam or air flows.

8. Meters Based on Increase of Weight due to Chemical Absorption.

Notes.

Meters of classes 1 (c), (d) and (e) can be made accurate to within plus or minus 1 per cent. from zero flow up to the maximum flow which they are designed to measure. The chief sources of error of meters of class 1 (d) are variation in the water level and wear of bearings, and of meters of classes 1 (b) and 1 (e) wear of the valves.

Meters of classes 2 (a), (b) and (c) are usually only accurate down to one-third or one-sixth of the maximum flow for which they are designed, as their indication depends upon the square (or the fourth power) of the velocity of the fluid. Few anemometers are accurate when working at less than one-tenth of their maximum rated capacity.

Meters of classes 3 (a), (b), (c), (d) and (e) are usually accurate down to one-fifth of the maximum flow. If specially sensitive differential pressure-measuring devices are provided, such meters may be made accurate down to one-twentieth or one-thirtieth of the maximum flow. By using a variable orifice, the range over which accurate measurement is possible with any given indicator or recorder is greatly extended. These meters have the very real advantage of having in the pipe line no moving parts which can be deranged by dirt or erosion. The Venturi tube and flume, with their smooth contours which eliminate eddying, are valuable devices when measuring dirty gas or sewage. Meters of class 3 show many ingenious arrangements for obtaining an accurate measurement of the differential pressure over a wide range and for compensating for variations in the specific gravities of the fluids or gases to be measured.

Meters of class 4 are not usually accurate in practice below one-tenth of the maximum flow, though many makers claim much higher ranges of accuracy. Endeavours have been made to increase the range of accurate measurement by opening up additional jets at low flows, or by introducing additional resistance at the high flows. While these devices frequently give excellent results under test conditions, they rapidly get out of adjustment under working conditions. Water meters of this class can often carry considerable overloads, thus greatly increasing the range over which accurate measurements may be obtained. Gas meters of this class can be fitted with devices which automatically correct for variations in gas pressure, or in gas pressure and gas temperature.

Meters of classes 5 (a), (b) and (c) are capable of high accuracy over a large range of flow when measuring clean fluids. They rapidly lose their accuracy, however, when measuring dirty fluids, owing to the small clearances becoming choked.

The accuracy of meters of class 6 (a) is dependent upon an accurate knowledge of the area of the channel and its resistance coefficient. These are apt to change owing to silting up and the growth of weeds. Since with meters of class 6 (b) the drop of pressure is directly proportional to the velocity, the accuracy of measurement is maintained down to very low rates of flow.

Meters of class 7 (a) register in weight units irrespective of the pressure and temperature of the gas.

In the following pages the main features of some of the best known, or the most noteworthy, meters are described and illustrated.

Water Meters.

The Reciprocating Piston Water Meter.

This meter is shown diagrammatically in fig. 1. Its sequence of operations is as follows :—

1. The piston A descends, and the disc P throws over the valve C.
2. The piston B descends, and the disc R throws over the valve D.
3. The piston A descends, and the disc Q throws over the valve C.
4. The piston B descends, and the disc S throws over the valve E ; and so on.

Stops M limit the motion so that an exact quantity of water is measured off each stroke.

Projections K enter the outlet passage at the end of the stroke and prevent jar by slightly throttling the flow.

The cylinders are lined with brass, and the valves and valve faces are made of gun-metal. The valves are caused to oscillate slightly each time they are thrown over in order to keep the rubbing surfaces polished. For the same reason the pistons are caused to rotate a slight amount at each stroke.

The valves are held up against the port block by rollers L carried by springs which press inwards towards the valve faces.

The meter body is jointed along the line XY, which enables all parts to be readily accessible (actually the inlet and outlet passages are at right angles to the positions shown in the diagram).

A recent modification of this type of meter, stated to have a high accuracy, uses four cylinders at right angles, their pistons driving a central crank pin by means of two Scotch-yoke connecting rods.

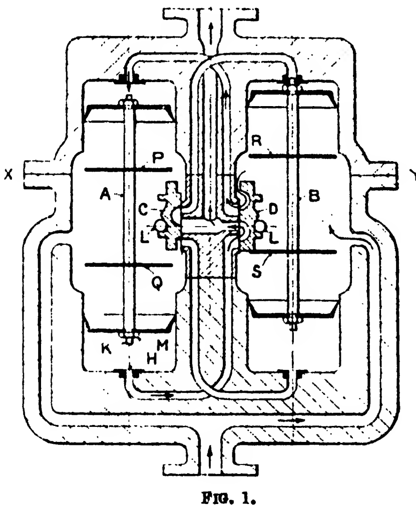

Fig. 1.

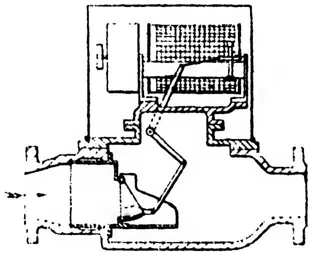

Fig. 2.

The Moving Flap Water Meter.

This meter (fig. 2) consists of a weighed gate pivoted on a horizontal axis and surrounded by a machined shield. The gate opens with increase in the flow, and takes up a definite position at each flow. Its motion is transmitted to the diagram through a stuffing box by means of link mechanism.

It is possible with this meter to measure with accuracy down to very small fractions of the full flow.

Owing to the absence of all sliding parts in this meter, the friction of the mechanism is extremely small.

The bulk of the meter, and the loss of pressure across it, are also reduced to a minimum by its arrangement, which allows of a direct flow between inlet and outlet.

For dirty water, the gate has been replaced in some cases by an aerofoil-shaped vane, the lift on which is balanced by a coil spring.

The Cylindrical Piston Meter.

In this meter (figs. 3 and 4) the motion of a cylindrical piston having a slot down the side is constrained by external and internal cylindrical walls and by a radial partition. The meter is suitable for measuring flows of water, petrol or oil.

For greater uniformity of recording, especially in the larger sizes, the piston is made an elliptical instead of a circular cylinder.

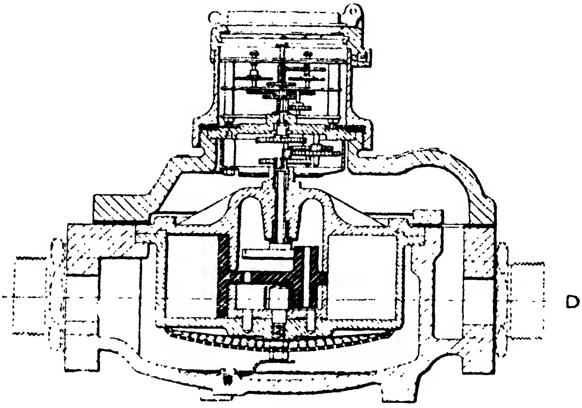

Fig. 3.

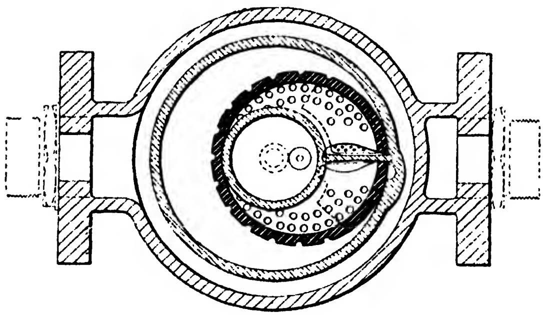

Fig. 4.

The Nutating Piston or Swash-Plate Water Meter.

In this meter (figs. 5 and 6) the spherical valve cap V rocks on its seating S, thus opening the lower parts of each of the three cylinders C successively to the inlet and discharge sides of the meter.

The valve cap V is prevented from turning round on its own axis by the projections Q, which engage in recesses left in the valve seat S. The ball-ended pin at the top of the valve cap thus sweeps out a cone and drives the counter through the arm A and the spindle D. The length of the stroke of the pistons is limited by the flange P on the valve cap V, which comes into rolling contact with a machined surface on the valve seat S.

It will be seen that the valve cap V moves with a lens-grinding action. This ensures that it and the seating will remain polished and unscratched even when gritty water is being measured.

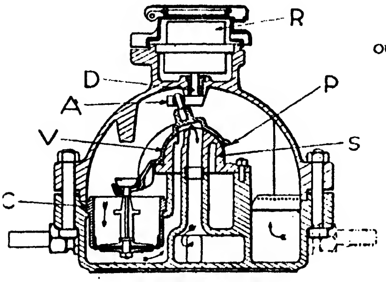

FIG. 5.

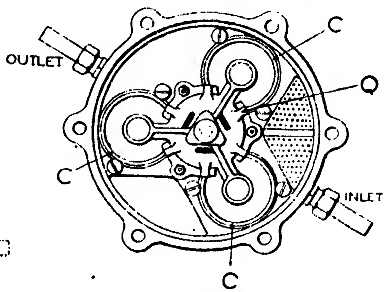

FIG. 6.

The valve cap and the pistons are made of hard gun-metal, the valve seat and bushes of vulcanite, and the cylinders of either vulcanite or gun-metal, vulcanite being used for water of exceptional hardness.

MOVING DISC WATER METER.

In this meter (fig. 7) a weighted disc or 'float' moves vertically in a conical shield. Its motion is transmitted to the diagram by means of thin wire passing through a gland. Guide plates are provided to steady the flow at the entrance to the conical shield. This principle is also used in several air and gas meters.

THE VENTURI WATER METER.

This meter (fig. 8) consists of (*a*) a Venturi tube VT through which the water passes; (*b*) a large mercury U-tube provided with floats FU and FT (which are displaced by the differential pressure which exists when water is passing between the upstream and throat pressure holes of the Venturi tube); and (*c*) diagram counter and recording mechanisms, which are actuated by the movements of the floats.

The motion of the floats is transmitted to the outside of the U-tube by means of gland spindles GU and GT, which actuate toothed wheels that engage with the racks RU and RT.

The law of flow through a Venturi tube is given by the equation :—

$$Q = \frac{\Omega a_1}{7\cdot 88}\left[\frac{hW}{n^2 - 1}\right]^{\frac{1}{2}}$$

where,

Q = flow in lbs. per sec.; Ω = coefficient of discharge for the tube (usually about 0·98); a_1 = area of tube at upstream pressure holes in sq. ins.; $\frac{a_1}{n}$ = area of tube at throat pressure holes in sq. ins.; h = difference of pressure between upstream and throat pressure holes in ins. of water; W = weight in lbs. of 1 cub. ft. of the fluid passing.

One form of counter recording mechanism for this meter operates as follows :—A cylindrical cam LC, which has a slightly raised portion, is rotated once every ten minutes by clockwork. A pivoted arm A, which carries the roller L, which is kept in contact with the surface of the cam by a spring (not shown), is lowered by the rack to which it is attached when the flow increases. The greater the distance the arm is lowered, the larger is the fraction of each revolution of the cam during which the roller is on the unraised portion of the cam. By means of mechanism (not shown) it is arranged that a toothed wheel which drives the counter is put into gear with the clock train during the period that the roller L is on the unraised portion of the cam. The boundary line between the raised and the unraised portions of the cam is so shaped that when the pivoted arm A carrying the roller L moves down a distance H from its zero position an amount proportional to $\sqrt{H}$ is added on to the counter reading. In this way, with suitable gear wheels in the counter train, a counter record of the amount of fluid that has passed is obtained.

Valves U and T are provided so that the upstream and throat pressures may be shut off, and the meter checked by opening the equalising valve E.

Any air that accumulates in the pressure pipes may be blown off through the air vents provided.

To reduce the chance of air getting into the pressure pipes, these should be taken off horizontally, and not at the top, as shown for clearness in the diagram.

These meters will measure accurately down to one-fourteenth of the maximum flow (and special meters of this type down to one-thirtieth of the maximum flow).

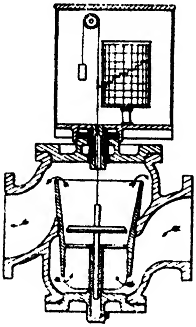

FIG. 7.

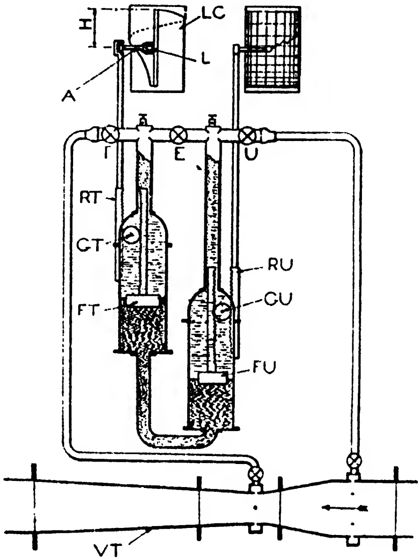

FIG. 8.

The functions of the downstream cone of the Venturi tube is to recover the kinetic energy which exists at the throat, thus enabling the major portion of the pressure difference which has been created between the upstream and throat pressure holes to be recovered.

The friction loss due to the insertion of the water Venturi tube is about 2 lbs. per sq. in. at the maximum flow.

Venturi meters have been used to measure water in all sizes of pipes from about ½ in. to 20 ft. in diameter. They provide the most convenient and accurate method known of measuring the flow of water in large mains. There is a minimum of obstruction to the flow, and there are no moving parts in contact with the flowing water.

Automatic Water Weighers.

In the automatic water weigher illustrated in fig. 9 the weight box B is suspended at one end of an equal-armed beam A, and the weigh hopper C at the other.

A quantity of water, determined by the weights in the weight box B, is allowed to enter the weigh hopper C through the feed valve D.

When the correct amount of water is obtained, the supply from the feed valve or valves D is, by means of a combination of levers, automatically cut off.

Immediately after the supply is cut off, the weigh hopper C automatically tips and discharges its load.

As soon as the contents of the weigh hopper C have been discharged, the weigh hopper automatically returns and assumes the weighing position, at the same time opening the feed valve or valves D, and the cycle of operations is repeated.

On the large-capacity machines there are two valves at D, the larger one feeding the main flow into the weigh hopper C, then closing, with the result that the final dribble of liquid to complete the weighing and ensure accuracy is fed through the supplementary small valve D.

A mechanical counter keeps an exact record of the number of times the machine operates.

Overbalancing bucket meters, which consist of two triangular buckets fixed together and pivoted below their common centre of gravity, are largely used in oil measurement. They operate

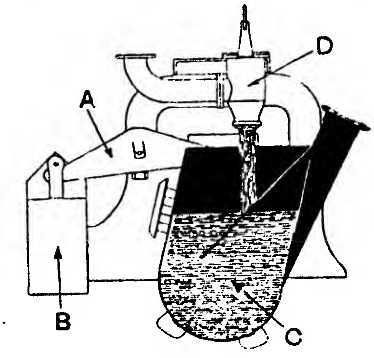

Fig. 9.

without interrupting the flow, and also usually take a small sample of the fluid passing each time they tip over. Where the oil is viscous and sticks to the buckets a correction is applied.

Weir Recorders and Venturi Flumes.

'V' Notch Weir Recorders.

These recorders are specially suitable for the measurement of boiler feed water and condensates, also rivers, streams, reservoir supplies, sewage effluents, etc., or in such cases where it is necessary to measure the water in some form of open channel.

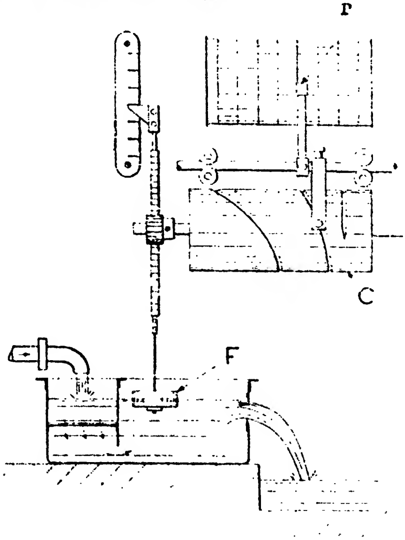

Fig. 10.

The discharge for a 90° V notch with sharp edges bevelled at 45° on the downstream side is given by the equation.

$$Q = 2{\cdot}48H^{2{\cdot}48}$$

where,

Q = discharge in cub. ft. per sec.; H = head, in ft. above the bottom of the notch.

In the Recorder shown in fig. 10 the movement of the float F in the weir chamber, which is proportional to H, is transmitted to a cylindrical cam C. By means of this cam a movement of the pen arm P. which is proportional to Q, is obtained.

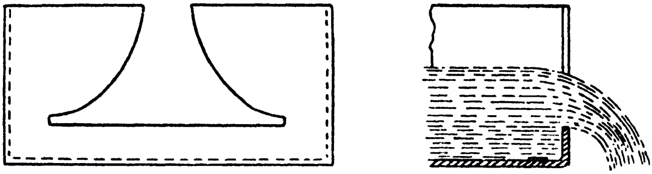

FIG. 11.

In another type of weir recorder **mechanism a flat cam is used, and the straight line movements are replaced by movements about fixed pivots, while in a third type the notch is made of such a shape that the motion of the float is proportional to the quantity passing. In this last recorder there is, therefore, no cam between the float and the recorder pen. The approximate shape of the weir notch is shown in fig. 11.**

Weirs, when used for stream measurement, are liable to considerable errors due to wind effects and other causes. A Venturi flume, or a nest of Venturi flumes (such as may be formed by the specially constructed piers of a bridge) enable much more reliable results to be obtained.

The discharge of a Venturi flume is given by the formula,

$$Q = C\sqrt{2g}\, bH^{\frac{3}{2}}x\sqrt{\frac{1-x^2}{1-S^2x^2}}.$$

where Q = discharge in c.f.s., C = coefficient of discharge (to be determined experimentally), b = width at throat (ft.), H = depth upstream of contraction, x and S = ratios of depth and width at throat to depth and width upstream, respectively.

Gas Meters.

THE 'DRUM' TYPE STATION GAS METER.

In this meter (fig. 12) gas enters through the hollow axis in the four compartments of the drum in a pipe which is put just above the water level, and fills each compartment successively, and by

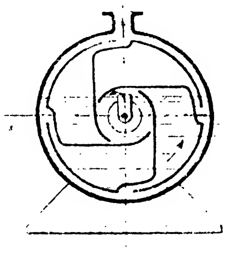

FIG. 12.

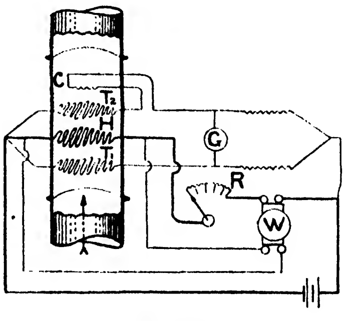

FIG. 13.

its pressure causes the drum to revolve in the direction of the arrow and to register the volume passed on a set of dials.

Meters of this type are used to measure gas in mains of all sizes, from ½ in. upwards.

Owing to their costliness, the larger meters of this description are now being superseded by meters of classes 3, 4 and 7.

The main sources of error of this meter are deformation or corrosion of the drum, deposition of naphthalene in the drum, and variations in the water level. There are various ingenious devices for preventing the meters from being over-filled, and for maintaining the correct water level. If the meter is overloaded, the water level is depressed, and the meter reads slow.

The Heat Injection Gas Meter.

In this meter (fig. 13) the gas is passed through a short length of pipe which contains two electrical resistance thermometers T_1 and T_2, which form part of a Wheatstone Bridge. An electrical heater H is placed between the two thermometers. Any increase in the flow of gas causes a lowering of the temperature of the downstream thermometer and a deflection of the needle of the galvanometer G. This is made automatically, by means of a suitable mechanism, to reduce the resistance in the heater circuit, so that the temperature of the gas is always raised the same amount (about 2° F.) by the heater.

The readings on a Wattmeter W, placed in the heater circuit, give the number of cubic feet of gas reduced to standard temperature and pressure.

The Venturi Gas Meter.

In this meter (fig. 14) the 'Venturi Head' $(p_1 - p_2)$ is measured by means of the bell B and an amount proportional to $(p_1 - p_2)$ is added on to the counter reading by means of the cam, feeler, ratchet, and pawl device C.F.R. every time the cam G, which is driven by the wet gas meter W, makes one revolution

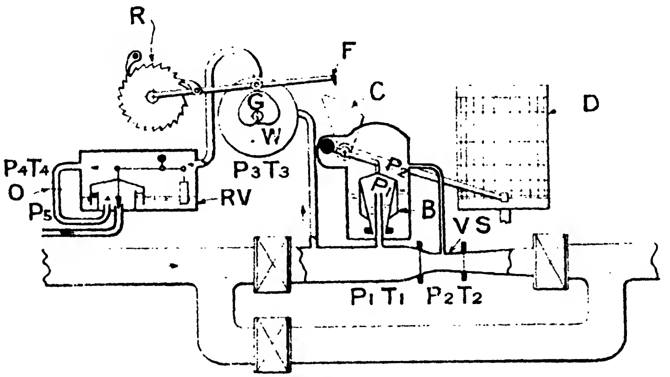

FIG. 14.

The speed of rotation of this meter is determined by the amount of gas that escapes to atmosphere through a small orifice at O, across which the pressure difference is maintained constant by means of the regulating valve RV.

In this way the counter is made to register the volume of gas passing through the Venturi tube, irrespective of variations in the specific gravity of the gas, the registration of the meter being identical with that of the ordinary Drum type Station Gas Meter.

A diagram, D, is provided which shows the rate of flow of gas at any instant. The readings of this diagram are, however, not corrected for variations in the specific gravity of the gas.

If tar, naphthalene, or other depositable matter settles in the Venturi throat, the meter tends to read fast. It is found that when measuring coal gas, such deposits can be entirely prevented by keeping the walls of the throat at a few degrees higher temperature than that of the gas passing through.

The Venturi tube is installed on a by-pass, and the throat section VS is made so that it can easily be swung out of the pipe line for inspection and cleaning.

The loss of pressure at the maximum flow due to the insertion of the gas Venturi tube is arranged not to exceed 1 in. of water gauge.

The range of accurate registration is down to one-tenth or one-fifteenth of the maximum flow.

If it is desired to reduce the meter readings to standard cubic feet of dry gas, corrections must be made for variations in the barometric pressure, atmospheric temperature, and the tension of aqueous vapour by means of tabular numbers, as is the case with the Drum type Station Meter.

The Venturi Gas Meter is also made in a cheaper form in which the integrating mechanism is driven by clockwork, and any variation in the specific gravity, temperature, and moisture content of the gas is corrected for by means of tabular numbers, *i.e.* the meter readings are multiplied by

$$\frac{(p_1 - p'_1)}{p_1}\sqrt{\frac{W_D}{W_S}} \cdot \frac{p_1}{T_1} \cdot \frac{T_S}{P_S}$$

where,

W_D = weight of a cub. ft. of dry gas at p_1 and T_1; W_S = weight of a cub. ft. of gas containing water vapour at p_1 and T_1; p'_1 = pressure of water vapour at temperature T_1, P_S and T_S the standard temperature and pressure.

See Hodgson. *Proc. Inst. C.E.*, vol. cciv., pp. 164–165.

THE ORIFICE GAS METER.

This uses a plate orifice with upstream and downstream pressure tappings either to the two sides of a U-tube with dial indication or (for low pressures) to a ring balance, *i.e.* an annular chamber partly full of liquid, to each of the free surfaces of which the pressure from one side of the orifice is applied. The chamber swings to regain its balance and in doing so moves an indicating pointer.

THE ROTARY GAS METER.

In this meter (fig. 15), a counter C is actuated by an anemometer fan F, which rotates about a vertical axis.

The gas, after being carefully guided by a series of nozzles N into a vertical direction, impinges on the underside of the blades, thus helping to take the weight of the fan off the bottom pivot. The rate of revolution of the fan is proportional to the actual volume of gas passing, except at low flows, when the friction of the mechanism is appreciable. At these flows a weighted valve V (which lifts at the higher flows) causes the whole of the gas to pass through a few jets J, and so to impinge on the fan at an increased velocity. In this way the friction of the mechanism is compensated for, and accurate readings obtained down to one-tenth of the maximum flow.

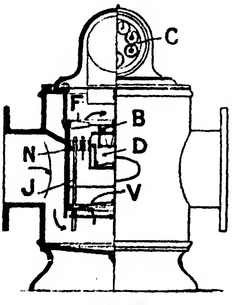

FIG. 15.

The dashpot D is provided to steady the motion of the weighted valve. A brake B is attached to this valve, which stops the fan immediately the flow is turned off, as the valve then falls.

This meter registers the actual volume of gas passed, and is subject to the same corrections for variations in the temperature pressure and moisture content of the gas as is the ordinary Drum type Station meter, or the Kent-Hodgson Venturi Gas meter.

Clogging of the nozzles through which the gas discharges on to the fan causes the meter to read fast. A special form of meter in which the nozzles can be cleaned from the outside, and in which any deposit thrown off from the fan does not accumulate r. . .d it, has been devised for measuring dirty gas.

The Shunt Gas Meter.

This meter (fig. 16) consists of a body casting inserted in the main, or by preference in a by-pass in the main, a turbine T placed in such a position that gas passing through the two nozzles J on the upstream side of the orifice K impinges on its blades, and a counter mechanism actuated by the turbine. The turbine, orifices, and nozzles can be inspected and cleaned through the hand-holes provided.

The meter carries the measurement of gas on the rotary principle to the utmost refinement. The speed of rotation of the turbine is kept low by means of the damping fan F, so that wear on the bearings is reduced to a minimum. The weight of the turbine is carried on a mercury float, so that the all-important pivot bearing never wears appreciably, and is also protected by being covered with mercury. The upper thrust bearing and the high-speed wheels of the counter train run in an oil bath. The motion of the turbine is transmitted to the counter dial by means of a magnetic drive similar to that shown in fig. 16, thus eliminating all gland friction and the possibility of moisture depositing on the counter glass.

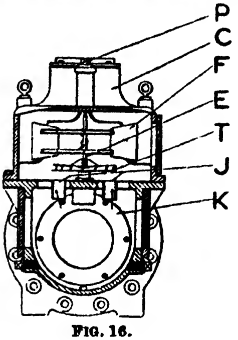

Fig. 16.

The turbine chambers and the mechanisms they contain are identical, whatever be the size of the main. The only parts of the meter which vary in size are the body casting which contains the orifice, the orifice itself, and the change wheels which are fitted into the counter train. The length of the body casting in practically all sizes is 24 ins., so that the meter is very light to handle and requires only a short length of pipe line for its installation. It is accurate down to one-tenth of full flow, and will stand considerable temporary overloads without damage.

The Hot Wire Anemometer.

In this instrument a bare wire with a large temperature coefficient is heated electrically and exposed to the gas flow whose velocity it is required to measure. The velocity V of the gas can then be obtained from the relation

$$I^2 = A\theta + B\theta\left[V.W\,K_p\right]^{\frac{1}{2}}$$

where,

θ = temperature elevation of the wire;
I = current in amps.;
V = velocity of the gas;
W = specific weight of the gas;
K_p = specific heat of the gas at standard pressure
A & B = constants.

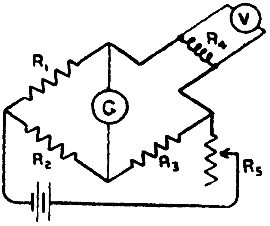

Fig. 17.

Referring to the diagram (fig. 17), R_1, R_2, and R_3 are resistances with no temperature coefficient, R_4 is the anemometer wire which is maintained at constant temperature when the gas velocity varies by adjusting the resistance R_5 so that the needle of the galvanometer G remains at zero. The current through R_4 is thus proportional to the reading of the high resistance voltmeter V.

The formula given above holds for ordinary gas speeds (9·5 to 30 ft. per second). At speeds below these, free convection currents carry away a considerable proportion of the heat, and the formula requires modification.

The accuracy of the instrument is affected by changes in the temperature of the gas itself, and for this reason it is desirable, when high accuracy is required, to work at a temperature elevation of about 1,000° C. In this case the anemometer wire should be of platinum. For ordinary work a temperature elevation of 200° C. or 300° C. is sufficient, and the anemometer wire may be made of electrolytic nickel.

It will be noticed that the velocity of the gas is approximately proportional to the fourth power of the current. This makes the accurate range of the instrument small, and it also makes it unsuitable for obtaining the mean velocity of fluctuating flows.

In a modification of the instrument the four arms of the Wheatstone bridge are made of electrolytic nickel. The wires which compose the two opposite arms of the bridge are shielded from the air current, and the two remaining wires are exposed to it. The instrument is thus automatically compensated for changes in the air temperatures, so that it is not necessary for the temperature of the wires to be more than 100° F. above that of the air current to be measured. A constant potential difference is maintained across the bridge, and the air velocity is measured in terms of the out-of-balance current of the galvanometer.

In a further modification, an electrically heated platinum wire and a thermocouple are enclosed in a double bore quartz sheath, and exposed to the wind velocity to be measured. If a constant current is sent through the platinum wire, the thermocouple reading will be a measure of the wind velocity.

The instrument is calibrated against known velocities in a wind tunnel.

An instrument of this type is adaptable for recording the proportion of any gas (*e.g.* CO_2) in the air travelling through a duct, since the heat lost from the wire will vary according to the composition (and therefore heat conductivity) of the ambient gas.

The Viscous Flow Air Meter.

This meter is designed to eliminate the serious errors which arise with pulsating flow in air meters of the orifice, Venturi, or other 'kinetic' types unless a very large smoothing capacity is provided. Those errors are due partly to 'root-mean-square' velocity effects and partly to the effect of the flow in and out of the connections to the indicating manometer as the pressure drop across the meter varies.

In the viscous flow air meter, the 'meter element' is a honeycomb of long narrow triangular passages each about 0·02 in. in width, formed by winding upon a core alternate layers of flat and corrugated strip metal. The manometer connections are tubes, spanning the upstream and downstream faces of the element, each with a row of holes along one side, those on the upstream connection facing downstream and vice versa.

Within the working range of the meter, the velocity through the passages of the element is below the critical, so that the flow is viscous and the resistance of the element is directly proportional to the velocity; this automatically eliminates the 'root-mean-square' error. The construction of the manometer connections provides a reverse kinetic head which automatically corrects the small pressure drop in the element due to entry effects, and the error due to flow in the manometer connections is corrected by providing these with felt pads which render the flow in the connections viscous.

Since the pressure difference across the meter is proportional to the flow rate, the range of flow measurable with reasonable accuracy is greater than with 'kinetic' meters where the pressure varies with the square of the flow rate. Viscous meters are, of course, not absolute standards and must be calibrated against a standard measuring nozzle or orifice. After proper calibration, a viscous meter can be relied on to repeat its readings to within 1 per cent. In order to prevent clogging of the meter element, an air filter is usually fitted upstream of the element.

Steam Meters.

The Orifice Steam Flow Meter.

A typical pressure-corrected steam-meter (fig. 18) consists of an orifice O placed in the steam main, two cooling chambers OU and OD (whose function it is to condense any steam that passes into them and to serve as reservoirs of water), and pressure pipes PU and PD which transmit the difference of pressure between the upstream and downstream sides of the orifice, due to the steam flow, to the two sides of the differential pressure diaphragms D and to the inside of the pressure diaphragms P.

Any increase of the flow causes an increase of the difference of pressure between the upstream and downstream sides of the orifice, and consequently causes the diaphragms D to contract and the pointer B to move about its pivot C (the motion of the diaphragms D is transmitted to the outside of the diaphragm case through a stuffing box G); while any increase in the pressure of the steam causes the diaphragms P to expland and the arm H to descend.

Air vents V and an equalising valve E are fitted.

The product of the angular movement of the arm B (which is proportional to the differential pressure $(p_1 - p_2)$) and the travel of the roller R in its slot (which is proportional to the absolute pressure of the steam p_1) is transmitted to the pen arm A, which is thus given a motion proportional to $(p_1 - p_2)p_1$.

Since the rate of discharge of steam through an orifice is represented approximately by the equation,

$$Q = K \sqrt{(p_1 - p_2)p_1}$$

where,

p_1 = absolute pressure of the steam on the upstream side of the orifice; p_2 = absolute pressure of the stream on the downstream side of the orifice; Q = lbs. of steam per hour; K is a constant depending upon the size and proportions of the orifice used.

THE ORIFICE STEAM FLOW METER.

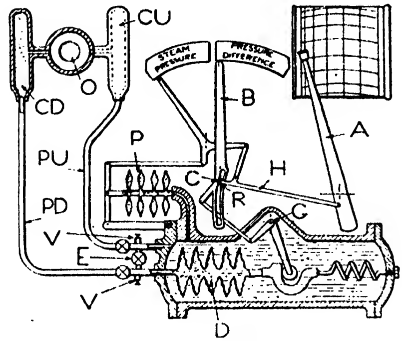

FIG. 18.

THE MERCURY U-TUBE STEAM METER.

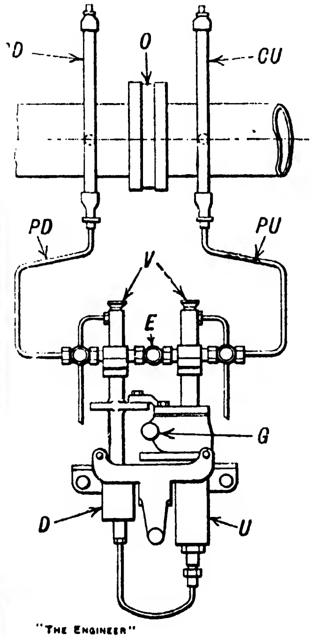

FIG. 19.

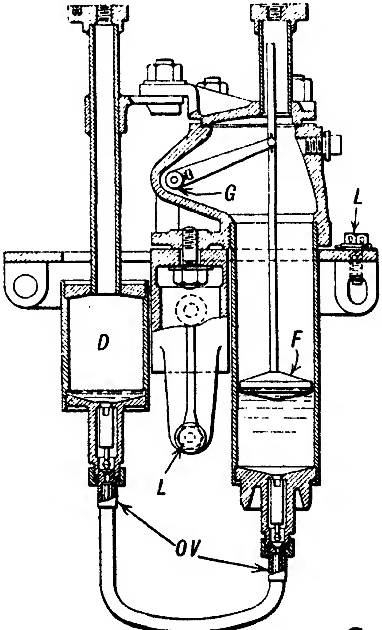

FIG. 20.

the diagram can be divided to show the rate of steam flow at any instant, automatically corrected for variations in the pressure. (The corrections for variations in the superheat or wetness of the steam* are made by means of tabular numbers.)

These meters can be arranged to record by counter also if desired.

With any given orifice plate the meter is accurate down to one-fifth of the maximum flow for which the plate is designed to deal. If it is desired to measure over a greater range of flow than this, a new orifice plate must be inserted. Each meter is designed to work in connection with any orifice plate. Each orifice plate is calibrated with actual fluid before leaving the works, and the accuracy obtained in practice with this meter is within plus or minus 1 per cent.

With slight modifications, such a meter can be used for the measurement of compressed air.

This meter, which is shown installed (fig. 19), and with the mercury pots in section (fig. 20), consists of an orifice, O, and cooling chambers, OU and OD, as in the case of the meter shown in fig. 18. The differential pressure across the orifice is measured by the motion of a cast-iron float, F, which transmits its motion to the gland spindle, G. The motion of the gland spindle is made to indicate or record the flow as desired. Overload valves, OV, are provided to prevent the mercury being blown out. Levelling screws, L, are also provided. The downstream pot, D, is made easily interchangeable so that a higher or lower maximum 'head' may be worked at.

This type of mercury pot unit is suitable for measuring air, gas, steam, water and oil flows.

The Rotary Steam Flow Meter.

This meter is shown in section by fig. 21. A portion of the steam passing through the instrument is diverted by means of an orifice plate through nozzles A, by means of which it is caused to impinge on a turbine. The speed of this turbine is kept low by means of a damping fan, O, which rotates in water, resulting in a minimum of wear on the turbine bearings. The retarding torque at any given speed due to this fan is made so great that any variation in the corresponding torque due to the turbine, caused by variations in the density of the steam in which it rotates, can be neglected. The turbine rotates at normal flows with a speed proportional to $Q\sqrt{W}$, where Q is the weight of steam passing per second, and W is the density of the steam in pounds per cubic foot. From this it will be seen that a variation of 2 per cent. in the density of the steam will involve a correction of only 1 per cent. in the flow reading. Besides reducing wear on the pivots, the use of the damping fan increases the range of the meter, since it increases the relative velocity between the impinging steam and the turbine. The counter E is mounted in a compartment below the main, a magnetic drive D from the turbine being employed so that leakage of steam or water into this compartment is impossible. Radiating fins assist in keeping the counter cool. The maximum flow which the meter will measure can be altered by changing the orifice plate B; and by fitting a blank plate in place of this orifice plate, and putting the meter in a by-pass in a large main into which a suitable orifice plate is inserted directly, the largest mains can be metered at a small cost.

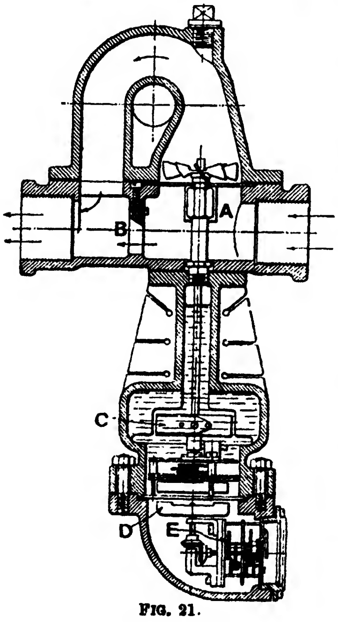

Fig. 21.

The ratio of the revolutions per minute to the rate of flow is constant.

The meters are accurate down to $\frac{1}{10}$ of the maximum flow, and will stand temporary overloads of 100 per cent. without damage.

The same type of meter is often used for compressed air in pipes up to 2 ins. diameter.

* About 1 per cent. for every 2 lbs. change in the pressure, or 20° F. change in the superheat, or 2 per cent. change in the wetness.

Conveyor Volume Meters.

The object of this meter, illustrated in fig. 22, is to measure the amount of coal consumed by a chain grate mechanical stoker.

The coal, as it passes from a hopper underneath a movable fire door, assumes the form of a continuous stream of rectangular cross-section. The volume of coal, therefore, having passed during any given time is the product of the width of the chain grate, the height of coal as it passes under the fire door, and the linear distance travelled by the grate.

Of these three factors two are variable : firstly, the depth of coal passing over the grate (due to the variation in lift of the fire door) ; secondly, the speed of the grate (or the distance travelled by the grate over a given time). The meter is so constructed as to take both these variables into account in the following manner :—

A specially cut toothed drum, having at one end teeth cut round the whole of its periphery, and a uniformly decreasing number of teeth cut along the whole of its length, is driven by a small driving chain from the grate itself ; thus the speed of the drum is proportional to that of the grate, and accordingly proportional to the linear distance travelled by the grate over any given time.

Meshing with this toothed drum is a sliding pinion, which is directly connected to the fire door by means of a steel cable ; its position on the toothed drum, and consequently the number of teeth with which it engages, is, therefore, dependent on the amount to which the fire door is raised or lowered. Thus, the rotation of this pinion is dependent on both the grate speed and the fire door lift, and, consequently, this rotation is in a direct proportion to the volume of coal having passed.

The principle of operation of this Meter is as follows :

If W = width of grate in ft. ; T = thickness of fire in ft. ; V = velocity of grate in ft. per hour ; then, cubic ft. per hour = W × T × V = cross-sectional area × V.

The rotation of the pinion is transmitted directly to a row of seven counting dials, the movement of which gives a visible indication of the volume of coal having been fed on to the grate.

Such Coal Meters can be fitted with a ' Rate of Flow ' Indicator, which, when worked in conjunction with the various speeds of the Stoker drive, gives, on specially graduated scales, the actual amount of coal being consumed at any moment in lbs. per hour.

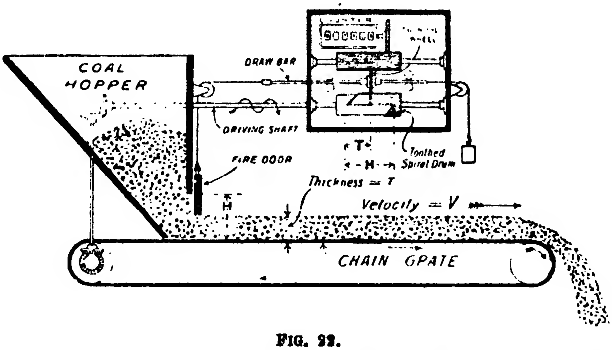

FIG. 22.

A modification of the above meter enables it to measure bulk supplies of coal, ores, grain, or any other similar granular material, in a continuous manner, in conjunction with elevators or conveyors, on which the material is being handled.

The principle of measurement is volumetric, and is as follows :—

The material to be measured is passed on to an endless belt, in a similar manner to the coal passing on to the grate of a chain grate stoker. The meter itself is similarly driven by a small chain from this belt.

As the material travels over the belt it passes underneath a swinging door, the lift of which varies with the thickness passing under it. Directly connected to this swinging door is a link

motion which operates the sliding pinion in the meter. Thus the rotation of the meter dials is proportional to the speed of the belt, and also to the height of the material passing along it, the two factors being combined in the meter giving a true indication of the volume of material having passed through the machine.

These machines may be accurate within 2 per cent. by volume.

In a meter of the volumetric type for measuring coal the counter is operated directly by the rams, or pusher plates, of stokers of the Proctor, Bennis, and other similar types. A granular substance such as coal may also be measured volumetrically by means of a counter, provided that this counter is so arranged as to take into account variations of both the speed at which the rams are operated and the differences of travel of the rams, so that a true record of the amount of coal fed into the furnaces is given.

Such a meter may be made to be correct within 2·5 per cent. by volume.

Conveyor Weight Meters.

These are usually applied to belt conveyors.

They record the product of the weight of stuff carried per unit length of conveyor passing a given point, and the total length passed.

In one such conveyor weigher the pull on a steelyard arm is balanced by a cylindrical float immersed in mercury, the movement of the arm being thus made proportional to the weight on the weigh-bridge. Integration is effected by means of a feeler and free-wheel device, the steelyard arm being clamped while the feeler is in contact with it.

Automatic Coal Weighers.

A coal weigher similar to the water-weigher shown in fig. 9 is shown in fig. 23.

In this instrument a weight box B is suspended at one end of an equal-armed beam A and the weigh hopper C at the other.

A quantity of coal, determined by the weights in the weight box B, is allowed to enter the weigh hopper C through the feed shoot controlled by the valve D.

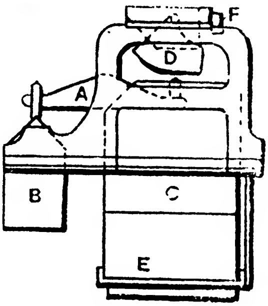

FIG. 23.

When the correct amount of coal is obtained, the supply from the feed shoot is, through a combination of levers, automatically cut off by the valve D.

Immediately after the supply is cut off, the door E of the weigh hopper C automatically opens and the load is discharged.

When the load is clear of the weigh hopper door E it closes again and automatically opens the feed valve D, and the cycle of operations is repeated.

A mechanical counter F keeps an exact record of the number of times the machine operates.

Chain Type Chute Coal Meter.

In this type of meter an endless chain passes down the chute, embedded in the coal, and then runs over a sprocket geared to an electric generator connected with a remote indicator or recorder.

Notes on the Use of Orifices, Nozzles, and Venturi Tubes for Test Purposes.

Q = discharge in lbs./sec.;
E = coeff. of discharge;
a_1 = area of main in sq. ins.;
a_2 = area of orifice or throat of nozzle in sq. ins.;
n = a_1/a_2;
N = $a_1 \div \sqrt{n^2 - 1}$;
d_1 = dia. of main in ins.;
d_2 = dia. of orifice on throat or nozzle in sq. ins.;
h = differential pressure across orifice or nozzle in ins. of water;
p_1 = abs. pressure in lbs./sq. in. at upstream pressure hole;
p_2 = abs. press. in lbs./sq. in. at downstream or throat pressure hole;
T_1 = abs. temp. in F.° at upstream pressure hole;
W_1 = specific weight of fluid at upstream pressure hole in lbs./cu. ft. = $2 \cdot 7p_1/T_1$ for air (values for water, steam, and other fluids can be obtained from various published tables):
μ = viscosity of the fluid in foot, pound, sec. units;
γ = ratio of the specific heats if the fluid is gaseous.

The discharge through an orifice, shaped nozzle, or Venturi tube for gaseous or liquid flows can be calculated from the formula:

$$Q = 0 \cdot 127\ EN\sqrt{hW_1}\ \text{lbs./sec.}$$

The value of the coefficient of discharge, E, is the same for the same values of the viscous flow criterion $Q/d_2\mu$, whatever be the density and viscosity of the fluid used, provided that when the fluid which is being metered is a gas, it does not appreciably change in density as it passes through the orifice or nozzle (*i.e.*, p_2/p_1 should be between $1 \cdot 0$ and $0 \cdot 98$).

For shaped nozzles and Venturi tubes, if the numerical value of the viscous flow criterion $Q/d_2\mu$ is greater than 3,000,

$$E = 0 \cdot 95–1 \cdot 00.$$

For orifices:

$$E = 0 \cdot 605–0 \cdot 615,$$

provided that:

(*a*) The numerical value of viscous flow criterion $Q/d_2\mu$ is greater than 10,000;
(*b*) d_2/d_1 is not more than $0 \cdot 6$, and that orifices are used which have;
(*c*) square edges if the orifice plate is thin (less than $\frac{1}{30}$th the diameter of the orifice);
(*d*) square edges bevelled off on the downstream side if the orifice plate is thick;
(*e*) pressure holes not more than one pipe diameter upstream, and not more than half a pipe diameter downstream of the orifice.
(*f*) the orifice or nozzle is installed with at least 10 diameters upstream and 5 diameters downstream of straight parallel pipe free from bends, tees, branch pipes and control cocks.

If the flow is gaseous and pulsating, sufficient capacity or throttling must be introduced between the source of pulsation and the metering point to smooth out the pulsation of flow at the metering point, otherwise the meter will read fast. In the case of liquid flows, an air vessel or an open tank may be used.

If gaseous discharge takes place above the critical pressure ratio (*i.e.* if p_2/p_1 is less than $\left(\frac{2}{\gamma+1}\right)^{\frac{\gamma}{\gamma-1}}$ when $n = \infty$), the following formulæ hold for shaped nozzles:

$$Q = 0 \cdot 325\ EN\sqrt{p_1W_1}\ \text{for air;}$$

$$= 0 \cdot 316\ EN\sqrt{p_1W_1}\ \text{for steam.}$$

SECTION VII

BEAMS — GIRDERS — STRESSES — BENDING MOMENTS — INFLUENCE VALUES—MOMENT OF INERTIA—DEFLECTION — COLUMNS — STANCHIONS — RIVETING — STEEL ROOF FRAMING AND COVERINGS—BRITISH STANDARD SECTIONS.

(Revised by J. D. W. Ball, A.M.I.C.E.)

STRESSES ON BEAMS AND GIRDERS.

When designing framed structures, the external forces (or those acting *on* the structure, are always known or assumed, and from these, and the configuration or design of the structure, the internal stresses set up in the several portions of the structure can be determined.

The external forces may be assumed as acting transversely, i.e., at right angles to the beam, or girder, the supporting forces or reactions necessarily acting parallel to and in the opposite direction to the applied forces. Where any force acts other than transversely, it should be resolved into two component forces, one acting in the direction of the length of the beam (and causing compression or tension throughout the complete cross-section), and the other acting transversely: to obtain the total stress at any section of the beam, the tension or compression due to the former component must be added algebraically to the stress from the transverse component.

The beam or girder, whatever its form may be, will tend to shear transversely, and to bend under any system of loading, and the values of these tendencies at any section are termed the 'shearing stress' and the 'bending moment' values at that particular section.

At any vertical section throughout a beam the shearing stress to be resisted is the algebraic sum of all the vertical forces acting to the right or the left of the section chosen; the forces being reckoned, say, as positive or negative as they act in an upward or downward direction.

For any series of transverse forces W_1, W_2, W_3, etc., acting to one side of the chosen vertical section, the general formula for the shearing stress is:—

$$S = \Sigma W = \pm W_1 \pm W_2 \pm W_3, \text{ etc.} \qquad (1)$$

At any vertical section throughout a beam, the bending moment to be resisted is the algebraic sum of the moments of the several vertical forces acting to the right or left of the chosen section, these moments being reckoned, say, as positive or negative as they tend to turn the beam about the section line in a clock-way or anti-clock way.

Thus, for any series of transverse forces W_1, W_2, W_3, etc., acting at the several horizontal distances l_1, l_2, l_3, etc., from the chosen vertical section, the general formula for the bending moment is:—

$$M = \Sigma(Wl) = \pm W_1 l_1 \pm W_2 l_2 \pm W_3 l_3, \text{ etc.} \qquad (2)$$

(In the case of uniformly distributed loads the value W is that for the total load under consideration, the horizontal distance being then measured from the chosen section to the centre of the load.)

Where the supports to a beam are not more than two in number, and the ends of the beam are free, the reactions or supporting loads can readily be found by the law of the lever. These values are then added to the list of external forces, and the shearing forces and bending moment values calculated from formulæ (1) and (2).

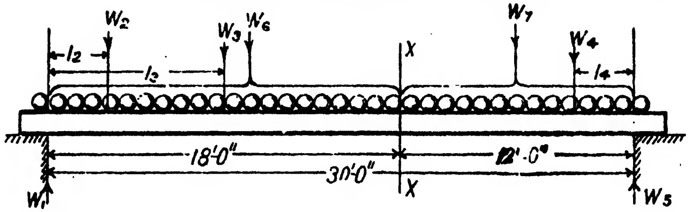

FIG. 1.

EXAMPLE :—A beam 30 ft. clear span between reactions carries three concentrated loads of 150 lbs. each, spaced as shown (fig. 1); weight of beam 60 lbs. per linear foot. l_2 $l_4 = 3'\text{-}0''$, $l_3 = 9'\text{-}0''$.

	Reaction, left $= W_1$.	Reaction, right $= W_5$.
Beam	$= 30 \times 60 \times \frac{1}{2} = 900$ lbs.	$= 30 \times 60 \times \frac{1}{2} = 900$ lbs.
Load W_2	$= 150 \times \frac{30-3}{30} = 135$ „	$= 150 \times \frac{3}{30} = 15$ „
„ W_3	$= 150 \times \frac{30-9}{30} = 105$ „	$= 150 \times \frac{9}{30} = 45$ „
„ W_4	$= 150 \times \frac{30-27}{30} = 15$ „	$= 150 \times \frac{30-3}{30} = 135$ „
	Total $= 1,155$ lbs.	Total $= 1,095$ lbs.

Shearing stress at section XX, fig. 1, calculated from left :—

Formula (1) $\quad S = W_1 - (W_2 + W_3 + W_6)$
$= 1,155 - [150 + 150 + (60 \times 18)] = -225$ lbs.

Calculated from right $\quad S = W_5 - (W_4 + W_7)$
$= 1,095 - [150 + (60 \times 12)] = 225$ lbs.

Bending moment at section XX, fig. 1, calculated from left :—

Formula (2) $\quad M = W_1 l_1 - (W_2 l_2 + W_3 l_3 + W_6 l_6)$
$= 1,155 \times 18 - [(150 \times 15) + (150 \times 9) + (18 \times 60 \times 9)] = +7,470$ ft. lbs.

and from right, $\quad M = -W_5 l_5 + (W_4 l_4 + W_7 l_7)$
$= -1,095 \times 12 + [(150 \times 9) + (60 \times 12 \times 6)] = -7,470$ ft. lbs.

Graphic diagrams for shear and bending moment values can be drawn so as to represent these values at all points throughout the length of a beam or girder, and such diagrams can always be used when setting out some preliminary or trial design, or checking a design; when carefully and accurately drawn they can be utilised directly in designing all ordinary structures, thus saving a large amount of time and labour which would be necessary if all required values were calculated arithmetically. Since these diagrams show the variations in stress throughout the beam, they can be further utilised to set out the sections or scantlings of the web and flange members, such as the thickness of the web or shear resisting members, and the cut-off in the flange plates or bending resisting members.

The tables of bending moments and shearing stresses given on pages 216 and 217 embrace all simple conditions for concentrated or uniformly distributed loads. Any complex loading occurring in practice can always be resolved into a series of simple loadings; so that diagrams for each simple loading can be drawn on one base line, and these diagrams combined to produce the required diagram for the complex loading, by adding together the several ordinates at any desired section. An example of this is given in fig. 2.

It should be noted that for any series of concentrated loads the bending moment line will form a polygon, the line changing its direction over each of the loaded points; at each of these points the shearing stress is suddenly changed in value, and the shearing stress diagram takes a stepped outline. For a uniformly distributed load, the bending moment line is always a parabolic curve, while the shearing stress changes by a regular gradation.

When beams or girders are of varying depth, the diagrams on pages 216 and 217, which are based on the condition of uniform depth, must be adjusted, for the following reason :—By formula (3) it will be obvious that the flange stresses are dependent on the depth, and, in fact, *vary inversely as this depth*; it is, therefore, necessary to alter the bending moment heights in the *inverse ratio to the alteration in depth of the beam.* Reducing the depth of a beam increases the extreme fibre stress, and necessitates the increasing of the height of the bending moment diagram. Fig. 3 and the brief explanation accompanying it will indicate how this adjustment can be readily carried out.

Where the shearing stress diagram is intended to be used in setting out the varying thickness of the web plate of a beam, the shear stress diagram must similarly be adjusted by altering its heights in *inverse ratio to the alteration in depth of the beam*; a shallower girder necessitates a thicker web, when the shear value remains unaltered (see fig. 3).

When these graphic diagrams on pages 216 and 217 are used in connection with panel or lattice girders, a modification is necessary, since the flange stress remains constant between the points of connection of flange to lattice bars; the diagram becomes stepped in outline and may not be the same in both flanges (see fig. 4).

For the majority of the simple panel or lattice girders met with in practice, the various stresses can be most readily obtained by the reciprocal diagram method or by the method of moments.

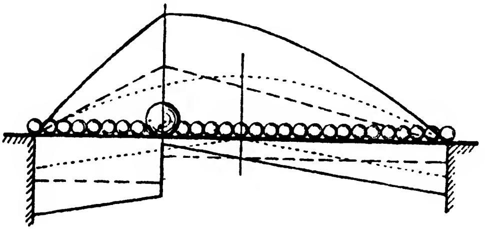

Fig. 2.

This example shows a free-ended beam supporting a uniformly distributed load (see Table 1, type (d)), the bending moment and shearing stress diagrams being indicated by dotted lines; and a single concentrated load (see Table 1, type (e)), the two diagrams being here indicated by broken lines. The combined diagrams for these two loads are shown by full lines, and are got by adding together the two heights at any section, to obtain the new height there.

In some cases, as for girders with fixed ends, negative moments may occur, and these must obviously be added algebraically to the positive moments to obtain the required new combined height.

This figure shows the adjustment of the bending moment and shearing stress diagrams due to a change in the depth of the girder, and a simple graphic method of arriving at this adjustment. The left half of fig. 3 shows diagrams for a free-ended girder of uniform depth carrying a uniformly distributed load (Table 1, type (d)); in the right half of the figure the depth of the girder is reduced as indicated. From the centre to the first section line the depth is uniform, so that the bending moment line remains unaltered, but beyond this section the *height of diagram must be increased in proportion to the reduction in depth of the girder*. This increase can be obtained graphically thus: — Take the vertical section line at point *a*, and draw any line *ab*; on this line mark off *ab* equal to the centre depth of the girder, and *ac* equal to the reduced depth at this section: join *cd* (*d* being at the point of intersection of original diagram line and section line), and draw *be* parallel to *cd* and cutting the section line at *e*. It is obvious that the new vertical heights *ae* and *ad* are proportionate to the original depth and the reduced depth of the girder, or to the lengths *ab* and *ac*, and consequently the adjusted bending moment diagram must pass through the new point *e*. Repeating this operation at a number of other sections will give a series of new points through which the complete adjusted diagram can be drawn.

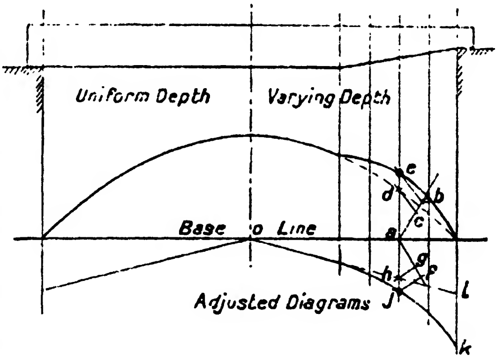

Fig. 3.

Similarly if the shear diagram is to be used for determining the thickness of web plate required, *its depth must first be increased in proportion to the reduction in depth of the girder*, since the sectional area of the web plate is directly proportionate to its depth. Graphically the same operation as above explained can be followed, marking off on the line *af* the lengths *af* and *ag* equal to the centre and reduced depths of the girder, drawing the lines *gh* and *fj* parallel to one another, and deepening the diagram at this section line to the point *j*. The complete adjusted diagram would take the form of the curved line *ojk*.

In determining the stresses on the several members of a lattice girder such as that outlined

in fig. 4, it is assumed that at the junctions between the several members the connections will allow of free movement, as if pin jointed: thus the flanges are assumed as hinged at each junction with the lattices, and no allowance is made for the stiffness due to their being actually formed in one piece.

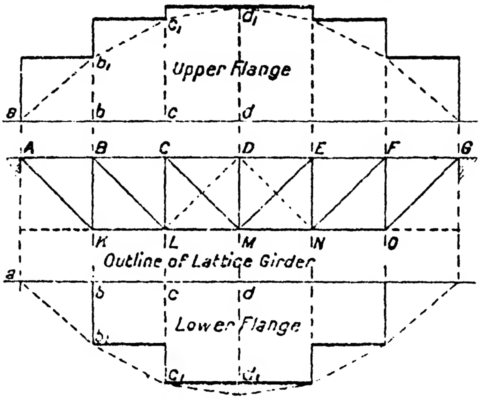

FIG. 4.

This girder rests on abutments at its ends AG, and is loaded at the points BCDEF, say by means of cross girders resting on and fixed to the top flange.

Considering first the load at centre point D, the upper flange does not support it, but the load passes downwards through the vertical strut DM, and is carried by the two inclined ties MC, ME. At the upper ends of these ties the tension due to load at D becomes resolved into compression stress between CE in top flange and compression stress in CL and EN, to which latter stresses must be added a further compression due to loads at points C and E. This transfer of stress is continued to the ends of the girder A and G, the final compression stresses at each end being equal to half the total load, and acting on the bearings at the abutments.

The dotted lines on upper and lower diagrams indicate the bending moment diagrams, and the full lines touching the same show the adjustments necessary owing to the breakage up of flanges and web into a series of members jointed together. The above referred to adjustment is made as follows:—The bending moment diagrams are divided up into sections to correspond with the number of bays in the girder, and as the stress in any section of top or bottom flange must be uniform from joint to joint, the several lines in the diagrams representing the stresses must be parallel to the base line of the diagram throughout the lengths between the joints or junctions between flanges and lattices, all variations in stress taking place suddenly, and being represented by vertical lines in diagram. The stress in the portion AB of upper flange is determined from the moment at point B, and is equal to *bb*; at BC it is equal to *cc*; and at centre portion CDE it is equal to *dd*. Similarly in the lower flange, since the girder is complete without any members extending from K or O to the abutments (as dotted lines), the first stressed bar in lower flange is KL, the amount of stress being determined from height *bb*; the centre portion LMN having its stress determined by the height *cc*; the stress in the two inclined members CM and EM being equal—on the assumption of equal loads at all upper flange joints—must balance one another, and consequently do not affect the lower flange stress at centre.

Influence Value Tables.

It has already been pointed out on page 212 that the several bending moment diagrams given on pages 216 and 217 may be combined to produce one diagram for a series of different loadings.

The same result may be readily obtained, particularly where the value at one particular section is desired, by calculating the bending moment value at that section for each loading and adding the several values together. This process can be much simplified by the use of the tables on pages 218–219, where the value is given of the effect or influence at a series of other points or sections throughout the length of the beam, of a concentrated load applied at certain points. These values are for a load of unit value for a beam of unit length, and for a beam with free ends, with one end fixed, and with both ends fixed; and reactions and inflection points are also noted. The brief notes accompanying the tables will explain their application.

INTERNAL STRESSES.

The tendency of a beam to shear, or to deflect, under any system of loading, is opposed by the resistance of the material of which the beam is composed to shearing, or to tension or compression.

It is the general practice to consider the flanges as resisting the bending moment stresses, the web providing the required shear resistance only.

Considering in the first instance the flange stresses, it is evident, if failure is not to occur, that the moment of resistance at all points in every beam or girder must oppose and balance the bending moment there; this resistance moment is the sum of the moments of all the fibre resistances reckoned about the neutral axis. In a beam of ordinary section the resisting fibres lie at various distances from the neutral axis (owing to the thickness of the flanges); but the simplest case is that of a girder with flanges whose thickness is small in comparison to the depth of the girder, so that without material error all the fibres of one flange may be considered to be practically at one distance from the neutral axis. Thus if d = vertical depth of girder between centres of gravity of the two flanges, M = bending moment due to the external loads, we have the general formula,

$$\pm F = \frac{M}{d} \qquad (3)$$

F being the horizontal stress in either of the two flanges, being compressive stress in the one and tensile strength in the other.

Where the flanges of a girder are of considerable thickness, in comparison with the depth of the girder, or the beam is of a non-symmetrical or irregular cross-section, the fibres of either flange cannot be considered as practically at one distance from the neutral axis, and it is necessary to take into account the varying distances of the fibres from the neutral axis, in the following manner:—

Under the action of any transverse bending, the intensity of the tensile and compressive stresses varies in different fibres of the beam, being greatest in the extreme fibres at the top and the bottom of the cross-section, while the fibre-stress will be zero at the 'neutral axis.'

Whatever may be the figure of the beam's cross-section, the neutral axis will be a horizontal line drawn through its centre of gravity; and the intensity of the stress in any fibre will be proportional to the vertical distance y of the fibre above or below the neutral axis.

If a denotes the sectional area of any thin layer of fibres lying at the height y above the axis, the total stress in that layer will be proportional to ay, and its moment about the neutral axis will be proportional to $ay \times y = ay^2$. The summation of the quantities ay^2 for the different layers is the so-called 'moment of inertia' of the beam, or

$$I = \Sigma\,(ay^2) \qquad (4)$$

When the bending moment, M, due to the external forces has been found in the manner already described, the problem will often be to find the maximum stress per square inch, f, in the extreme layer of fibres; and if y denotes the vertical distance of that layer from the neutral axis, we have

$$f = \frac{My}{I} \qquad (5)$$

Where the section of the beam is symmetrical about the neutral axis, as in rolled joists y = half the vertical depth of the beam between centres of gravity of the two flanges, or $\frac{1}{2}d$, and for such sections the above formula may be written.

$$f = \frac{Md}{2I} \qquad (6)$$

In the case of cast iron, whose strength in compression is much greater than in tension, the tension flange should be made considerably larger than the compression flange. In rolled steel joists the two flanges are made of equal area, and an approximate value for the moment of resistance may be readily found by adding to the actual area of each flange $\frac{1}{6}$th of the area of the web, and then reckoning the depth d as the depth between the centres of gravity of the two flanges; then with A = area of one flange and $\frac{1}{6}$th web, and F = max. safe stress on steel,

$$\text{Approx. resistance moment} = A \times F \times d \qquad (7)$$

When the thickness of the web is small in comparison with the width of the flanges, the extreme tensile strength, f, under the breaking load, as determined by formula (5), corresponds nearly with the ultimate tensile strength of the material; but should the girder have a very substantial web, or should the section be that of a solid rectangle, the calculated breaking load will generally be found to be lower than the actual breaking load. For such cases see formula on page 222.

TABLE I.—BENDING MOMENTS, SHEARING STRESSES, AND DEFLECTION OF STEEL GIRDERS. Graphic Diagrams and Formulæ.

Type.	Formulæ. Bending Moment.	Shearing Stress.	Maximum Deflection.
(a) 	$M = WL$	$S = W$	$\frac{WL^3}{3EI}$
(b) 	$M = \frac{WL}{2}$	$S = W$	$\frac{WL^3}{8EI}$
(c) 	$M = \frac{WL}{4}$	$S = \frac{W}{2}$	$\frac{WL^3}{48EI}$
(d) 	$M = \frac{WL}{8}$	$S = \frac{W}{2}$	$\frac{WL^3}{76{\cdot}8EI}$
(e) 	$M = \frac{Wxy}{L}$	$S_1 = \frac{Wy}{L}$ $S_2 = \frac{Wx}{L}$	$\frac{Wxy(2L-x)}{27EIL} \times \sqrt{3x(2L-x)}$
(f) 	$M = \frac{Wx}{2}$	$S = \frac{W}{2}$	$\frac{Wx(3L^2-4x^2)}{48EI}$
(g) 	$M_1 = \frac{WL}{4}$ $M_2 = \frac{WL}{8}$	$S = \frac{W}{2}$	$\frac{WL^3}{192EI}$

TABLE II.—BENDING MOMENTS, SHEARING STRESSES, AND DEFLECTIONS—*contd.*

Type.	Formulæ.		
	Bending Moment.	Shearing Stress.	Maximum Deflection.

These tables are calculated for a unit load, and for a girder of unit length; the length of the girder is divided into 20 equal sections and the bending moment values are given at each section point for unit load placed on each section line in turn. For any weight and any length of span it is necessary only to multiply the proper tabular coefficient by the number of units in the load and in the span to obtain the actual

(*Continued on p.* 219.)

TABLE IV.—INFLUENCE VALUE

BEAM FIXED AT RIGHT END.

bending moment value desired. Thus for a load of 2 tons on a girder of 20 feet span the tabular values multiplied by 2 × 20 will give the actual values in foot tons.

Taking the above load and span, and a free-ended girders, with load at ¼th span (or line ·25) the bending moment under the load and at centre of span will be respectively (·187 × 2 × 20) 7·48 and (·125 × 2 × 20) 5 foot-tons respectively. For a girder fixed at one end the corresponding values will be (·158 × 2 × 20) 6·32 and (·066 × 2 × 20) 2·64 foot-tons respectively.

·95	·002	·002	·002	·001	·001	·001	·000	·000	·000	·001	·001	·002	·002	·002	·003	·003	·003	·004	·004	·004	·045	·007	·993	·333	·045

In some cases the values are only approximate, since the tabular values give 3 decimal figures only: for example, in the first calculation the full tabular value would be ·1875, and the accurate result 7·5 foot-tons. The values for a load distributed over a part or the whole of the span may be obtained approximately by assuming the total load as formed of a number of equal loads placed at adjoining section points; the result here would generally be near enough to the true value for all practical purposes.

TABLE VI.—MOMENTS OF INERTIA, SECTIONAL AREA, ETC., FOR VARIOUS SIMPLE SECTIONS.

Section.	Area.	Neutral Axis.	Moment of Inertia.
(a) 	$\frac{\pi D^2}{4}$ $\pi = 3{\cdot}1416$	Through centre	$\frac{\pi D^4}{64}$
(b) 	$\frac{\pi(D^2 - d^2)}{4}$	Through centre	$\frac{\pi(D^4 - d^4)}{64}$
(c) 	D^2	Through centre	$\frac{D^4}{12}$
(d) 	D^2	Through centre $y = \frac{D}{1{\cdot}4142}$	$\frac{D^4}{12}$
(e) 	BD	Through centre	$\frac{BD^3}{12}$
(f) 	$BD - bd$	Through centre, parallel to B Through centre, parallel to D	$\frac{BD^3 - bd^3}{12}$ $\frac{DB^3 - db^3}{12}$
	$\frac{BD}{2}$	$y = \frac{2}{3}D$ Through Base Line, through Apex, and parallel to Base	$\frac{BD^3}{36}$ $\frac{BD^3}{12}$ $\frac{BD^3}{4}$
(h) 	$B(D - d)$	Through centre and parallel to B	$\frac{B(D^3 - d^3)}{12}$

The value for the moment of inertia for the standard steel sections of rolled joists, angles, tees, etc., can be got from British Standards Nos. 4 and 4A.

The value for the moment of inertia about any other axis parallel to and at a distance y. from the neutral axis = I for neutral axis + (area × y^2) . . . . . . (8)

The value for the radius of gyration is $R = \sqrt{\frac{I}{\text{Area}}}$ . . . . (9)

Solid Rectangular Beams.

Where the strength can be shown to vary directly as the breadth of the beam and as the square of the depth, it is better, simpler, and more direct to calculate the strength by means of coefficients derived from direct experiments in cross-breaking; thus

$$\text{Breaking load in tons} = \frac{\text{Breadth in inches} \times \text{depth in inches}^2}{\text{Span in inches}} \times c \times k \qquad (10)$$

TABLE VII.

Material.	Coeff. c.	Ends of Beams.	Coeff. k.
Mild Steel	3·50	One fixed, other end loaded	1
Cast Iron	2·30	,, ,, load distributed	1
Fir (Spruce)	0·60	Both supported, load in centre	4
English Oak	0·75	,, ,, ,, distributed	8
Red Pine	0·65	Both fixed, ,, in centre	6
Yellow Pine	0·50	,, ,, ,, distributed	12
Pitch Pine	0·75		

The factor of safety for steel may be ¼th to ⅙th breaking load; for the other materials it may vary between ⅛th and 1/10th breaking load. If the beam carries a heavy live load the safe load should be further reduced.

TABLE VIII.—BENDING STRESSES.

In tons per sq. in.

British Standards 449—1948, for the Use of Structural Steel in Building.*

Mild Steel B.S. 15.	High Tensile Steel. B.S. 548 Up to 1½ in. thick.	B.S. 548 Over 1½ in. thick.	B.S. 968. Up to 1 in. thick.	B.S. 968. Over 1 in. thick.	Other Steels.
In tension: Beams					
10	15	13	13·5	12·25	$0{\cdot}65\,f_y$†
	Plate girders				
10	14·25	12·25	12·75	11·5	$0{\cdot}65\,f_y$†

In compression: the above values or $1{,}000K_1 \div l/r$ tons per sq. in., whichever is the lesser, where l is the length between effective lateral restraints, r is the radius of gyration of the section perpendicular to the plane of bending, and K_1 is a factor taken as unity except for rolled steel joists, compounds and plate girders, symmetrical about both principal axes and subject to bending about xx axis. For these the value of K_1 shall be :—

r_{xx}/r_{yy}	5·0	4·5	4·0	3·5	3·0 or less
K_1	1	1·125	1·25	1·375	1·5

There are special clauses dealing with cased beams and encased filler beams.

SHEAR STRESS IN WEBS.

The average sheer stress on the gross cross section of the web shall not exceed the lesser of (1) and (2) below for unstiffened webs, and of (1) and (3) below for stiffened webs.

(1) 6·5 tons per sq. in. for steel to British Standard 15.
9 tons per sq. in. for steel to British Standard 548 up to and including 1½ in. thick.
8 tons per sq. in. for steel to British Standard 548 over 1½ in. thick.
9 tons per sq. in. for steel to British Standard 968 up to and including 1 in. thick.
8 tons per sq. in. for steel to British Standard 968 over 1 in. thick.
$0{\cdot}42\,f_y$ for other steels, where fy is the guaranteed yield stress in tons per sq. in.

* By permission of the British Standards Institution.

† f_y is the guaranteed yield stress in tons per sq. in.

(2) $\left(\frac{225}{d/t}\right)^2$ tons per sq. in. for unstiffened webs, where d is the clear distance between flange angles, or where there are no flange angles, the clear distance between flanges, and t is the thickness of the web.

(3) $\left(\frac{225}{b/t}\right)^2\left[1+\frac{3}{4}\left(\frac{b}{a}\right)^2\right]$ tons per sq. in. for effectively stiffened webs, where a is the greater unsupported dimension of web in a panel, b is the least unsupported dimension of web in a panel and t is the thickness of the web.

PERMISSIBLE STRESSES IN RIVETS AND BOLTS.

In tons per sq. in.

	Steel to B.S. 15.	H.T. Steel to B.S. 548.
In tension—		
Axial stress on gross area of rivets and net area of bolts:		
Shop-driven rivets	5	7·5
Field-driven rivets	4	6
Bolts $\frac{3}{4}$ in. and over in diameter	6	9
Bolts less than $\frac{3}{4}$ in. diameter	5	7·5
In shear—		
Shear-stress on grass area of rivets and bolts:		
Shop-driven rivets	6	9
Field-driven rivets	5	7·5
Turned and fitted bolts	6	9
Black bolts	4	6
In bearing—		
Bearing stress on gross diameter of rivets and bolts:		
Shop-driven rivets	12	18
Field-driven rivets	10	15
Turned and fitted bolts	12	18
Black bolts	8	12

Permissible bearing stress for high tensile steel to B.S. 968: 18 tons per sq. in.

DEFLECTION OF BEAMS.

Deflection formulæ for various arrangements of loading are given in Tables I. and II., pp. 216 and 217. For structural steel the value of E (the modulus of elasticity) may be taken at 30,000,000 lbs. and the value of W must then be expressed in lbs. also.

CONTINUOUS BEAMS OR GIRDERS.

When a beam is carried upon more than two supports the reactions of the several supports cannot be directly determined, and, in consequence, the bending stresses can only be found by reference to the changes of form which must always accompany those stresses, and which are fixed or limited at certain points by the conditions of the structure—conditions which vary in each case with the width and the number of spans, as well as with the disposition of the load.

When the beams are of uniform section, such as rolled steel joists or rectangular timber beams, the strength or load which may be safely carried will depend on the greatest bending moment of *either kind* which occurs throughout the whole length of the bridge, and the advantage of a continuous beam to cover a number of spans will depend on the number and spacing of the supports. In cases where all the spans are of uniform length, and the load is uniformly distributed throughout, the maximum bending moment values for varying numbers of spans can be found in many text-books.

For the General Problem, however, where the spans are of different lengths and the loads vary, the determination of the stresses in continuous beams is a very complex one. The easiest solution is to be found in the Graphic Method, generally known as the 'Method of Characteristic Points,' described by Professor Fidler in a paper read before the Inst. C.E. (*Proc.*, vol. lxxiv.), and treated in detail in Fidler's 'Bridge Construction.'

Before proceeding to determine graphically the stresses in a continuous beam, it is necessary to find the Characteristic Points, and the following examples will illustrate how these points can be fixed for any bending moment diagram for a free-ended single span beam.

In fig. 5, AB represents the span, and the parabola ACB the bending moment diagram due to a uniformly distributed load. Divide the span into three equal parts, AE, EF, and FB, and at points E and F erect perpendiculars EJ and FK. The height of the points J and K (which lie on the line GH) above the base line is fixed by the condition that *the moment of the area ACB about one end of the span shall equal the moment of the rectangle AGHB about the same point*. This

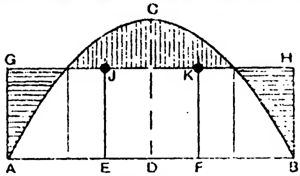

FIG. 5.

diagram being symmetrical about the vertical centre line, the centre of gravity of these two areas will fall on this centre line, and the moment arm for each area will be equal to ½ AB, or one-half span.

In this case of the *parabolic B.M. diagram*.

$$\text{Area } ACB = \tfrac{2}{3}\, CD \times AB, \text{ and area } AGHB = AG \times AB$$
$$\therefore EJ = FK = \tfrac{2}{3}\, CD.$$

The Characteristic Points for a uniformly distributed load, therefore, occur at a height equal to ⅔ the central height of the parabola.

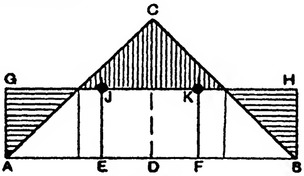

FIG. 6.

Fig. 6 shows the diagram for a *concentrated central load*, represented by the B.M. diagram ACB, and by the same reasoning as for a distributed load, the height EJ and FK will now be equal to ½ the central height CD.

FIG. 7.

Fig. 7 shows another symmetrical case where two equal concentrated loads are placed at the same distance from the centre line; here again the same reasoning as before is adopted. Assuming a span AB = 20 ft., with the two equal loads of 6 tons at 4 ft. from ends A and B. BM = 6 × 4 = 24 ft.-tons = scale height for CL and DM. Then moment of area ACDB about A = AM × MD = 16 × 24 = 384, and height of an equal rectangle AGBH = $\frac{384}{20}$ = 19·2 = EJ and FK.

Where the *B.M. diagram is not symmetrical about the centre vertical line*, the two Characteristic Points, although still situated on the two perpendicular lines at ⅓ AB from each end, *are not now at the same height above the base line*, since the moment of a non-symmetrical B.M. diagram will not be the same about the ends A and B.

For example, fig. 8 shows a beam, say, 30 ft. long with a load at D of, say, 10 tons placed at a distance of 8 ft. from B. The upward reaction at end A = $\frac{8}{30}$ of 8 tons = 2·13 tons, and the height DC of B.M. diagram ACB = 2·13 × 22 = 46·9 ft.-tons. Draw a line from the centre point

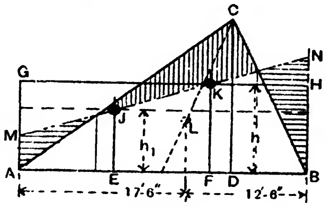

Fig. 8.

of AB to O, and set off OL = ⅓ of the total length, then L is the centre of gravity of the B.M. diagram AOB. The moment of the area AOB will be greater about end A, thus h (= height of rectangle to balance the greater moment) will be found thus:—

$$\text{Area AOB} \times 17\cdot5 = h \times 30 \times 15.$$

or, $$\frac{30 \times 46\cdot9}{2} \times 17\cdot5 = h \times 450$$

$$\therefore\ h = \frac{704 \times 17\cdot5}{450} = 27\cdot4,$$

and similarly about B,

$$\text{Area AOB} \times 12\cdot5 = h \times 30 \times 15;$$

$$\therefore\ h = 19\cdot6.$$

These values, therefore, give the relative heights of the Characteristic Points K and J.

This method of locating the Characteristic Point is applicable for any condition of loading, as it is only necessary to set up the combined B.M. diagram for any desired combination of loads, calculate the area, and the positive of the centre of gravity of this combined diagram, and proceed as indicated to calculate the height of the Characteristic Points, noting that two calculations will be required if the B.M. diagram is not symmetrical about the vertical centre line.

In the case of any Bending Moment Diagram for a simple free-ended beam, the bending stress at any point in its length is proportionate to the vertical height at the required point, measured from the original base or datum line AB, *and Characteristic Points are unnecessary*. Should the beam be rigidly fixed at the ends, use must be made of the new base or datum line found by drawing a line through the Characteristic Points and scaling the required bending moment values from this new line (marked GH in figs. 5–7, and MN in fig. 8). The positive B.M. stresses (in the middle portions of the beam) are measured *upwards* from the new base line to that of the B.M. diagram, while the *negative* stresses are measured downwards. The B.M. is zero at the contraflexure points, where the bending stresses change from positive to negative. Thus theoretically each span consists of two end cantilevers supporting a hinged or free-ended beam, it being obvious that at the points where the bending *directions* change, the bending stress must be zero. (*Note.*—The bending stress in the end portions are generally termed negative stresses and represented thus −, while the centre portions are positive stresses and represented thus +. In the diagram, negative stressed portions are indicated by horizontal line shading, and positive stressed portions by vertical shading.)

Bending Moment for Continuous Girders.

If the rigid fixing at either end of a beam is altered or interfered with, the alteration in bending stresses which then follows throughout the length of the beam can be represented by an alteration in the position of the straight base line, so that it would pass above or below the Characteristic Points. When a continuous length of beam is carried over two or more spans, this interference occurs at the points of support between the several spans, and Fidler's method enables the effect of this interference to be graphically represented in the following manner: see fig. 9, which represents a four-span continuous bridge carrying a distributed load; the B.M. diagrams in this case take the form of a parabola. For any other form of loading the suitable diagram must be used.

Calculate the bending moment for each span separately as for a free-ended beam, draw the corresponding diagram for each span on the base line AB, and set off the Characteristic Points, as previously explained, marking these points 1 to 8 as shown. If the outer ends of end spans,

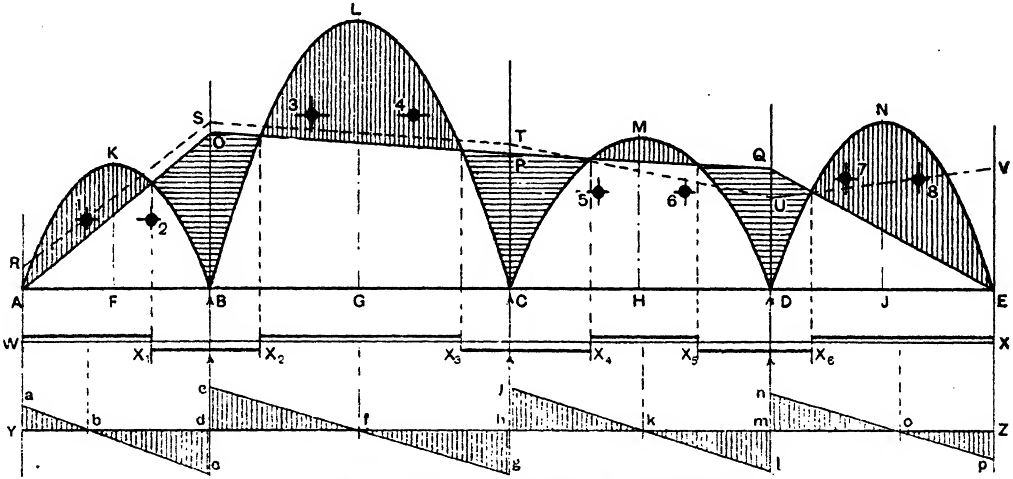

FIG. 9.—Four-Span Continuous Bridge carrying a Distributed Load.

If this bridge is designed so that the outer ends of the end spans are rigidly fixed, the new base line must pass through the two extreme Characteristic Points 1 and 8, and the new line will take the form indicated by the line RSTUV, the heights AR and EV indicating the maximum amount of negative bending moment at the extreme end points.

These diagrams should be drawn out to as large a scale as possible, and it will facilitate the fixing of the irregular base or datum line if tracing paper is first placed over the bending moment layout, and the necessary trial lines pencilled on same, the correct setting out, when found, being pricked through to the diagram below.

THERE IS ONLY ONE SERIES OF BROKEN LINES WHICH WILL FULFIL THE CONDITIONS REQUIRED IN ANY ONE CASE, and some difficulty may at first be experienced in drawing this line.

at A and E, rest freely on the supports, the two end Characteristic Points 1 and 8 are disregarded. The problem now is to draw a series of straight lines, AO, OP, PQ, and QE, but *these lines must be so placed that they pass above and below, or below and above the Characteristic Points on either side of the vertical lines over the supports B, C, and D, at distances inversely proportionate to the adjoining spans*; for instance, in fig. 9 the distance of the line AO above point 2 should be greater than that of the line OP under point 3 in the proportion of the lengths BO to AB. These conditions are carried to the end, points 4 and 5 being at proportionate distances above and below, and points 6 and 7 below and above the broken line, which finally must end at E. This broken line, AOPQE, will now represent the new base line from which the positive or negative bending moment values for any point in the bridge can be scaled off. As in the simpler diagrams previously given, the portions subjected to positive bending are shown by vertical shading, and negative bending by horizontal shading.

The sketch diagram WX (p. 226) indicates graphically the system or combination of simple beams and cantilevers into which a continuous beam over several supports may be divided.

The sketch diagram YZ gives a graphic representation of the shears and reactions: the reaction is always equal to the shear. The shear at the points of maximum bending becomes zero, or passes from positive (+) above the base line, to negative (—) below the base line at these points.

The shear and reaction can be readily calculated from a consideration of diagram WX.

Shear at A (+) = reaction as from a free-ended beam WX; this value is set up on line YZ, at Y*a*, shear left of B (—) = total load on span less left reaction (set off *dc* on line YZ). Shear on right of B (+) = load on cantilever X_1, X_2, plus half-load on suspended span X2, X3 (set up *de* on line YZ). Reaction on support B = sum of above (—) and (+) shears. By the same reasoning, the remaining shears and reactions can be determined. Draw lines connecting the points *ac*, *eg*, *jl*, and *np*, to complete the shear diagram; and note that the shear zero points *b*, *f*, *k*, and *o*, should occur at the centres of the imaginary beams in diagram WX.

COLUMNS AND STRUTS.

BRITISH STANDARD 449—1948, FOR THE USE OF STRUCTURAL STEEL IN BUILDING.*

Effective Length of Struts.

Effective Length.—The effective length (*l*) of a compression member for the purpose of determining allowable axial stress shall be completed as follows:—

Where both ends are held in position and restrained in direction, 0·7 of the actual length.

Where both ends are held in position and one end restrained in direction, 0·85 of the actual length.

Where both ends are held in position but unrestrained in direction, the actual length.

Where one end is held in position and restrained in direction and the other end is partially restrained in direction but not held in position, 1·5 times the actual length.

Where one end is effectively held in position and restrained in direction and the other end is not held in position or restrained in direction, twice the actual length.

The effective lengths of stanchions relative to end and beam connections are illustrated in fifteen pages of drawings, the effective length and slenderness ratio for design being indicated in each case.

Maximum Slenderness Ratio of Struts.

The ratio of effective length to the appropriate radius of gyration shall not exceed the following values:

(*a*) For any member carrying loads resulting from dead weights and superimposed loads: 180.

(*b*) For any member carrying loads resulting from wind forces only, provided the deformation of such member does not adversely affect the stress in any part of the structure: 250.

(*c*) For any member, normally acting as a tie in a roof truss but subject to possible reversal of stress resulting from the action of wind: 350.

There are separate tables for the permissible working stresses for discontinuous angle struts, both for single bolted or single riveted end connections and for double bolted, double riveted or welded end connections.

There are special clauses, also, relating to cased struts.

---

ECCENTRICITY FOR STANCHIONS AND SOLID COLUMNS.

The assumed eccentricity of loads on stanchions and solid columns shall be:

(i) At the mid point of stiffened seating of a stiffened bracket.
(ii) At the outer face of vertical leg of an unstiffened bracket.
(iii) At face of strut in the case of cleat connections to web of beam.
(iv) *a.* At the mid point of cap bearing continuous beams of approximately equal span and load.
b. At the edge of stanchion towards span of beam in the other cases, excepting roof truss bearings.
c. No eccentricity for simple roof truss bearings without connections capable of developing an appreciable moment.

Axial Stresses in Tension.

The direct stress in pure tension on the net area of the section in tons per sq. in. shall not exceed the following values:

Mild Steel to B.S. 15.	H.T. Steel to B.S. 548. Up to 1½ in. in Thickness or Diam.	H.T. Steel to B.S. 548. Over 1½ in.	H.T. Steel to B.S. 968. Up to 1 in. in Thickness or Diam.	H.T. Steel to B.S. 968. Over 1 in.	Other Steels.
9	13·5	11·5	12·5	11	$0{\cdot}59 f_y$

where f_y is the guaranteed yield stress in tons per sq. in.

Combined Stresses.

Bending and axial compression.—Members subject to both axial compression and bending stresses shall be so proportioned that the quantity

$$\frac{f_a}{F_a} + \frac{f_{bc}}{F_{bc}}$$

does not exceed unity,

where f_a = the axial compressive stress.
F_a = the permissible compressive stress in axially loaded struts.
f_{bc} = the sum of the compressive stresses due to bending about both rectangular axes.
F_{bc} = the minimum permissible compressive stress for members subject to bending.

Bending and axial tension.—Members subject to both axial tension and bending stress shall be so proportioned that the quantity

$$\frac{f_t}{F_t} + \frac{f_{bt}}{F_{bt}}$$

does not exceed unity,

where f_t = the axial tensile stress.
F_t = the permissible axial tensile stress.
f_{bt} = the maximum tensile stress due to bending about both principal axes.
F_{bt} = the permissible tensile stress in bending.

Permissible Stresses in Welds.

There are special clauses relating to the permissible stresses in welds for mild steel and for high tensile steel.

Stresses due to Wind Forces.

The working loads and stresses per sq. in. specified for beams, pillars, and all their connections in B.S. 449, as computed for all loads and forces other than wind pressure may be increased by 25 per cent. in cases where such increase is solely due to stresses induced by wind pressure.

Riveted Joints in Girderwork.

The riveted joint of a tension-member may fail either by the tearing of the plate, or the shearing of the rivets, or in some special cases by the crippling of the bearing area between plate and shank of rivet.

The tearing of the plates is resisted by the tensile strength of the plate per square inch of area taken over the *net effective section* between rivet holes. When the assumed line of fracture is at right angles to the direction of the pull, the sectional area measured on this line between the rivet-holes is the net effective section. But when the line of fracture may follow a zigzag or inclined direction, the effective sectional area should be taken at about three-fourths of the area measured on such a line. The fraction is not universally applicable, but will generally meet the case of ordinary zigzag riveting.

The shearing of the rivets is resisted by the shearing strength of the rivet-material per square inch of area taken over the effective section of the rivets engaged. Assuming all the rivets to take an equal share in the work, the number of rivets engaged in resisting the total pull upon the tie will be the whole number of rivets in the case of a lap-joint such as that shown in figs. 13 and 14; while in the case of a butt joint, such as No. 2 of fig. 15, it will consist only of the rivets employed on either side of the joint. But in any large assemblage of rivets allowance should be made for unequal distribution of the work when calculating the number of rivets required for a joint.

For rivets in 'single shear,' as in the case of lap joints, and in butt joints covered by a single cover-plate, the effective section of each rivet is simply the area of its cross-section. But wherever practicable double cover-plates should be employed, placing the rivets in 'double shear,' and in this case the effective section of each rivet should be reckoned at $1\frac{3}{4}$ times the sectional area of the rivet.

In wrought-iron work the shearing strength of good rivet iron per square inch is fully equal to the tensile strength of the plates; and the effective rivet section is often made equal to the effective plate section, an allowance of 10 per cent. being sometimes added in the case of large joints.

The shearing strength of steel rivets may be taken at 24 tons per square inch, while the plates have often a tensile strength of 26 to 32 tons; and the rivet section will generally require to be somewhat greater than the plate section.

The 'efficiency' of a riveted joint is the ratio between its strength at the weakest part and the strength of the unperforated plate.

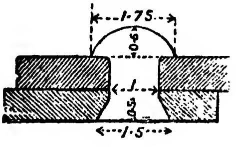
RIVETS AND RIVETING.

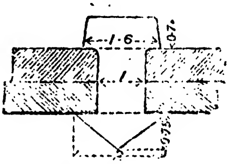
Rivets.

The heads (fig. 10) are usually either snap or pan. Snap heads are used generally in machine riveting. The points are countersunk, conical, or snap; the former are largely employed in iron shipbuilding, where a flush surface is required, the latter in ordinary boiler and bridge work. Conical, also called *staff* or *hammered*, points are chiefly used where the restricted space only allows of hammering.

The following figures give ordinary proportions of rivet heads in terms of diameter of shank.

SNAP HEAD. PAN HEAD.





Countersunk point. FIG. 10. Conical point.

If d = diameter of shank of rivet,

Length allowed for forming pan head				= 2 to $2\frac{1}{4}d$;
"	"	"	snap head	= $1\frac{1}{2}d$.
"	"	"	countersunk head	= $1d$.
"	"	"	conical head	= $1\frac{1}{4}d$.

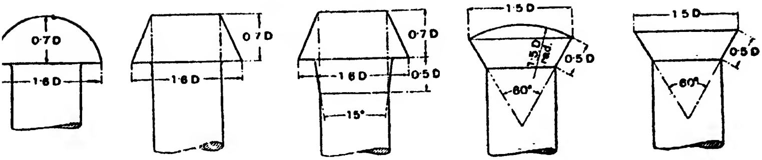
When a conical form is given under the rivet head an additional length of about $\frac{1}{8}''$ is usually allowed in making the rivet.

BRITISH STANDARD SPECIFICATION FOR DIMENSIONS OF RIVETS.*

(½ Inch to 1¾ Inch Diameter.)

(No. 275—1927.) (*Abstract.*)

(This Specification does not apply to Boiler Rivets.)



Snap Head. Pan Head. Pan Head with Tapered Neck. Rounded Countersunk Head. Flat Countersunk Head.

FIG. 11.

D = Nominal diameter of rivet.

Diameter of Rivets or Rivet Holes.

d = diameter of rivet hole ; t = thickness of thickest plate.

Fairbairn's Rule, commonly used { When t is less than ½", $d = 2t$. When t is equal to, or greater than, ½", $d = 1\frac{1}{2}t$

With rivets so proportioned the total number in single shear, such as lap, single cover and grouped, joints will, when the resistance to shearing is taken at 4 tons and bearing at 5 tons, depend on the number required for shearing, in ½" plates and over ½", and for bearing with plates under ½" thick.

When more than 2 plates, besides the covers, are riveted together, as in flanges of girders, some engineers add $\frac{1}{16}$ to d for each extra plate.

Unwin's Rule for Rivets : $d = 1 \cdot 2\sqrt{t}$.

Rivets of more than 1½" diameter are rarely used.

The rivet holes are made about $\frac{1}{16}$" larger than the rivets, to allow for expansion when heated. For ordinary work the proportions of diameter of punch to that of bolster hole in the die varies from 1 : 1·15 to 1 : 1·2 ; the greater the difference, the less cleanly cut will the burr be, but the metal round the hole will be stronger, being less reduced and more compressed. The hole when punched is slightly conical.

It is hardly practicable to temper a punch so as to punch a great number of holes if it is of less diameter than the thickness of the plate, or even with a diameter of equal thickness. Punched holes should never be less than 1½ diameter apart or from edge to plate. For drilled holes the limit may be 1 diameter.

Pitch of rivets = distance from centre to centre of rivet. *Longitudinal pitch* = pitch in direction of stress. *Transverse pitch* = pitch at right angles to stress. *Zigzag pitch* = minimum pitch when placed zig-zag ; this should slightly exceed the transverse pitch. *A pitch line* is a straight line running through the centres of a longitudinal or transverse row.

Minimum pitch = 2½ diameters for punched or 2 for drilled holes.

Maximum longitudinal pitch in compression plates = 12 times thickness of weakest outside plate.

* By permission of the British Standards Institution.

Strength of Rivets and Plates.

Mean tensile breaking strength of best iron, such as BBB Staffordshire, best Yorkshire or Lowmoor (and the best only should be used), is from 26·33 tons per square inch (Fairbairn) to 25·98 tons per square inch (Kirkaldy); while the contraction of fractured area should not be less than 40 per cent.

Forge Tests for Rivets.—When cold they should stand being hammered double, or being upset endways, a ¾" rivet 2¼" long being hammered down to a cylinder 1" long, without any sign of cracking. A rivet ready heated for use should now and then be taken, allowed to cool, and treated as above, to see if they are being overheated. Much overheating is detected by the burnt, scaly appearance of the surface of shank; ¾" or even 1" rivets should not be over 20 minutes in the fire. When *hot* the heads should stand hammering down to less than ¼" thick without cracking at edges; and the stalks should stand having a punch, even more than their own diameter, driven through them without cracking round the hole.

The foregoing tests are equally applicable to steel rivets.

Careful punching does not injure soft plates, but weakens hard or steely iron plates from 15 to 30 per cent.

Sharp edges of drilled holes reduce the shearing resistance of rivets, but rounding the edges of the holes increases resistance of rivet.

Drilled rivet holes reduce the strength of a plate by 1¼ per cent., and punched holes about 6 per cent. Punching and counter-sinking reduce the strength 4 per cent., but if the holes are punched, reamered, and countersunk, there is little reduction in the strength of the plate. Comparative tests of high tensile plates, connected by iron and by high tensile rivets, show that ½-in. iron rivets worked cold in single shear have a shearing strength of 3·6 tons compared with 6·6 in the case of high-tensile steel worked cold, and 9·6 in case of the same steel worked hot. For double shear the same figures are 6·6, 13·1, and 18·4. Experiments show that the bearing pressure with high tensile steel rivets does not exceed 60 lbs. per square inch.

(*Sir P. Watts.*)

Riveting.

Riveting gangs consist of a holder-up, two riveters, and one or two boys for heating and supplying rivets. Rivets are heated in a portable hearth or a reverberatory furnace. Before inserting the rivet the plates round the hole should be hammered into positive contact, and the holes ascertained to be concentric.

Riveting hammers vary from 2 to 7 lbs., the holding-up hammer or 'dolly' from 10 to 40 lbs. 120 to 150 rivets is a day's work of 13 hours of a riveting gang. 360 to 720 can be put in by a riveting machine;

Riveted Joints.

The loss of strength is ordinarily, for chain-riveted joints (fig. 12), 15 per cent.; for double-riveted, 30 per cent.; for single-riveted joints, 44 per cent., as compared with the strength of the plate unpunched.

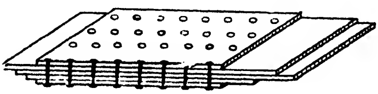


FIG. 12. Grouped Butt Joint. Chain Riveting.

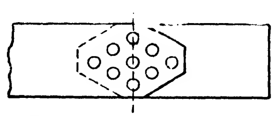

FIG. 13. Lap Joint. Lozenge Riveting.

Zigzag Riveting.—In this (fig. 14) the distance between the transverse pitch lines should be at least two-thirds the transverse pitch of the rivets.

Lozenge Riveting.—Arranging the rivets in this way, as illustrated by the lap-joint of fig. 13, and calculating the plate strength and rivet strength at each of the possible lines of fracture, it is possible to obtain a strength of joint equal to the strength of the whole plate less one rivet hole. With the same efficiency a still better joint for a plate-tie may be made with two cover-plates of lozenge form, the maximum row of rivets being repeated on each side of the butt joint.

Cover-Plates.—In the special case last mentioned the united thickness of the cover-plates will have to be considerably greater than that of the main tie, and will be determined by the net section of cover taken through the maximum row of rivets. In chain riveting generally it would be theoretically sufficient to make the united cover thickness equal to the plate thickness, but in practice it is often made somewhat greater, both in single and double covers. If there is

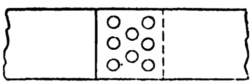

Fig. 14. Lap Joint. Zigzag Riveting.

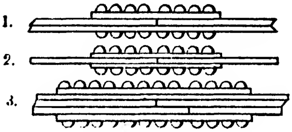

Fig. 15.

a whole plate on one side, as in No. 1, fig. 15, a single cover-plate may be used on the other side equal in thickness to the jointed plate. When the member consists of several thicknesses of plate, as in No. 3, they may with advantage be all jointed between one pair of cover-plates, arranging the several layers to break joint one with another, and leaving between every two joints a space containing a sufficient number of rivets to take up the pull of one layer of plates.

STEEL ROOF FRAMING AND COVERING.

Some points to be considered in designing steel roofing :—

(a) *Nature of Covering.*—If of corrugated sheeting, either ridged or curved type may be adopted ; in the latter the joints near crown of roof lie nearly horizontal, and leakage through rain being blown in must not be overlooked. A continuous covering, such as tarred felt or asphalt laid on timber boarding, is applicable to ridged or curved types.
With slates or tiles, the ridged type (except in very large spans) is necessary.

(b) *Rise of Roof.*—Where this is not controlled by architectural requirements, a rise of about $\frac{1}{4}$ span will generally prove most economical. Where water-tightness is essential. $\frac{1}{4}$ rise may be adopted ; a rise of even $\frac{1}{3}$ may be used with slates or tiles. In very exposed positions a low rise of $\frac{1}{6}$ has been provided, but here leakage is likely to prove troublesome.

(c) *Lighting and Ventilation in Roof.*—Skylights can be arranged in any position on the slope of a ridged roof, or set low down on curved roofs. Lights are often combined with ventilators at the centre or ridge of the roof. Ventilation at the ridge may consist merely in slightly raising the ridge cap above the sheets ; by the use of special ridge sheeting (often curved) supported on raised purlins ; or where greater ventilation is desired, the cover may be raised to a considerable height and louvres provided for weather-tightness. See sketch examples.

(d) *Temporary Structures.*—Here the framing and covering can be designed as light as possible, and factor of safety reduced to about 3, since allowance for rusting and general deterioration need not be considered. The self-supporting type of curved roof should be considered in this case.

(e) *Special Headroom* generally requires a special type, as the main tie cannot economically be raised much over $\frac{1}{10}$ rise for ridged or curved trusses of ordinary design. Two suggestions are given in sketch examples to meet this requirement.

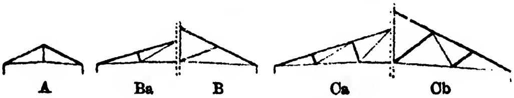
Struts, or members in compression, should be kept as short in length as possible. The strength of *ties* to resist tension is independent of their length, and no consideration on this point is necessary, except that relating to the carrying of their own weight.

The Purlins (or horizontal bearers which carry the weight of the roof covering, and the wind and snow load on the same, and transmit these loads to the roof trussing) should rest, wherever possible, on the rafters close to the points where the struts and ties meet, and stiffen the same: loads applied between these junction points (usually termed 'joints') may induce considerable *bending stresses* which must be carefully allowed for, generally at considerable expense, owing to the large increase in section which may be necessary.

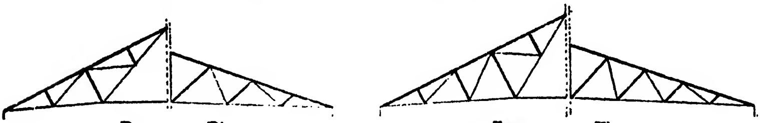
The unsupported length of the Rafter, that is to say the length between the joints, should not exceed 7 to 8 feet where the purlins are fixed close to the joints; where purlins occur between the joints, this length should be considerably reduced, or the section of the rafter increased to resist the bending stresses.

In the brief notes accompanying the outline types of roofs shown here, the application of some of the preceding hints will be evident.

For ordinary conditions the types shown below are suitable up to the following spans:—A, 14 to 16 feet; B, 25 to 30 feet; C, 45 to 50 feet; D, 55 to 60 feet; and E, 70 to 80 feet.

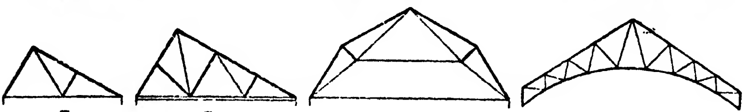


A Ba B Ca Cb



Da Db Ea Eb

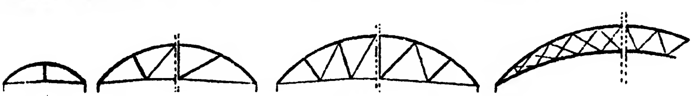
The two rises indicated in B to E are ¼ span and ⅙ span. Where special conditions do not arise, the form of bracing should be decided by considerations of length and inclination of the several struts, and convenience for designing efficient junctions between the struts and ties.



F G H J

Types of ridged roofs designed to provide special lighting, such as is required in spinning and weaving factories, are shown in F and G; the long slope is covered with sheets or slates, and the short, upright slope glazed and turned towards the north, thereby ensuring efficient light free from direct sunshine. These types are frequently called 'Saw Tooth' or 'Northern Light' roofs, and are suitable for spans of 18 to 20 ft., and 25 to 30 ft. respectively.

Types H and J show a high rise, with main tie raised to give increased headroom; the former may frequently be adopted for factories, the lower slopes being glazed and the upper slopes sheeted or slated.

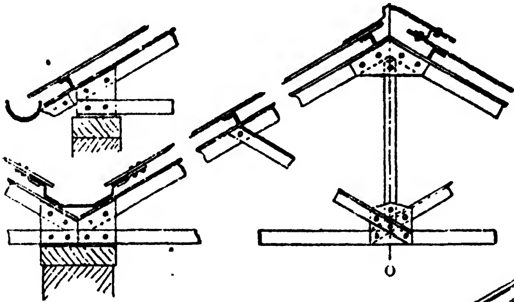


K La Lb Ma Mb Na Nb

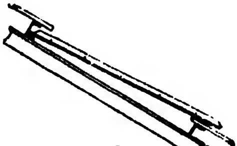
The curved types K, L, and M, are similar to A, B, and C, but arranged for a curved sheet covering, and may be adopted for similar spans.

Types N are in reality curved lattice girders, and may be designed for large spans such as are required for markets, railway stations, public halls, or the like.

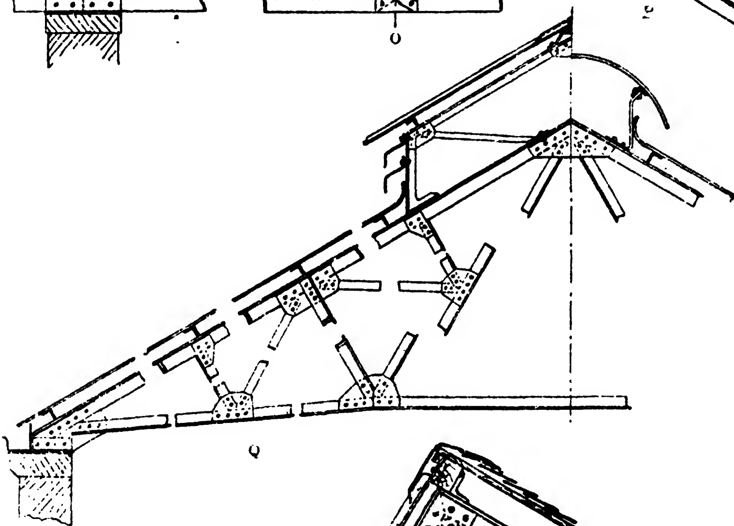
Sketch Details.—Sketch O suggests details for a ridged roof, type Bb ; on left two spans meet and a valley gutter is provided, and above this a sketch of an eaves gutter. At the apex, or ridge an ordinary ridge cap is shown on the left, and on the right a plain ridge cap is slightly raised on light brackets to provide a small amount of ventilation.



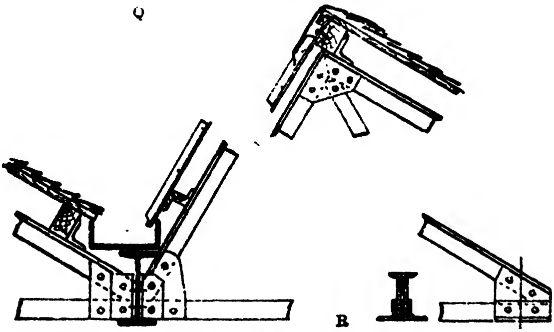
O



P



Q



R

Sketch P indicates a skylight in the slope of a roof. Sketch Q gives suggestions for type Da. At apex a simple ventilator is shown on the right, and a larger louvred ventilator on the left. In the latter arrangement the straight cover may be glazed, thus forming a combined skylight and ventilator.

Sketch R is that for a 'Northern Light' roof, types F or G. A valley detail (showing this part supported on a rolled steel beam) with valley gutter is given, also an eaves shoe detail. The long slope is covered with timber and slates, and the short slope is glazed.

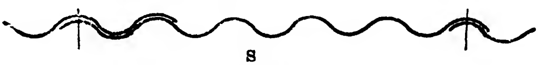
Corrugated Sheets and Fixings.

Sheets can be procured in lengths from 5 to 10 feet, and in thicknesses from No. 16 to No. 26 B.G.; for special or very temporary purposes, No. 28 B.G. might be adopted.

Corrugations from 2 inches width in light sheets to 6 inches in heavy sheets may be got, but for usual conditions the following sizes will meet all requirements :—

5–5 inch corrugated sheets (depth of corrugations 1½ in.)
6–5 " " " (" " ") See Sketch S, Fig. 16.
8–3 " " " (" " ¾ ")
10–3 " " " (" " ")

For ordinary conditions, a side lap of one corrugation (see right-hand of Sketch S) would be adopted, but for special water-tightness or stiffness, two corrugations lap could be given (see left hand of Sketch S). The effective width of the above sheets would be 25 inches or 30 inches, for single lap, and 20 inches or 25 inches for double lap.



S

FIG. 16.

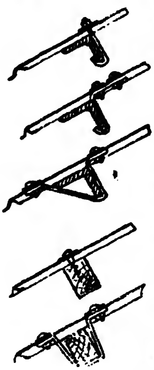
In the 3-inch corrugated sheets, the corresponding widths would be 24 and 30 inches for single lap, and 21 and 27 inches for double lap.

The end lap is generally given at 6 inches.

Sheets should be connected together by means of galvanised rivets or bolts and washers: these would be placed about 9 inches apart along the side laps, and at every second corrugation in the end laps, being in all cases placed on *top* of the corrugations to check leakage. For *double* corrugation side lap, place rivets or bolts in edge of outer sheets 6 inches apart, and 12 inches apart in inner corrugation.

Five-inch corrugations should always be adopted for No. 16 B.G. sheets, and may be used for No. 18 or 20 B.G.: 3-inch corrugations may be used for 18 or 20 B.,G., and always for No. 22 B.G. and upwards

In very exposed positions, and particularly with light gauge sheets, Wind Ties of flat or light angle section are sometimes carried along the length of the roof, and held in position by means of the purlin bolts. A line of these wind ties near each eaves level will considerably strengthen the roofing; and it is sometimes also desirable to add ties over some of the intermediate horizontal joints in the roof sheets, to further resist excessive winds.



T

U

V

W

X

In addition to connecting the roof sheets together, they must be securely fixed to the roof purlins, and suggestions for doing this are here indicated :—

Sketch T, simple hook bolt, with nut and washer outside, connecting sheets to steel angle purlin.

Sketch U, similar to above, but formed of flat clip bolted to sheets.

Sketch V, a more secure form of flat clip carried round purlin and connected to sheets by bolts and washers at ends.

Sketch W, galvanised nail or wood screw and washer, for simple connection to timber purlin.

Sketch X, flat stirrup carried round timber purlin; generally made with slight clearance in width, to admit of adjustment due to change of temperature in the sheet covering.

The washers used with the bolts are sometimes formed of lead, or of some special form, to check leakage at the bolt holes. Red lead putty, or rope yarn soaked in red lead paint, is sometimes specified to be placed under the nut or washer, but such special sreatment is seldom justifiable, or really necessary.

Corrugated Sheets are generally galvanised, but in localities near the sea, or in manufacturing districts near chemical works where acid fumes are likely to be given off, the galvanising quickly disappears, and the sheets become eaten through and spoiled. In such conditions the galvanised sheets should receive two good coats of metallic oxide paint shortly after erection, or plain corrugated sheets used, these being well tarred and sanded after erection, and at such intervals as may be necessary to efficiently protect the sheets from corrosion.

Self-Supporting Roofing.

This term is generally applied to a type of curved roofing in which the curved rafters of the trussing are dispensed with, their place being supplied by the corrugated sheets themselves.

In the smaller spans, say up to 15 to 20 feet, the roof sheets are connected to timber or steel eaves beams, and the bracing (generally as types K or L) bolted direct to the curved roof sheets.

In the larger spans angle purlins are securely clipped to the curved sheets and extend for the whole length of the roof, and the bracing is bolted to these purlins.

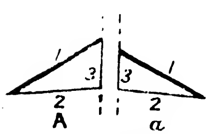
By this method of construction, and the use of corrugated roof sheets of sufficient strength to serve the double purpose of acting as a curved rafter, and as a weather protection, spans over 55 feet have been erected. It will not, however, as a rule be found economical to exceed about 35 feet span with this type of roofing; and as the life of this structure depends on the strength of the covering, it is seldom justifiable to provide self-supporting roofs for permanent use, as this would entail great watchfulness and cost in protecting the sheeting against corrosion or decay.

The curved form of covering must be used for this type of roof, and for the larger spans the sheets may be arranged to *break joint* in the longitudinal joints; greater stiffness may be obtained in the complete sheeting by this arrangement of joints. The lower sheets of the roof, which have to resist a much greater strain than the upper ones, are sometimes made of a heavier gauge. Special attention is also necessary to ensure sufficient strength when bolting or riveting the several sheets together.

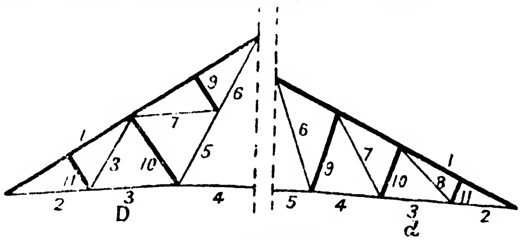
Ridged Roof Truss Multipliers.

The determination of the stresses in the several members of any roof truss is usually a comparatively simple matter, although a considerable amount of time may sometimes be required

Rise of rafters, $\frac{1}{3}$rd and $\frac{1}{4}$th span. Rise of main ties, $\frac{1}{18}$th and $\frac{1}{12}$th span.

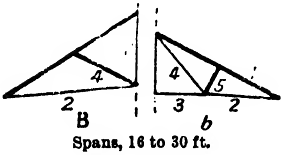


Spans to 15 ft.

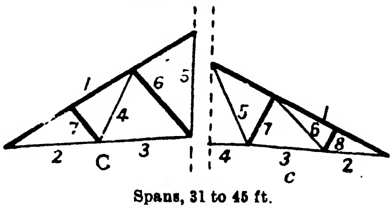


Spans, 46 to 60 ft.

Compression shown by heavy lines. Tension shown by light lines.



Spans, 16 to 30 ft.



Spans, 31 to 45 ft.

to carry out this operation. Where any of the following types of trusses can be adopted, the above calculations can be much simplified and shortened.

For special water-tightness with slate or tile covering, one-third rise (shown by capital letters) should be adopted; one-fourth rise is usual for corrugated sheet covering.

In spans up to 60 feet the rafter is usually kept the same section throughout the full length; the table gives only the max. stress multiplier for rafters.

The max. practical span for any type of truss is indicated by multiplying the numbers of sections formed in the rafters by the joints in the same by 7½ feet. Thus Type B gives 4 × 7½ = 30 feet max. span, and Type D = 8 × 7½ = 60 feet max. span.

Purlins are assumed to be set at the joints; if not, allowance must be made for the extra stress due to the bending tendency produced.

It is also assumed that the trusses are fixed at both ends; if this is not so, the stress in some members may be increased by about 10 per cent.

The multipliers in the following table are calculated as for *unit load and unit span*. Thus for dead-load stress the actual dead load of truss covering, etc., is multiplied by the particular dead-load multiplier for the required member; for live-load stress, the live load from the actual normal wind pressure on one side of the truss is used along with the particular live-load multiplier. Both stresses added together give the max. stress on the member.

D. L. = Dead Load. L.L. = Live Load.

Galvanised Corrugated Steel Sheets. Approximate Weight.

(Sheets 26 inches in width; 8–3 inch corrugations.)

British Standard 798, Galvanised Corrugated Steel Sheets, specifies that the weight of the galvanised coating shall be not less than 1½ oz. per square foot of sheet (including both sides).

In the case of 8–3 inch corrugations the width of the sheet before corrugation shall be not less than 29½ inches but may be ½ inch over.

The tolerance on weight of black sheets shall be plus or minus 7½ per cent., so that the following figures are only approximate.

Approximate Number of Sheets per Ton.

Length of Sheet in Feet.						
5	6	7	8	9	10	B.G.*
70	58	50	44	39	35	16
89	74	64	56	49	44	18

2 1 21	1 3 21	1 2 7	1 1 7	1 0 7

One ton of Galvanised Corrugated Iron Sheets will cover when fixed, and after **allowing for** laps, the undermentioned **areas**:—

16	18	20	22	24	26	28	B.G
600	800	1020	1280	1530	2100	2250	Square Feet.

It is a bad practice to fasten zinc-iron sheets together with iron or steel rivets. These soon rust if not painted, and the rust penetrates through the edges of the iron encircling the rivets, and thus proves disastrous. Only zinc, or zinc-covered rivets, should be so used.

The great objection to iron as a roofing material is the drip from the moisture which **condenses** on the **underneath** side of it.

Painting for Galvanised Iron Roofs.

Paint adheres badly to new galvanised iron, but after a few years it will do so readily and will add greatly to its life. In order to make paint adhere to new galvanised **iron**, brush it over with the following mixture: Chloride of Copper, 1 part; Nitrate of Copper, 1 part, Salammoniac, 1 part; Water, 64 parts, to which is added 1 part of Hydrochloric Acid. This mixture turns the galvanised iron black; it should be left for at least 12 hours before being painted.

It is stated that paint will **adhere** to galvanised iron if the **surface** is washed with vinegar before painting.

(See also 'Painting,' Section XLII, Vol. II.)

Varnish for Galvanised Iron Roofs.

Heat 100 gallons of tar to a low boiling point, and add 100 lbs. of fresh slaked lime, sifted over the top and then worked down. Boil this mixture until it becomes pasty. Let it settle for a few minutes and then add 20 lbs. of tallow and 5 lbs. of powdered resin. Stir until thoroughly mixed and all ingredients dissolved; then allow to cool. The mixture should not be raised to a higher temperature than 100 degs. F. If too thick, it can be thinned down with paraffin or naphtha.

Transverse Strength of Corrugated Iron.

If W = breaking weight in tons (distributed); L = unsupported length of sheet in **inches**; t = **thickness** of sheet in inches; b = breadth of sheet in inches; d = depth of **corrugations in inches**:

$$W = \frac{44{\cdot}6\,t\,b\,d}{L}.$$

BRITISH STANDARD SECTIONS.*

(B.S. 4, 4A & 6.) ***(Abstract.)***

The British Standards Institution list of Rolled Steel Sections for structural purposes comprises seven different sections, viz. (1) Equal Angles, (2) Unequal Angles, (3) Bulb Angles, (4) Bulb Plates, (5) Channels, (6) Beams, and (7) T Bars.

The following are abbreviated tables showing some of the standard dimensions recommended.

SECTION VIII

SURVEYING—SURVEYING INSTRUMENTS—ASTRONOMY—ASTRONOMY IN FIELDWORK (pp. 249-274)

(Revised by Reginald Ryves, M.Cons.E., and Percy M. Ryves, F.R.A.S.)

SECTION VIII

SURVEYING.

(Revised by Reginald Ryves, M.Cons.E., and Percy M. Ryves, F.R.A.S.)

Chaining.

Chains.—The surveying chain is 22 yards = 66 feet long. It consists of 100 links, and each link = 7·92 inches. This chain is known as 'Gunter's' chain.

Another chain is known as the '100-foot' chain, and consists of 100 links, each 1 foot long. It is used almost exclusively for work done abroad.

A third form is the 'Decimetre' chain; this is divided into 100 links, each of which measures a decimetre = ·328 foot.

Chain Measurement.—The most careful measurement that can be made with the common surveying chain is liable to an error of $\frac{1}{3000}$ of the distance measured, and an ordinary measurement across fields, &c., to an error of $\frac{1}{500}$.

Chain measurement alone will not suffice for a greater extent than a square mile on a scale of 6 inches to a mile; or than $\frac{1}{16}$ square mile on a scale of 20 inches to a mile.

Arrows.—With each chain 10 arrows or pins of strong wire about 1½ feet long, and preferably having a piece of red cloth tied to the ring of each, are carried.

Ranging.

Poles and Ranging Rods.—The former are poles of red pine about 15 feet high, 2 inches thick at the bottom and ¾ inch at the top; each should be shod with an iron shoe. The ranging rods are about 6 feet high, and have a white and red flag about 9 inches square at the top.

Offset Staff.—A narrow slip of deal about 1½ inches wide, 1 inch thick, and 10 links long, divided into links. It is used for the purpose of measuring small distances from the line to hedges, &c.

The statute acre in England consists of 10 square chains, that is, of 10 square blocks of land whose length and breadth are 1 chain each; or, taking 10 blocks as one whole block, then an acre is equal to the area of a rectangle whose base is 10 chains and perpendicular 1 chain; or to any other rectangle, the product of whose base and perpendicular also equals 10 chains: thus, 4 chains base with 2½ chains perpendicular, and 2 chains base with 5 chains perpendicular, are each equal to 1 acre.

With any quantity less than 1 chain, to bring feet into links add ½ more; to bring links into feet take ⅓ less.

MENSURATION.

To find the Area of a Triangle when the Base and Perpendicular Height are given.—**Multiply the base by half the height, or *vice versa*.**

To find the Area of a Triangle when the Three Sides are given.—**Take half the sum of the sides, subtract each side severally from this sum, then multiply this and the three remainders together, and take the square root for the area.**

To find the Area of a Rectangular Figure.—**Multiply the length by the breadth the product will be the area.**

To find the Area of a Trapezoid.—**Multiply half the sum of the two parallel sides by the distance between them.**

To find the Area of a Parallelogram whose Angles are not Right Angles.—**Multiply the length of any one of the sides by the perpendicular let fall on it from the angle opposite that side.**

To find the Area of a Trapezium.—**Divide the trapezium into two triangles, and find the area of the latter by the first rule.**

To find the Area of an Irregular Polygon.—**Divide the polygon into trapeziums and triangles, and find the sum of the areas of each.**

To find the Area of an Irregular Figure.—**Draw the figure on fine cardboard or thin sheet-metal, cut the same carefully out, and weigh it with an accurate balance. Then this weight, compared with the weight of a piece of the cardboard or metal of a definite size—say 1 inch square—gives at once the area required.**

Calculation of Areas from Co-Ordinates.

If necessary adjust the traverse so that the co-ordinates correctly close the figure.

Consider each line round the figure, not the stations.

Take the total, or reduced, departures of the stations at each end of one line, add them algebraically, and divide by two. This gives the 'middle departure' of that line.

Repeat for all the lines of the figure.

It makes no difference from what initial point the departures are reckoned, whether from one of the stations on the figure, or from another point either inside or outside the figure.

Taking each line round the figure in order—it makes no difference which way round—take the difference between the reduced latitudes of the stations at each end of the line. The result is the same as the actual amount of Northing or Southing made by that particular line.

Multiply these results for each line by the middle departure of the same line, paying attention to the algebraic sign of each factor, and add all the results together algebraically.

The result is that the area of the figure in squares of the units employed in measuring the length of the sides.

If these are feet, then

divide by 27,878,400 (Log 7·445 2678) for sq. miles; divide by 43,560 (Log 4·639 0878) for acres.

In the logarithmic computation of middle departures by latitudes, it is convenient to use the arithmetical complements of the logs given in preceding paragraph, adding all three logs, and thus avoiding taking out differences.

The terms latitude and departure are mutually interchangeable throughout the above.

TRIANGULATION.

For large surveys a base line is accurately measured and triangles built upon it, the sides being for 6 inches scale from ¾ to 1½ mile. Each point should, if possible, be fixed by three distances.

EXAMPLE.—AB (fig. 1) is the base line: C, D, E, F are convenient points to be fixed by triangulation.

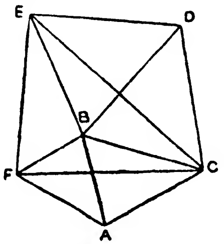

FIG. 1.

AC, AF, BF and BC being obtained, two values of FC can then be found from FBC and FAC, and then two values of FE from FEB and FEC, and so on. In plotting the triangulation the long lines EF, FC, EC should be first laid down.

AB = 5,230 feet measured by chain.

$$\left.\begin{aligned} BAC &= 55^\circ\ 30'\ 15'' \\ CBA &= 64^\circ\ 21'\ 25'' \end{aligned}\right\}\text{ measured by instrument.}$$

$$BCA = 60^\circ\ 8'\ 20''$$

$$BC = \frac{AB \sin BAC}{\sin BCA}.$$

$$\begin{aligned} \text{Log } AB &= 3{\cdot}7185017 \\ \text{Log sin } BAC &= 9{\cdot}9160154 \\ &\overline{\ 13{\cdot}6345171\ } \\ \text{Log sin } BCA &= 9{\cdot}9381368 \\ \text{Log } BC &= 3{\cdot}6963803 \\ BC &= 4970 \end{aligned}$$

The triangles are then broken up into smaller ones and measured by the chain.

Simson's Rule for Area Computation.

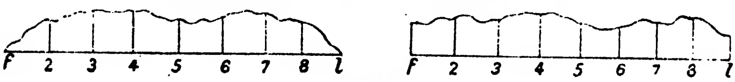

FIG. 2.

Divide base into any even number of equal parts, and measure length of perpendiculars or ordinates through each division.

If S = sum of lengths of first (f) and last (l) ordinates; E = sum of lengths of intermediate even ordinates; N = sum of lengths of intermediate odd ordinates; d = common distance between ordinates; then

$$\text{Area} = \frac{S + 4E + 2N}{3} \times d.$$

Rate of Surveying.

The average daily progress of a good surveyor in England, surveying with one chainman, for the 6-inch-to-a-mile scale, is, according to Frome—

Close large village	about	5 acres.
Villages and surrounding fields, etc.	"	14 acres.
Close country, gentlemen's houses, etc.	"	20 acres.
Medium country, ordinary fields, and scattered farms	"	30 to 32 acres.
Open moorland, with roads, streams, boundaries, cart tracks, etc. (no fields)	"	55 acres.

A survey of a piece of country of about 6 square miles, on a scale of 6 inches to a mile (which would comprise measuring and levelling base line, triangulating, finding variation of the compass, traversing the principal roads, filling in detail by prismatic compass, contouring to every 25 feet, and completing fair plan), would take a good surveyor thirty working days.

A greater area takes less time in proportion, for the base is the same, as also variation of compass and part of the triangulation.

TO ASCERTAIN THE DISTANCE OF AN INACCESSIBLE OBJECT.

To measure a Base Line across a River.

Let DA (fig. 3) be the direction of the line which has been measured up to the river. It is required to ascertain the distance BA at once upon the ground, so as to continue the measurement of the line.

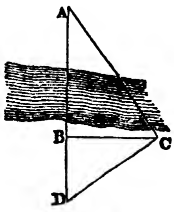

FIG. 3.

On the line DA take any point, B, whence a perpendicular, BC, can be taken, which will be free from obstruction, so that BC can be accurately measured; carry the range on across the river, and at A set up a flag; on BC take any point, C, whence A can be seen; and at C erect a perpendicular to AC, intersecting the line AD on D.

Measure DB; then

$$AB = \frac{BC^2}{BD}.$$

These angles can either be taken by a cross-staff or by the chain, with the distances of 30 links, 40 links, and 50 links; 50 being the hypotenuse of a right-angled triangle when the base and perpendicular are respectively 30 and 40.

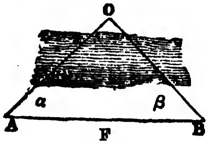

FIG. 4.

To measure the Width of a River with the Base Line alongside of it.

Take at the ends of the base line, AB (fig. 4), with a theodolite, the angles α and β, made between the base line and a flag, O, placed at the edge, on the other side of the river; then width OF is

$$OF = AB\,\frac{\tan\alpha\tan\beta}{\tan\alpha + \tan\beta}.$$

To find the Distance of one Object from another, where a River divides them, without using the Theodolite.

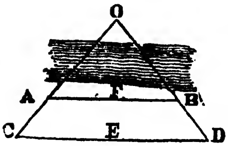

FIG. 5.

Let O and A (fig. 5) be the given objects, and AO the distance required. From A draw AB at *any* angle to AO, and produce OA to C, measuring AC about one-third length of AB; from C measure CD, parallel to AB, OBD being in one straight line. To make CD parallel to AB, at A and B erect equal perpendiculars, which can be done either by a cross-staff or by means of the unit proportion of the sides of a right-angled triangle, viz. 3, 4, and 5, or any multiples of them whatever. Then

$$AO = \frac{AB \cdot CA}{CD - AB}.$$

If the perpendicular distance OF be required, then this can be obtained by the formula—

$$OF = FE\,\frac{OA}{AC}.$$

Or we can so select the point A as to have OAC at right angles to the river, and make AB and CD at right angles to OAC, when AO, given by the foregoing formula, gives, of course, the required perpendicular distance.

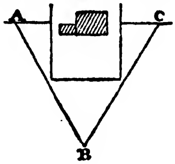

FIG. 6.

To continue the Measurement and Direction of a given Line when any Obstacle stands in the way, which cannot be crossed but can be avoided by going to the right or left.

At any point, A (fig. 6), on the given line, AC, take an angle with the given line, of 120° if you would turn to the left, or 240° if to the right, as in the present case, and proceed measuring to B till an angle of 60° made with this line towards the first line, AC, will carry you clear of the obstacle. Take this angle, ABC, 60°, and measure BC the same distance as AB: the point C will then be on the given line, and AC will be equal to AB or BC. By taking an angle of 240° with the line BC, the range of the line can be continued.

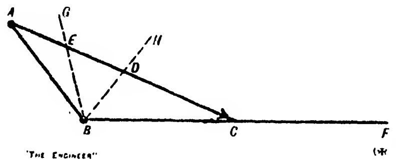

FIG. 7.

Line and Angle Bisector.

The following simple contrivance, based on Euclid, Proposition 3, Book 6, and devised by H. R. Kempe, may be found useful to draughtsmen.

AB and AC are two links hinged at A, AB being pivoted at B; AC is twice as long as AB. E and D are points on AC such that D is midway between A and C, and E is midway between A and D.

If, now, the end C of the link AC be slid along BF, then HB will always bisect GBF, and EB will always equal $\frac{BC}{2}$.

General Remarks.

1. Avoid taking bearings and distances along a circuitous boundary line like *abc* (fig. 8), but run the straight line *ac*, and at right angles to it measure offsets to the crooked line. 2. If it is desired to survey a straight line from *a* to *c*, but the instrument cannot be directed precisely towards *c*, on account of intervening obstacles, first run a trial line, *am*, as nearly in the proper direction as can be guessed. Measure *mc*, and calculate a distance, *y*, say, so that *am* is to *mc* as is 100 ft. to *y*. Lay off *ao* equal to 100 ft., and *os* equal to *y*, and run the final line *asc*. Or, if *mc* is quite small, calculate offsets like *os* for every 100 ft. along *am*. 3. When *c* is visible from *a*, but the intervening ground difficult to measure along on account of marshes, &c., extend the side *ya* to good ground at *t*; then, making the angle *ytd* equal to *yac*, run the line *tn* to that point, *d*, at which the angle *ndc* is found by trial to be equal to the angle *atd*. It will rarely be necessary to make more than one trial for this point *d*;

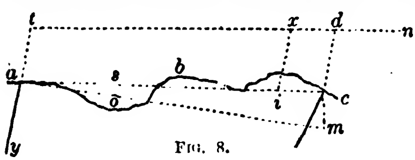

FIG. 8.

for, suppose it to be made at x, see where it strikes ac at i; measure ic, and continue from x, making $xd = ic$. 4. In the case of a very irregular piece of land, or a lake (fig. 9), surround it by straight lines. Survey these, and at right angles to them measure offsets to the crooked boundary. 5. When between two objects, m and n (fig. 10), and it is wished to place oneself in range with them, lay a straight rod, cb, on the ground, and point it to one of the objects, m; then go to the end c, and see if it points to the other object; if it does not, then, by successive trials, find the position, ed, in which the rod points to both objects, and consequently is in range with them. If no rod is at hand, two stones will answer, or two chain-pins. A plumb-line (a pebble tied to a piece of thread) will add to the accuracy of ranging the rod, or stones, &c.

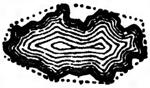

FIG. 9.

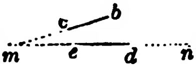

FIG. 10.

TO MEASURE THE HEIGHT OF AN OBJECT.

(1) When the Base is Accessible.

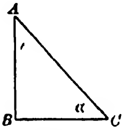

FIG. 11.

Measure any distance from the base of the object as nearly equal as possible to the height, and take the angle of elevation by the theodolite.

Let BA (fig. 11) be the object; measure BC, and take the angle a; then

$$BA = BC \tan a.$$

(2) When the Object is Inaccessible.

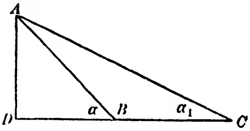

FIG. 12.

If the object be inaccessible, so that DB *cannot be measured*, range DB (fig. 12) on to C, and taking BC nearly equal to DB, measure BC, and at B and C take the angles of elevation, a and a_1; then

$$AD = BC \tan a_1 \left(\frac{\tan a}{\tan a - \tan a_1}\right).$$

Chaining on Slopes.

A = angle of slope with horizon. L = length of line chained on slope.
l = length of line reduced to the horizontal.

$$l = L \cos A.$$

5	·381	8·749	10	1·519	17·63	15	3·407	26·79	20	6·031	36·40

The foregoing table gives deductions or additions to be made every 100 ft. as actually chained along sloping ground in order to reduce the sloping measurements to horizontal ones. Even when it is so nearly level that the eye cannot detect the slope, an over-measurement of an inch or two in 100 ft. may readily occur. It is plain that if we measure all the undulations of the ground we shall get greater totals than if we measure horizontally, as is *supposed* always to be done; but since few surveyors pretend to measure horizontally until the slope becomes apparent to the eye, their lines are usually too long by from 1 to 2 inches in 100 ft. To counteract this to some extent chains are frequently made from 1 to 2 inches longer than 100 ft.; and for ordinary purposes the precaution is a good one. When greater accuracy is required the chainmen should be attended by a third person, with a rod and slope-level, for taking the inclinations of the ground. These deductions being made, the remainder will be the actual horizontal distance.

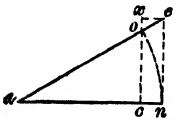

FIG. 13.

For example, in fig. 13. each 100 ft. *ao* measured up or down the slope *ae* plainly corresponds to the shorter horizontal distance, *ac*, the difference or deduction being *cn*. Taking *ao* as radius, then *ac* is the cosine, and *cn* the versed sine of the angle *ean* of the slope. Therefore *ae* multiplied by the nat. cosine of the angle *ean* gives the reduced horizontal distance, *ac*, which, taken from *ao*, gives the deduction *cn* of our table.

But if, while chaining along the slope *ae*, we wish to drive stakes that shall correspond with horizontal distances, *an*, of 100 ft., it is evident that we must add *cn* to each 100 ft. *ao*, as shown at *xe*, and the stake must be driven at *e* instead of at *o*. Observe that $xe = cn$ must be measured horizontally.

When the ground is very sloping all this calculation may be avoided, where great accuracy is most required, by actually holding the chain horizontal, as nearly as can be judged by eye, and finding, by means of a plumb-line, where its raised end would strike the ground. A whole chain at a time cannot be measured in this way, but shorter distances must be taken, as the ground requires—at times, on very steep ground, not more than 5 or 10 ft.

The following short rules may be used for finding the approximate correction to be made :—

(1.)

Square the number of degrees in the slope, multiply by $1\frac{1}{2}$, and obtain correction in hundredths of a foot.

Example.—10° slope. $10^2 \times 1\frac{1}{2} = 150$, or 1·50 ft. correction.

(2.)

Square the rise in feet per 100 ft. horizontal, and divide by 2; this gives correction in hundredths of a foot.

Example.—10 ft. rise in 100. $10^2 \div 2 = 50$, or 0·50 ft. correction.

To reduce a Measured Base to the Level of the Sea.

Let r represent the radius of the earth corresponding to the base b at the level of the sea, and $r + a$ the radius referred to the level of the measured base, B; then

$$r + a : r :: B : b, \quad \text{or,} \quad b = B \times \frac{r}{r+a}, \quad \text{and,} \quad B - b = B - B\frac{r}{r+a} = B\left(1 - \frac{r}{r+a}\right)$$

$$= B\left(\frac{a}{r+a}\right) = B\left(\frac{\frac{a}{r}}{1 + \frac{a}{r}}\right) = \frac{Ba}{r}\left(\frac{1}{1+\frac{a}{r}}\right) = \frac{Ba}{r}\left(1 - \frac{a}{r} + \frac{a^2}{r^2} - \&c.\right) = B\left(\frac{a}{r} - \frac{a^2}{r^2} + \frac{a^3}{b^3} - \&c.\right).$$

But the radius of the earth being very great in comparison with the difference of level, a, we have the correction, $B - b$, or d, say, sufficiently accurate by retaining only the first term. Hence

$d = \frac{Ba}{r}$ is the value to be deducted from the measured base.

Spherical Excess.

$$E, \text{ in seconds} = \frac{S}{r^2 \sin 1''} = \frac{ab \sin C}{2r^2 \sin 1''},$$

S = the area of the triangle. r = the radius of the earth.

$$S = \frac{ab \sin C}{2} = \sqrt{s(s-a)(s-b)(s-c)}, \quad s \text{ being} = \frac{a+b+c}{2}.$$

Between latitudes 45° and 25° the spherical excess amounts to about 1′ for an area of 75·5 square miles.

Hence, if the area in square miles be known, a close approximation to the spherical excess will be had by dividing the area by 75·5. Log mean radius of the earth in yards = 6·8427917. If the three angles of a triangle are assumed to have been equally well determined, the previous determination of the spherical excess is not necessary for the calculation of the sides, though it will be required for estimating the relative value of the observations. For the sides of a spherical triangle may be computed as if they were rectilineal if one-third the excess of the sum of the three angles above 180° is deducted from each of the three observed angles, in which case

$$\text{side } b = \text{side } a \sin\left(B - \tfrac{1}{3}E\right) \div \sin\left(A - \tfrac{1}{3}E\right).$$

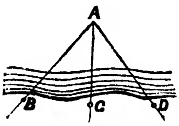

FIG. 14.

Surveying Soundings.

To determine the position of any sounding, A (fig. 14), when afloat, take simultaneously the bearings of three known objects on shore, B, C, D, plot the angles on tracing-paper, and move them on plan until the lines cut the points B, C, D.

Another method.—B, C, and D being known points on shore, and the angles BAC, CAD having been measured—

Double the angle BAC, and deduct this doubled angle from 180°. Halve the remainder, and set off from B and C angles, each equal to the half remainder—that is, BCE, CBE; then BE = EC. With E as a centre and radius EC, describe the circle BCA. Then the point A will be in the circumference of this circle.

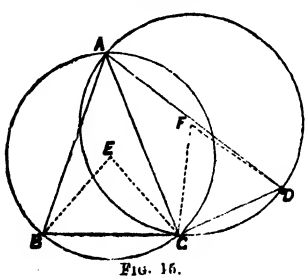

FIG. 15.

In like manner, double the angle CAD and proceed as before; the point A will be in the circumference of the circle CAD. Being in the circumference of the two circles, the point A will therefore be at the intersection of the two.

Suppose the angle BAC to have been 40°, CAD 30°, the double of BAC is 80°; then 180° − 80° = 100°, which divided by 2 gives 50°. Set off from B and C angles equal to 50°. In like manner, 2CAD = 60°, and 180° − 60° = 120°; half 120° = 60°; from C and D set off 60°. With E and F as centres (fig. 15), and radii EB, FC, describe the two circles, whose intersection determines the position, A, of the observer.

To reduce a Sounding to Low Water.

h = vertical rise of tide, in feet. h' = height of tide above low water, in feet, at the time t.
= time between high and low water. t' = time from time of sounding to low water, in hours

$$\frac{h}{2}\left(1 \mp \cos \frac{180t'}{t}\right) = h'; \quad - \cos \text{ when } \frac{180t'}{t} < 90^\circ, \text{ and } + \cos \text{ when } > 90^\circ.$$

EXAMPLE.—Low water occurring at 3.45, and high water at 10.15 P.M., a sounding taken at 5.30 P.M. was 18·25 feet; what was the depth at low water, the vertical rise being 10 feet?

$$h = 10\,\textit{feet};\ t = 5h.\ 30m. - 3h.\ 45m. = 1h.\ 45m. = 1{\cdot}75\ \textit{hours}.$$
$$t = 10h.\ 15m. - 3h.\ 45m. = 6h.\ 30m. = 6{\cdot}5\ \textit{hours}.$$

Then

$$\frac{10}{2}\left(1 \mp \cos \frac{180 \times 1{\cdot}75}{6{\cdot}5}\right) = 5(1 - 48^\circ\ 27') = 5 \times (1 - {\cdot}662) = 1{\cdot}69\,\textit{feet}.$$

Sounding	18·25 *feet.*

SURVEYING INSTRUMENTS.

ADJUSTMENT OF THE THEODOLITE.

(*R. T. Hancock.*)

The first and most important adjustment consists in correctly levelling the instrument with its vertical axis pointing truly to the zenith, every time it is set up. Other errors in adjustment can be corrected or compensated by special methods of observation, but correct results are impossible if the theodolite is out of level. This adjustment must precede all others.

Set the instrument up firmly with its legs well spread and bring it approximately level by means of the base adjusting screws, with the aid of the bubble tubes on the vernier plate. Place the telescope as nearly horizontal as possible, with the vertical arc clamped to zero if desired, and bring it over one pair of the base levelling screws, or parallel to a pair in the case of a tribrach base, and observe the position of one end of the bubble of the telescope level in relation to the gradations on the tube. Select and use one end throughout, say, the end of the bubble nearest the eyepiece. Revolve the upper part of the theodolite through 180°, bring the bubble back half way, if it has moved, by means of the base levelling screws. Check by turning the instrument back to its original position. If the bubble remains in its mean position, turn the upper part of the instrument through 90°, so that telescope lies over the other pair of levelling screws, or the remaining one of the tribrach, and bring the bubble to the same position by these. Finally check by turning the instrument slowly through 360°, and see that the bubble remains unmoved. If not, repeat adjustment from the beginning. The bubble may not finally occupy the centre of its tube: this is unimportant. What is important is that it should not move when the instrument is revolved about its vertical axis. If the bubbles of the levels on the vernier plate are not well centered when the instrument is thus levelled, it will be convenient to make them so now by means of the turret screws at the ends of the cases, so that a close approximation to true levels may be obtained when setting up on future occasions. It should make no difference in levelling up whether the two plates revolve together or whether the lower is clamped and the upper free. If it does, it shows that the cones require regrinding.

Adjustment for parallax consists in moving the eyepiece in or out, altering the focus of the object glass to correspond, until the crosshairs of the diaphragm do not appear to move relative to the point viewed when the eye is moved slightly from side to side of the lens opening. Care should be taken not to revolve the eyepiece tube in its casing, as this affects the optical centering of the system of lenses. For this reason the lens cell and its casing are usually provided with corresponding marks by the maker.

The transit axis upon which the telescope swings should be accurately at right angles with the vertical axis of the instrument. The adjustment of this is effected by sliding bearings at the top of the standards, but in cheaper instruments no provision for adjustment in this respect is made, the makers supposedly securing it once and for all by correctly proportioning the height of the standards. Direct the telescope to some high object, such as the finial of a spire. Depress the telescope and mark on the ground the point where the intersection of the hairs falls. Transit the telescope, sight up again, and mark where the intersection falls on the ground the second time. Raise or lower one bearing so that the intersection falls one-quarter of the distance between the marks from the second mark. Check, and repeat if necessary.

The collimation line may be defined as a line joining the optical centre of the object glass and the intersection of the crosshairs. To make it at right angles to the axis on which the telescope swings, set up, level, and sight to a well-defined mark about 100 feet away; transit the telescope, and mark where the intersection falls in the opposite direction, at about the same distance away and on the same level as near as may be. Revolve the plates through 180° about, and sight to the original mark. Again transit, and mark the new point of intersection, if altered, near the former one. Measure a point one-fourth of the distance between the two from the latter, and move the diaphragm carrying the crosshairs by means of the adjusting screws holding it in the telescope until the intersection covers the measured mark. It will be necessary to loosen all four screws to do this, but care should be taken not to move the diaphragm up or down more than can be helped, and to keep the crosshairs vertical and horizontal. Check by transiting back again to the original mark, which will now not fall under the crosshairs; bring it under the intersection by the slow motion tangent screw, and transit back again. The intersection should now fall half way between the two original marks.

Having performed the foregoing adjustment we now have the vertical axis of the instrument pointing truly to the zenith, the horizontal axis on which the telescope swings truly at right angles to the vertical axis, and the line of collimation truly at right angles to the horizontal axis. The collimation line then lies wholly in a vertical plane cutting the horizontal axis at right angles, but does not necessarily lie parallel to the axis of the level on the telescope in that plane. It can be made to do so by altering the lie of one or the other, and in order to avoid disturbing the adjustment just completed, it is better to bring the axis of the telescope-level parallel to the collimation line as it now lies. This is why it was recommended not to disturb the up-and-down position of the collimation line more than can be helped, so as to avoid the necessity for much alteration in the telescope level. This adjustment is not really required for the theodolite, unless it is intended to use it occasionally as a level, and the surveyor who desires to effect it can proceed as described below for the level, except that after setting up beyond the levelled pegs, the telescope is lowered or raised by the slow-motion tangent screw of the vertical arc till the crosshairs read the same on both pegs; the bubble of the telescope level is then brought to the centre of its run by altering the capstan-headed screws at each end of its casing.

Subtense Measurements. Tacheometers.

It is quite common at present to place a pair of webs—or much better, a pair of points—in the diaphragm of a theodolite or level, these being at such a distance from each other that they will by vision correspond to a measurement (upon a distant levelling staff), which is proportional to the base of the subtense angle, so as to show thereby, in the space between the lines or points, the true distance of the instrument from the staff. FIG. 16 shows the form these points appear in focus of the eye piece. By the employment of this system chain measurements are entirely dispensed with, and the system has the merit of a simple sight measurement, as upon a rule, without any calculation. Theoretically it is scarcely as exact as the work of the Omnimeter, as there is great difficulty of exact adjustment of the points without the use of complicated optical means, but practically, as testified in some recent work by the Surveyor-General of Lagos and Nigeria, a good instrument in correct adjustment may be read within less than ·001 of total distance, which is nearer than is possible by chaining over uneven ground. One merit over the Omnimeter is that the instrument is not touched by the hand during the observation of the points, cut by vision upon the staff, which give the distance.

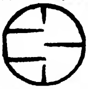

FIG. 16.

THE DUMPY LEVEL.

This is a perfect knock-about instrument. If stations are taken at equal distances apart, say one chain, this form of level will act correctly although out of adjustment. Thus with the level

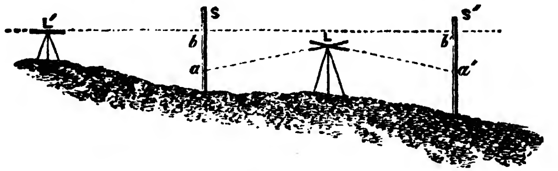

FIG. 17.

at L (fig. 17), place a staff vertically at one chain distance from the instrument at S. The inaccurate instrument will read the staff at *a*. Now place the staff vertically at S′. It will read at *a′*. The distances and verticality being equal, *a* and *a′* will be level. If we now place the level at some distant position nearly in line L′ and adjust the level by the bubble screw to read equal distances above *a* and *a′* and *b* and *b′*, the level must be true.

Adjustment of the Level.

(*R. T. Hancock.*)

Select a fairly level piece of ground, set up the instrument, carefully levelled up as described for the theodolite (p. 257), and drive a peg at a distance of 100 feet or so away. Hold the levelling staff on the peg and note the exact reading. On the opposite side of the instrument, and exactly the same distance away, set another peg, driving it down till the staff held on it reads exactly the same as on the first peg. The tops of the pegs are then on the same level, independent of instrument error. Set up on the prolongation of the line beyond one of the pegs, level up carefully, and make the crosshairs read the same on both pegs by raising or lowering the diaphragm cell by means of the screws holding it in the telescope tube. The collimation line is now horizontal.

It is not necessary to level the pegs if the difference in level is noted, and the crosshairs are altered to read the same difference. To facilitate the adjustment in this case, set up beyond the pegs at a distance which bears some simple relation to the distance between the pegs, make a sketch of the position of instrument and staffs, insert readings and distances, and calculate the amount it is necessary to alter the reading on either staff (by moving the crosshairs), on the principle of similar triangles.

The telescope bubble may not finally occupy the centre of its tube when the collimation has been put horizontal as described. This is unimportant, as the instrument can always be correctly levelled up if the procedure as described for the theodolite is followed, in fact the central position of the bubble should never be relied on as a test for levelling up, even if it has once been secured by adjustment. It may be brought to the centre of its run by adjusting the screws holding the level to the telescope, care being necessary not to disturb the instrument.

The Plane Table.

This instrument is now generally used in new countries and in our colonies, for filling in details of work with the theodolite. It has the great merit that an intelligent native without technical education can be instructed to do valuable detail work with it. In its simplest form it consists of a sighted rule placed on a small board supported by a light tripod, the work being performed on the surface of paper. Many civil engineers find its work extremely convenient, because this work being made most definite by sketches upon the paper used, from these sketches they have a certainty of position in making maps from the same; so that they employ plane tables with all the refinement of means of observation possessed by the theodolite.

Prismatic Compass.

Details of small surveys or filling-in work are made by this compass, which is sighted for observation of direction, so that the eye may also see the compass ring by reflection through a prism at the instant of sighting. A reflector is commonly fixed to the forward sight so that distant objects may be seen up or down hill. The instrument is generally held in the hand for work, but where greater refinement is desired it is supported on a tripod stand. 2½ in. or 3 in. instruments are used by hand; 3½ in., 4 in., and 4½ in. are each set on a stand.

To Find the Variation of the Compass.

1. By the Pole Star (Polaris).

The pole star is on the meridian, either above or below the pole, when a vertical plane passes through it, and the bright star at the root of the tail of the Great Bear ε Ursæ Majoris (Alioth), Thus, during the twenty-four hours, two opportunities will be presented of finding the pole star on the meridian. Set up a fine plumb-line in a convenient place, free from currents of air, and the observer, placing himself behind the thread, waits until the moment when the two stars are hidden by the thread. If the bearing of the pole star be then read, it will show the variation of the compass. But as it is not very easy to read a compass at night, it is best to fix a stick with a light on it in the line of the pole star, and as far off as possible, the line joining the observer's position, and the light is the meridian line, and its bearing may be read in the morning.

2. By a Single Altitude of the Sun.

1. Compare watch with chronometer to get correct mean time.
2. Note readings of barometer and thermometer.
3. Adjust theodolite and note index error.
4. Set up instrument at . . . . Δ station; make the temporary adjustments, and set instrument at 360° on . . . . Δ station.

5. About three hours from 12 o'clock, morning or afternoon, unclamp upper horizontal plate and vertical arc. See that the dark-eye piece is down, and move upper part of instrument till the sun is in the field of object glass. Clamp upper horizontal plate and vertical arc, and with the two tangent screws follow (morning observation) the sun's movement till the sun's upper limb just touches the intersection of the cross-hairs. Note the time by watch, and read on horizontal arc the azimuth, and on vertical arc the altitude of $\overline{\odot}$, sun's upper limb.

6. Unclamp horizontal plate, and either with a slight motion, or, if plate be clamped, wholly with tangent screw, follow the sun's motion in azimuth till the sun's lower limb ($\underline{\odot}$) becomes tangent to the intersection of cross-hairs, the vertical arc being untouched. Note the time and the reading on the horizontal arc.

7. The mean of the times and the mean of the azimuths will give the time and azimuth at which the vertical reading of the arc denotes the apparent altitude of the sun's centre $\odot$.

8. Correct apparent altitude, $\odot$.

Correction 1. For index error of instrument. Correction 2. For refraction, modified by barometric and thermometric readings; corrections to be found in tables in Frome's 'Surveying,' Drayson, or Chambers. Correction 3. For parallax. To be found in tables in 'Nautical Almanac,' and modified to noted altitude by formula:—Sin par. in alt. = sin hor. par. × cos. alt.

9. Apparent altitudes thus corrected gives true alt. $\odot$.

10. The true alt. $\odot$ subtracted from 90° gives the zenith distance ZS.

11. As the altitude of the elevated pole is equal to the latitude of the place, 90° minus latitude = zenith distance of the pole, viz. PZ.

12. The declination of the sun is given in the 'Nautical Almanac' for each day at apparent noon. The variation of declination for each hour is also given, and the direction of declination, N. or S. Hence the declination at the time of observation is obtained. If the time of observation be 9 A.M., and declination increasing, the correction for three hours' variation must be subtracted from the declination at apparent noon, *vice versa* if the declination be decreasing.

13. Then we have the three sides of the astronomical triangle to ascertain the angle Z, which is the measure of the angular deviation of the sun from the true meridian.

14. Compute the angle Z by the formula

$$\cos\frac{Z}{2} = \sqrt{\frac{\sin S \sin (S - PS)}{\sin PZ \sin ZS}}$$

where $S = \frac{1}{2}$ sum of the three sides of the triangle.

15. The magnetic bearing of the Δ station from which the sun's azimuth was taken should be noted two or three times with great care. If possible a stand to be used for the compass.

16. Then, knowing the sun's azimuth from a station and the direction of that station as regards the magnetic north, we get the deviation of the sun from the magnetic north. The computed angle, Z, is the deviation of the sun from the true north, and the difference of the two deviations is the variation of the compass.

17. Note that for afternoon observations the computed angle, Z, is to be subtracted from 360° before comparison with sun's magnetic bearing.

Magnetic Elements.

At Abinger Magnetic Station, near Leith Hill, Surrey (in connection with the Royal Observatory, Greenwich).

Mean values October 1948.

Declination, West, 9° 33′. Inclination (or dip) 66° 46′. Horizontal intensity, 0·1858 gauss. Vertical intensity, 0·4327 gauss. Average annual decrease in declination, 8′ E.

Declination at Greenwich, 14·0′ less than at Leith Hill. On any particular day, and even at different times of the same day, the departures from these values may be considerable. It is meaningless to give estimated values to decimals of a minute or five significant figures of intensity.

For other places in the British Isles, very rough values may be found by increasing 0·5° for each degree of longitude, W., and increasing 0·3° for each degree of latitude, N.; but local variations are considerable.

To Determine the South by Means of a Watch.

Point the hour hand of the watch at the sun, then half-way round (see note *a*) between the hour hand and 'XII' on the dial points 'south.' Thus, suppose it to be 8 P.M., point the hour hand at the sun, then the 'IIII' of the dial points to south. In southern latitudes, to find 'north,' point 'XII' at the sun, then half-way round between 'XII' and the hour is due 'north.'

This method is accurate only about the times of the equinoxes. The allowance for the actual times of the sun's southing (see Whitaker's Almanack) increase to and decrease from about 15 minutes at the times of the solstices.

(*a*) The half-way round is clockwise in the forenoon and counterclockwise in the afternoon.

To Determine a True East and West.

Set up a *vertical* rod (any size) on a flat floor. Describe a circle round the base about twice (this varies with the latitude) the height of the rod. Some time in the forenoon mark the point where the shadow of the rod just touches the circle, and repeat this in the afternoon on the other side of the circle; mark this point also. A line through these points will be true east and west.

As a guide to the true north, the following notes as to the whereabouts of the pole star at convenient hours in the evening or night will be useful, and correct enough for the purpose for the next hundred years.

The times given (Local mean time) are for the first day of each month, and become about 4 minutes (3 mins. 59·34 secs.) *less* every day.

Length of a degree of longitude at $\phi°$ latitude = $\cos \phi_1°$ × 69·174 statute miles; where $\tan \phi_1° = b \div a \tan \phi°$; a = equatorial radius (3963·36 miles), and b = polar radius (3950·06 miles); $b \div a$ = 3950·04 ÷ 3963·36 = 0·99664.

Example: What is the length of a degree of longitude at 50° latitude?

tan 50° = 1·1917536, therefore,

$\tan \phi_1°$ = ·99664 × 1·1917536 = 1·1877493 = tan 49° 54′ 18″; cos 49° 54′ 18″ = ·6440569, therefore length of degree = ·6440569 × 69·174 = 44·552 statute miles.

Length of a degree of latitude at $\phi°$ latitude ($\phi°$ being at the middle of the arc) = 69·174 × ·99330 + ·01005 $\sin^2 \phi°$) = 68·711 + ·6952 $\sin^2 \phi°$ statute miles.

Example: What is the length of a degree of latitude between 30° and 31°? $\phi°$ = 30° 30′, sin 30° 30′ = ·5075384, therefore length of degree = 68·711 + (·6952 × ·5075384 × ·5075384) = 68·711 + ·179 = 68·890 statute miles. (*H. R. Kempe.*)

APPROXIMATE DISTANCE OF OBJECTS WHEN FIRST SEEN AT SEA, THE OBSERVER'S EYE BEING SUPPOSED AT SEA LEVEL.

20	5·1	41	7·4	110	12·1	280	19·2	490	25·5	900	34·5
21	5·3	42	7·5	115	12·3	290	19·6	500	25·7	920	34·9

Example: From what distance will a hill 300 feet high be visible to an observer 20 feet above the sea?

To an observer on the summit of the hill the horizon would be 21·2 miles distant, and to the observer in the example it would be 5·5 miles distant, hence two such observers facing one another would just see each other at a distance of 21·2 + 5·5 = 26·7 miles, which is therefore the distance the hill will be visible.

ASTRONOMY.

The Earth and Sun.

Equatorial radius of the earth = 6,378,200 metres (3963·30 miles) (*Helmert*) = 6,378,388 metres (3963·42 miles) (*Hayford*); mean value, 6,378,294 metres (3963·36 miles). Polar radius of the earth = 6,356,818 metres (3950·01 miles) (*Helmert*) = 6,356,909 metres (3950·06 miles) (*Hayford*); mean value, 6,356,864 metres (3950·04 miles.

Equatorial horizontal parallax of sun (angle under which the equatorial radius of the earth would appear at the sun's centre) = 8″·80. Mean distance of sun from earth $= \dfrac{3963{\cdot}23}{\text{sine } 8''{\cdot}80}$ $= \dfrac{3963{\cdot}23}{{\cdot}0000426664}$ = 92,890,000 miles. Maximum distance (1st July) = 93,950,000 miles. Minimum distance (1st Jan.) = 90,950,000 miles.

Angle under which the radius of the sun would appear at the earth's centre, at the earth's mean distance from the sun = 16′ 1″·18 (*Auwers*).

Radius of sun $= 3963{\cdot}23\ \dfrac{\text{sine } 16'1''{\cdot}18}{\text{sine } 8''{\cdot}8} = 3963{\cdot}23\ \dfrac{{\cdot}0045699}{{\cdot}000042664}$ = 424,500 miles.

None of the foregoing numerical values can be accepted as absolute, as authorities are not agreed on the subject.

Identification of Stars.

In stellar observations for time, latitude, or azimuth, the star selected for observation may be conveniently found from the following notes, which describe the relative positions of the larger stars in the constellations. The angular distance between two stars can be closely estimated by comparison with half the distance between the observer's zenith and the horizon—*i.e.* 45°.

(*a*) In the constellation *Ursa Major* the two well-known stars α and β (THE POINTERS) point directly to POLARIS, the Pole star. The latter also forms the end or tail of *Ursa Minor*.

(*b*) If the curve of the tail of *Ursa Major* be continued, about 30° along it will be found ARCTURUS (α *Bootes*).

(*c*) A line from POLARIS at right angles to the line from THE POINTERS gives 50° from the former, CAPELLA (*α Auriga*).

(*d*) A line from POLARIS through the last star but one of the tail of *Ursa Major* passes through SPICA, 30° beyond ARCTURUS.

(*e*) The POINTERS' line continued through POLARIS for 60° indicates THE GREAT SQUARE OF PEGASUS. The star in the corner opposite to the Pole is MARKAB.

(*f*) Midway between the SQUARE and POLARIS is the constellation *Cassiopeia* (five stars grouped like W).

(*g*) A diagonal through the SQUARE S.E. to N.W. produced 40° gives DENEB (*α Cygni*).

(*h*) 25° further and 10° to the right the same line gives VEGA (*α Lyræ*), a large white star.

(*j*) 35° south of DENEB and VEGA is ALTAIR (*α Aquilae*). This star is between two companions, and forms the apex of an isosceles triangle with DENEB and VEGA.

(*k*) A line from POLARIS through CAPELLA will touch RIGEL, 65° from CAPELLA. This line passes between ALDEBARAN (*α Tauri*), 10° west and 30° from CAPELLA, and BETELGEUSE, 10° east and 40° from CAPELLA. RIGEL and BETELGEUSE are diagonal stars in *Orion*.

(*l*) A line from ALDEBARAN through *Orion's Belt* passes near SIRIUS (*α Canis Majoris*) at an equal distance from ALDEBARAN. This is the brightest star in the heavens.

(*m*) 50° east of BETELGEUSE, forming nearly an equilateral triangle with BETELGEUSE and SIRIUS, is PROCYON.

(*n*) 30° north of PROCYON is CASTOR, and 5° S.E. of CASTOR is POLLUX.

(*o*) The apex of an isosceles triangle with CASTOR and PROCYON, 45° east, is REGULUS (*α Leonis*).

(*p*) Eastward from PROCYON to REGULUS 30° is DENEBOLA. DENEBOLA forms an equilateral triangle with ARCTURUS and SPICA.

ASTRONOMY IN FIELD WORK.

(*Fred. Simpson, A.M.I.C.E.*)

Choice of Instrument.

Choice of Instrument.—The most suitable instrument is the Transit Theodolite provided with a delicate level attached to the vernier arms of the vertical circle, and a sensitive striding level for use on the pivots of the horizontal axis. The adjustments must be made as perfectly as possible, and the residual index error carefully ascertained. The value of a division of each of the sensitive levels should be determined, and the position of the bubbles should be noted at the time of observing, and an allowance made for any variation in their readings. The most suitable form of diaphragm for astronomical work is that with simple vertical and horizontal cross hairs. For night work on stars it is necessary to illuminate the cross hairs, if the instrument is not provided with an illuminated axis; a lamp held a little distance in front of, and a little on one side of the object glass, may be used for this purpose.

With the ordinary eyepiece, altitudes exceeding 60° cannot be conveniently taken; for greater altitudes some form of diagonal attachment to the eyepiece is required. A makeshift arrangement can be improvised with a small piece of mirror held in the hand, or provisionally attached in front of the eyepiece at an angle of 45° to the axis of the telescope.

In observing the sun, a very convenient method, less trying to the eyes, is to cast the image of the sun and cross hairs on to a piece of white paper or card (to act as a screen) held about

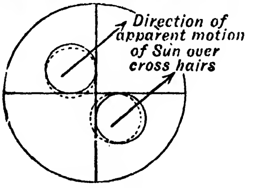

FIG. 18.

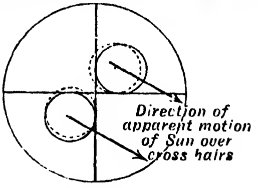

FIG. 19.

three or four inches from the eyepiece; the telescope must be focused for long-distance vision, with the cross hairs in focus; the telescope is then directed to the sun, and the eyepiece drawn out until perfect images of the sun and cross hairs are projected on the screen, the diameter of the image of the sun being smaller as the eyepiece is withdrawn. If the telescope inverts with direct vision, the image on the screen will be erect.

The limbs of the sun are observed when tangential to the respective cross hairs; the image of the sun should be allowed to leave one cross hair clamped a little in advance and followed with the other cross hair, using the tangent motion, so that the moving hair is brought tangential to the other limb as the first limb is just leaving the fixed hair; in this way only one hand is occupied with the tangent motion. The correction for semi-diameter must be applied to the readings in altitude and azimuth. In the case of the altitudes, the correction for semi-diameter is applied as taken from the Almanac; in that of the azimuths, the correction to be applied to the horizontal circle reading is approximately the semi-diameter, taken from the Almanac, multiplied by the secant of the angle of altitude. These corrections apply to observations taken on any one limb of the sun to reduce the reading to the centre of the sun; but by taking the means of pairs of observations, on the upper and lower limbs for altitude, and on the right and left limbs for azimuth, the necessity for correction for semi-diameter is eliminated.

In a double observation on upper and lower and right and left limbs, a pair of observations are made, one in which the horizontal hair is fixed in advance, the vertical hair being moved by the tangent motion of the horizontal circle; the other observation is then made with the vertical hair fixed in advance, the tangent motion of the vertical circle being then used to follow the lower or upper limb with the horizontal cross hair, up to the time of the vertical hair, with the right or left limb which is being observed.

The cross hair which is being moved should always be kept slightly on the disc of the sun, up to the time of contact with the other hair, as it becomes indistinct when off the disc.

The means of the circle readings of the altitudes and azimuths taken in this way will be thus reduced to the centre, and will correspond to the mean of the times of observations, and no correction for semi-diameter is required.

Altitudes require correction for index error (+ or −), for refraction corresponding to altitude (always −), parallax (in case of sun or planets) corresponding to altitude (always +); semi-diameter in case of sun or planets, + if lower limb is observed, − if the upper; this correction is eliminated if observations on upper and lower limbs are combined.

Refraction.—The mean refraction values are near enough for ordinary purposes when the altitude observed is over 20°, but for lower altitudes a correction may be necessary, corresponding to the altitude, temperature, and barometric pressure; refraction decreasing with higher temperature and increasing with higher barometric pressure.

Parallax.—The horizontal parallax of the sun is approximately 8·8″, and for any given altitude = 8·8″ × cosine of altitude, in seconds.

Declination as taken from the Almanacs must be corrected to correspond to the time of observation referred to time at the principal meridian adopted in the Almanac; generally it is sufficient to know his time to within ten minutes in spring or autumn, or within thirty minutes in summer or winter.

To Find Latitude.

Latitude may be deduced from a single altitude of a star, or the upper or lower limb of the sun, when crossing the meridian. This altitude is corrected for index error and refraction in the case of a star; in that of the sun a further correction is required for parallax and semi-diameter to reduce the altitude to the sun's centre. The declination is corrected to the time of observation.

In the case of the sun, and of stars with declination less than the latitude if of the same name:—
Latitude = 90° − (altitude + declination), if declination is of the opposite name to latitude.
Latitude = 90° − (altitude − declination), if declination is of the same name as latitude.
In case of stars with declination of the same name, but greater than latitude:—
Latitude = (altitude + declination) − 90° at the upper transit.
Latitude = altitude + (90° − declination) at lower transit of circumpolar stars.

More exact determination of the meridian altitude can be obtained from a series of ex-meridian altitudes taken about the time of the star or sun's meridian passage, provided three altitudes are taken at equal intervals of time, or equal intervals of azimuth (it is immaterial what intervals are taken, but they must be equal and not extend more than about twenty minutes on either side of the meridian passage).

The corrected altitude at the meridian may be obtained by the following reduction:—

Subtract the lowest altitude from the other two and let these differences, reduced to seconds, be denoted by d_1 and d_2; then the meridian altitude will be = lowest altitude + $\dfrac{(4d_1 - d_2)^2}{8(2d_1 - d_2)}$ seconds.

Example.—Three altitudes of the upper limb of the sun were taken at intervals of 6 minutes as follows:

	° ′ ″	° ′ ″	° ′ ″
	38 10 35	38 12 40	38 12 30
+ correction	2 17	− 38 10 35	× 38 10 35
= altitude on meridian, upper limb	38 12 52	2 05 = 125′	1 55 = 115

$$\frac{(4 \times 125 - 115)^2}{8(2 \times 125 - 115)} = 137'' = 2'\ 17''$$

To Find Time and Azimuth.

Time and Azimuth **from sun or star altitudes.**

Let a = altitude observed (corrected for under error and refraction in case of star, as well as for parallax and semi-diameter in case of sun);

l = latitude

p = polar distance = 90° − declination, if latitude and declination are of the same name, = 90° + declination, if latitude and declination are of different names.

$s = \dfrac{a + l + p}{2}$;

then,

$$\log \sin \tfrac{1}{2} \text{ Hour Angle} = \frac{\log \sec l + \log \operatorname{cosec} p + \log \cos s + \log \sin (s - a)}{2}$$

$$\log \cos \tfrac{1}{2} \text{ Azimuth} = \frac{\log \sec a + \log \sec l + \log \cos s + \log \cos (p - s)}{2}$$

The Hour Angle in arc is reduced to time; if from a P.M. observation of the sun this will be Apparent Time P.M., but if from an A.M. observation this Hour Angle in time should be deducted from 12, the result being Apparent Time A.M. To arrive at Mean Time, the Equation of Time must be added or subtracted as directed in the Almanac, this Equation of Time being first corrected to correspond to the approximate time of the observation at the principal meridian to which the Almanac refers.

In star observations for time, the Hour Angle found and reduced to time is deducted from or added to the Right Ascension of the star (deducted from if before the meridian transit, but added to if after), this gives the Sidereal Time of observation. Take the Right Ascension of the Mean Sun for the previous noon from the Almanac, and correct this to the meridian of the place of observation; this deducted from the Sidereal Time of observation, and the difference reduced to Solar Time, will give the Mean Time of the observation.

		h. m. s.
E.g., suppose Hour Angle found after transit of meridian .		4 30 24
Right Ascension of star		8 10 43
Sidereal Time at observation		12 41 07
	h. m. s.	
R.A. Mean Sun	1 35 28	
Correction for longitude 8 h. 54 m. West	+ 38	
		1 36 06
Interval in Sidereal Time from Mean Noon		11 05 01
Correction of interval, Sidereal to Mean Time . .		− 1 49
Mean Time of observation		11 03 12

The horizontal circle reading of the azimuth found as above should be corrected for the inclination of the horizontal axis of the vertical circle as denoted by the reading of the cross striding level; the difference of level in seconds of arc multiplied by the tangent of the altitude taken will give the correction to the horizontal circle reading this being added if the left-hand pivot is highest, and subtracted if the right-hand pivot is highest. The circle reading of some distant well-defined object should be used as a Reference Point to which the azimuth observed will then be connected.

In a series of observations where the sun has been utilised in the daytime, and it is desired to connect up a series of observations on stars, the adjustment of the instrument should be carefully gone over after sundown, and when the instrument has attained an even temperature, the Reference Point being utilised to check the results of the day observations with those of the night.

The degree of accuracy of the results will depend upon the care taken to eliminate slight errors in the data assumed or instrumental defects. In the case of observations for time, the taking of the mean of a combination of A.M. and P.M. observations will to a great extent eliminate the slight errors that may be due to instrumental defects, incorrect latitude assumed, or almanac corrections to date. The same remarks apply also to Azimuth except that the cross level error can only be eliminated by observations taken with reversed positions of vertical axis. In observations for latitude the errors of the instrument can be to a great extent corrected by taking the mean of meridian observations on stars to the north and to the south of the zenith.

Example (in time and azimuth; P.M. observation). Data: latitude (l) 53° 29′ 05″ N.; corrected declination, 0° 35′ 13″ S.; corrected altitude of the sun's centre (a) 20° 37′ 18″; polar distance (p) 90° + 0° 35′ 13″ = 90° 35′ 13″.

To Find Azimuth from Greatest Elongation of Circumpolar Stars.

At instant of greatest elongation :—

$$\sin \text{Azimuth} = \cos d \sec l;$$
$$\cos \text{Hour Angle} = \tan l \cot d;$$
$$\sin \text{Altitude} = \sin d \operatorname{cosec} l.$$

The Hour Angle, reduced to time, is added to the Right Ascension of the star if the Greatest Elongation is to the west of the meridian, or subtracted if to the east; this will give the Sidereal time of the Greatest Elongation. The sidereal time of the mean sun's passage of meridian for the succeeding noon subtracted from this will give the sidereal interval of time from noon, which, reduced to mean time, will give the Mean Time of Greatest Elongation. The altitude at Greatest Elongation is useful in setting the instrument for the observation.

Without knowledge of the latitude the Azimuth may be obtained from two observations on stars, one to the east, the other to the west of the meridian, and from the horizontal angle between them, which will be the sum of their Azimuths. Let this angle be denoted by $(A + A_1)$, and let d and d' be the respective declinations of the stars used, then,

$$\tan\left(\frac{A - A_1}{2}\right) = \tan\frac{d + d_1}{2} \times \tan\frac{d - d_1}{2} \times \tan\left(\frac{A + A_1}{2}\right),$$

giving the half difference of Azimuths, which added to and subtracted from the half sum of Azimuths will give A and A_1 respectively. The latitude can then be computed from one of the Azimuths and found by formula

$$\cos l = \cos d \operatorname{cosec} A.$$

Example.—Taking stars β Crucis (d_1 = 59° 06′ 30″ S.); γ Hydri (d = 74° 33′ 59″ S.); angle between their Greatest Elongations 57° 33′ 33″ ($= A + A_1$).

	° ′ ″	
$\frac{d + d_1}{2}$ =	66 50 14½	l tan 0·36874
$\frac{d - d_1}{2}$ =	7 43 44½	l tan 9·13264
$\frac{A + A_1}{2}$ =	28 46 46½	l tan 9·73980
$\frac{A - A_1}{2}$ =	9 53 05	l tan 9·24118
	± 28 46 46½	
Greatest Elongation γ Hydri	18 53 41½	
β Crucis	38 39 51	

The latitude may then be calculated as follows, from γ Hydri :—

Azimuth	18° 53′ 41½″	*l* cosec	0·48968
d	74 33 59	*l* cos	9·42508
		l cos	9·91476
latitude =	34 43 55 S.		

To reduce Mean Solar Time intervals to Sidereal Time intervals (approximate).

Reduce interval into hours and decimals of an hour, multiply by 10 and diminish product by $\frac{1}{70}$; the result will be correction in seconds to be *added* to Mean Time interval.

	h. m. s.		
EXAMPLE.	16 30 18 M.T.	$16{\cdot}505 \times 10 = 165{\cdot}05$	
Correction +	2 42·7	$-\frac{1}{70}$	2·36
	16 33 00·7 Sidereal T.		162·69 sec
			= 2 m. 42·69 sec.

To reduce Sidereal to Mean Time intervals.

Reduce intervals into hours and decimals of an hour, multiply by 10 and diminish product by $\frac{1}{60}$; the result will be correction to be *subtracted* from Sidereal Time interval.

	h. m. s.		
EXAMPLE.	16 33 00·7 Sid. T.	$16{\cdot}5502 \times 10 = 165{\cdot}50$	
Correction −	2 42·7	$-\frac{1}{60}$	2·76
	16 30 18 M.T.		162·74 sec.
			= 2 m. 42·74 sec.

The error in using these approximations will be less than $\frac{1}{10}$ second in a 24-hour interval.

To Find Longitude by Moon Culminating Stars.

This is a convenient method for determining the longitude when the Mean Time at Greenwich cannot be obtained by wireless time signals, the only requirements being a well-adjusted transit theodolite, a watch the rate of which can be depended upon for a short interval of time but the actual error of which need not be known, and a Nautical Almanac.

The moon varies comparatively rapidly in Right Ascension (R.A.), but its R.A. at the instant of its transit across the plane of the meridian can be accurately determined by comparing its time of transit with that of a star or stars which pass the meridian about the same time.

The theodolite is adjusted with its line of collimation in the plane of the meridian by the aid of one of the methods before described for obtaining azimuths; the time of transit, over the centre thread, of the selected stars of reference and the moon's bright limb are carefully noted.

The intervals (reduced to Sidereal Time) between the times of transit of the respective stars and the time of transit of the moon's bright limb, added to the R.A. of the respective stars (in the case of stars which transit before the moon), or subtracted from the R.A. of any stars which transit after the moon, will give the R.A. of the moon's bright limb at the instant of its transit over the meridian.

We have, under the heading of 'Moon at Transit at Greenwich,' the R.A. of the moon's bright limb at its transit at Greenwich, and also the variation of the Moon's R.A. in one day expressed in seconds; the difference between the R.A. of the moon's bright limb when passing the meridian of Greenwich and the R.A. as found when passing the meridian at the place of observation gives the change of R.A., and this difference (reduced to seconds), being divided by the variation corresponding to one hour difference of longitude, will give the difference of longitude between Greenwich and the place of observation expressed in hours and fractions of an hour.

From the table 'Apparent places of Stars' in the Nautical Almanac there must be selected convenient pairs of stars which transit within half an hour or so of the time of transit of the moon, and which have a declination nearly that of the moon, so that a slight movement of the telescope of the instrument in altitude will bring them within its field. As these stars are generally of small magnitude and not easily distinguishable it is advisable to (approximately) calculate the altitude at which they cross the meridian; the instrument may then be set in advance so that the star will cross approximately in the centre of the field. The moon's right ascension at the moment of transit will be found in the Nautical Almanac under the heading: 'Moon: at Transit at Greenwich.'

When the longitude of the place of observation differs considerably from that of Greenwich the 'variation for one hour' given in the tables should be corrected by interpolation to correspond to the approximate middle interval of time between the transit at Greenwich and that of the observed transit.

Let

t_1 t_2 be the observed times of transit of the star and the moon's bright limb;

RA_1 RA_2 be the Right Ascensions of the star and the moon's bright limb taken from the catalogue;

c the hourly variation (corrected, if necessary, to the middle time);

then the longitude in time $= \dfrac{(t_1 - t_2) - (RA_1 - RA_2)}{c}$,

the interval $(t_1 - t_2)$ if in Mean Time must be reduced to Sidereal Time,

$(RA_1 - RA_2)$ must be expressed in seconds,

the longitude will be expressed in hours and fractions of an hour, and to the west if positive and to the east if negative.

Timing Observations.

When working with an assistant the time may be noted at the instant a signal is given by the observer, but when observing alone it is difficult to note the exact time of contact or transit on watch or chronometer when the hands are employed in manipulating the instrument and the eye engaged in taking the sight.

In this case a convenient method is to use a watch whose time of beat is known (in modern watches usually $\frac{1}{5}$ second); this watch should be in such a position that the beats are distinctly heard, for example, suspended over the ear from the cap, in a small bag or watch pocket. The beats are then counted from the instant of contact or transit and continued until the seconds finger of the standard timepiece can be noted on some convenient second; this time noted, less the number of beats of the auxiliary watch, reduced to seconds and fractions, will be the actual time of the observation.

As probably some little time may elapse after the observation before the standard timepiece can be read, especially at night where a lamp has to be used, this extended counting of beats of say $\frac{1}{5}$ second becomes difficult when arriving at the double syllable numbers; but by adding a 'dummy' syllable to the first twelve counted and then continuing with 'thir-teen,' 'four-teen,' and so on, giving one syllable to each beat, the counting of $\frac{1}{5}$ seconds becomes quite easy, even, if carried to 100 beats and over, e.g. taking the dummy syllable as 'and,' and starting the instant of observation with 'nought,' the counting would continue:—'nought-and,' 'one-and,' 'two-and,' 'three-and,' . . . ''leven-and,' 'twelve-and,' 'thir-teen,' 'four-teen,' . . . 'twen-ty, 'twent'-one,' and so on. Then taking the first syllable as units and the second syllable as half, the counted beats multiplied by 4 and divided by 10 will give the required intervals in seconds and tenths, in the case of the auxiliary watch beating fifths of seconds.

Taking examples, say the beats counted between the instant of observation and the time noted on the timepiece was on the first syllable to thirty-seven, the time at that beat being 3 hrs. 47 mins. 15 secs.; then the interval to be deducted would be $\dfrac{37 \times 4}{10} = 14 \cdot 8$ seconds, and the corrected time of the observation would then be 3 hrs. 47 mins. 15 secs. $- 14 \cdot 8$ secs. $=$ 3 hrs. 47 mins. $0 \cdot 2$ secs. In another case, say the second syllable of 'nine-and' corresponded to 6 hrs. 22 mins. 55 secs. on the timepiece, the correction would then be $\dfrac{9\frac{1}{2} \times 4}{10} = 3 \cdot 8$ seconds, and the corrected time of observation 6 hrs. 23 mins. 55 secs $- 3 \cdot 8$ secs. $=$ 6 hrs. 23 mins. $51 \cdot 2$ secs.

This method of measuring short intervals of time is useful in other instances; for example, in estimating distacces by the velocity **of sound, etc.**

Graphic Method of finding Time and Azimuth from Altitude of Sun or Star.

Describe a circle, fig. 20, of any convenient radius; through the centre O draw diameter MOM_1. From O draw PO making angle POM equal to the latitude; draw OQ at right angles to PO. Through O draw OA, making AOM equal to the corrected altitude, and OD, making DOQ equal to the corrected declination, and on the side of OQ towards P if the declination and latitude are of the same name, or on the opposite side if of different names.

Through A draw AA_1 parallel to MM_1 and through D draw DD_1 parallel to QO, intersecting AA_1 in *s*.

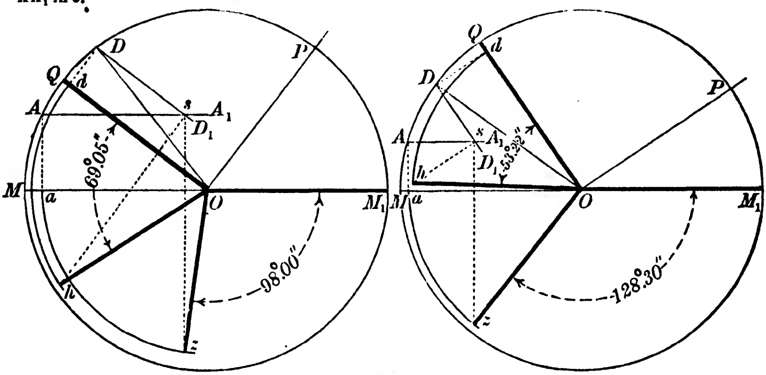

Fig. 20.

Data.	Result.	Data.	Result.
Lat. 53° 30′ N.	Azimuth N. 98° 00′ W.	Lat. 34° 30′ S.	Azimuth S. 128° 30′ W.
Dec. 14° 50′ N.	Hour Angle 69° 05	Dec. 19° 50′ N.	Hour Angle 53° 22′
Alt. 24° 20′ P.M.		Alt. 15° 40′ P.M.	

To find the Azimuth.

Drop a perpendicular from A to OM, intersecting this latter in *a*; from centre O and radius O*a* draw arc *as*, and from *s* draw *sz* perpendicular to MOM_1, intersecting arc *as* in *z*; through *z* draw O*z*. Then the angle M_1Oz will represent the azimuth from the elevated pole east or west of the meridian according as the time (A.M. or P.M.) at which the observation was made.

To find the Hour Angle.

Draw D*d* at right angles to QO, and with centre O and radius O*d* draw arc *dh*; from *s* draw line *sh* perpendicular to QO, intersecting arc *dh* in *h*; draw line O*h*. Then QO*h* will be the hour angle at the time of observation before or after apparent noon.

This diagrammatic method may be utilised for approximate determination of other problems, such as azimuth and time of sun or stars at instant of rising or setting; altitude and azimuth at a given time; or for altitude and time of passing prime vertical.

Geodetic Formulæ.

From measurements made of various meridians and parallels it has been found that the earth has the form of an ellipsoid of revolution with its greatest diameter at the equator and its least between the poles; and that the radius of curvature of the meridian varies with the latitude, being least at the equator and greatest at the poles, so that the length of a degree of latitude is more at the poles than at the equator. The length of a degree of longitude varies also with the latitude, being greatest at the equator and zero at the poles.

In treating with measurements of an extensive character over the surface of the earth, it is necessary to take into account its ellipsoidal shape, and it is convenient to employ certain approximations, so that spherical trigonometry may be used in the solution of the problems involved. The following formulæ enable the radius of a spherical surface to be found that approximates most nearly to the ellipsoidal surface embracing the area under consideration.

In these formulæ

a = the equatorial radius of the earth; e = the eccentricity; ϕ = the mean latitude; A = the azimuth.

Radius of curvature of meridian $= Q = \dfrac{a(1-e^2)}{\sqrt{(1-e^2\sin^2\phi)^3}}$

Radius of curvature of normal section perpendicular to meridian $= N = \dfrac{a}{\sqrt{(1-e^2\sin^2\phi}}$.

Radius of curvature of a normal section which cuts meridian at an angle A

$$= \frac{QN}{Q \sin^2 A + N \cos^2 A}.$$

Radius of curvature of an area of the earth's surface, or mean curvature $= \sqrt{QN}$.

Radius of a parallel of latitude $= N \cos \phi = \frac{a \cos \phi}{\sqrt{1 - e^2 \sin^2 \phi}}$

The logarithms of the most probable values of the constants used above are as follows (taking a in statute miles):—

$$\log. a = 3{\cdot}59806. \quad \log. e^2 = 7{\cdot}83047. \quad \log. (1 - e^2) = 9{\cdot}99853.$$

Adopting the radius which most nearly corresponds to the surface considered at the mean latitude ϕ, any measured length l on this surface may be reduced to arc by one of the following formulæ, ρ being the radius adopted reduced to the same unit as l:—

$\frac{l \times 57{\cdot}2958}{\rho}$ in degrees of arc; $\frac{l \times 3437{\cdot}747}{\rho}$ in minutes of arc; $\frac{l \times 206265}{\rho}$ in seconds of arc.

The table on page 262, 'Length of a Degree of Longitude and Latitude,' is calculated from the accepted dimensions of the earth. Values for intermediate latitudes may be obtained from this table, by interpolating, with sufficient exactitude for most purposes. The length of a degree on a great circle at right angles to the meridian at a given latitude may be obtained by multiplying the length of a degree of longitude (as taken from the table) by the secant of the latitude.

Convergence of Meridians.

In traverses and route surveys, a survey line is referred to a meridian at a certain point crossing the meridian with an azimuth A, this line, if continued in the same direction, having increased or diminished azimuths. The differences of azimuth can be approximately determined by calculating the convergence of the meridian corresponding to a given unit departure at the mean of the latitudes, and multiplying this by the departure as calculated from the traverse. To obtain the azimuth on crossing the second meridian, the convergence obtained in the manner just explained is added to or subtracted from the azimuth crossing the first meridian, being added where the longitude is increased and subtracted where the longitude is diminished.

The convergence, corresponding to various unit lengths of departure, may be calculated by the following formulæ, with sufficient approximation for use in ordinary traverse surveying. The length of a degree of longitude corresponding to the mean latitude is taken in miles from table, page 262, interpolating if necessary; then :—

Log. of convergence in seconds per mile of departure

$= \log. \sin \phi + 3{\cdot}55630 - \log.$ miles per 1° longitude.

Log. of convergence in seconds per 1,000 feet of departure

$= \log. \sin \phi + 2{\cdot}83367 - \log.$ miles per 1° longitude.

Log. of convergence in seconds per 1,000 metres of departure

$= \log. \sin \phi + 3{\cdot}34966 - \log.$ miles per 1° longitude.

To range a parallel of latitude by setting out chords of a given length :—

The chords are ranged making an angle to the meridian of 90° − half the angle of convergence corresponding to the length of the chord at the proposed latitude. The succeeding chords will have an angle of deflection from the preceding chord produced, equal to the convergence corresponding to the length of chord used.

To range a parallel of latitude by means of offsets :—

A line is run, perpendicular to the meridian, then the lengths of offsets are equal to the distances along this perpendicular line multiplied by the sine of half the angle of convergence corresponding to the lengths.

If the offsets are equidistant the length of the second offset will be four times the length of the first; the third, nine times the first, and so on; the n^{th} offset will be n^2 times the length of the first.

Horizontal Sun Dial.

On a line NS, fig. 21, mark off a convenient length NO; from O set off a line towards L making an angle NOL equal to the latitude of the position (taken in diagram 53° 30′), and from N draw a perpendicular to OL, cutting the latter in point L. From N and with length NL mark off a point C in the line NS, and with C as centre and the same length NL as radius describe the quadrant NQ and join NQ with a straight line.

Divide the quadrant NQ into six equal parts (each corresponding to one hour) and from these divisions on the arc draw lines towards the centre C and mark the points at which these radial lines cross the line NQ.

From O draw a line perpendicular to NS and mark off OE equal to CQ and join NE.

From each division on line NQ draw a line paralle' to NS, marking where this line crosses the line NE in each case.

Then lines drawn from O through each of these points, marked off in NE, will be the dial lines corresponding to the hour divisions on the quadrant from which they were found respectively.

Having completed the divisions of one quadrant, these angles may be transferred to the other quadrants but in reverse order (VI–VII equals VI–V, VI–VIII equals VI–IIII, and so on).

An allowance must be made for the thickness of the style between the AM and PM portions of the dial, the AM dial being exactly similar to the PM dial but drawn with the XII lines the thickness of the style apart.

The style is constructed with the angle of inclination of the inclined face equal to the latitude of the site, its lower point at O and its upper towards the elevated pole, so that its

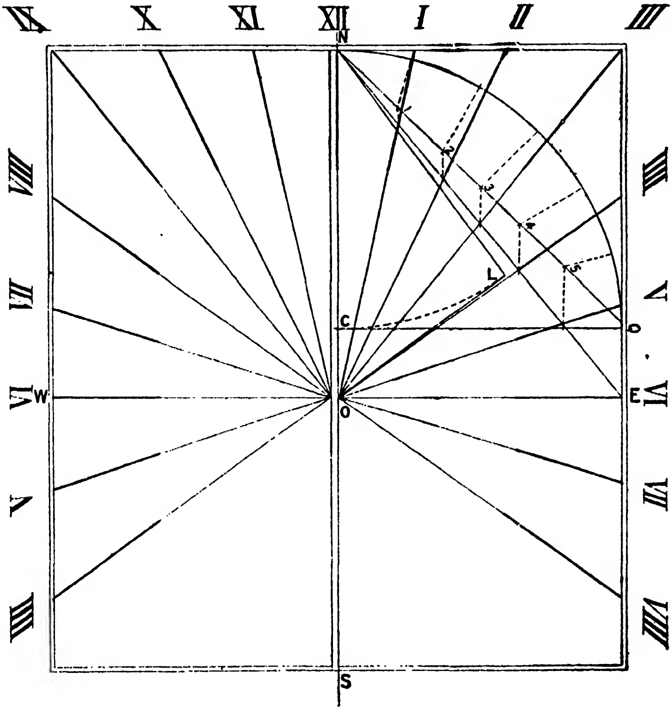

FIG. 21.

plane is in that of the meridian, the XII (noon) lines pointing towards the north in northern latitudes or towards the south in southern latitudes, and the VI–VI lines pointing east and west, so that the upper face of the style will be parallel to the Polar axis. The plane of the dial should be perfectly level.

(Methods of fixing the direction of the true north and south line will be found on page 261.)

The time indicated by the dial is sun time, and to get mean time the table of Equation of Time, page 261, should be applied as there directed. To arrive at standard time a constant correction must be applied according to the difference of longitude between the dial and the standard meridian (Greenwich in Great Britain) adopted in the country (subtracted if to the east or added if to the west).

The dial angles may be calculated if preferred by formula

$$\tan t = \sin l \tan h$$

where

t = angle at O from NO to the hour line on dial corresponding to h; l = latitude of position; h = hour angle.

SOURCES OF INFORMATION.

TIMBER — SEASONING — PRESERVING — STRENGTH PROPERTIES.

(Revised by Forest Products Research Laboratory.)

TIMBER.

In all specifications for building materials and construction, it is customary to use the terms 'Timbering,' 'Joiners' work,' and 'Cabinet work.' The first-named applies only to the wood used in constructional work. These terms are again subdivided into the following :—

Baulks.—Pieces of sawn or hewn timber of equal or approximately equal cross dimensions of greater size than 4 ins. × 4½ ins.

Planks. (softwood)—Pieces of square-sawn timber 2 ins. to 4 ins. in thickness by 11 ins. and over in width.

Planks (hardwood).—Pieces of square-sawn timber 2 ins. and over in thickness by 6 ins. and over in width.

Deals.—Pieces of square-sawn softwood timber 2 ins. to 4 ins. in thickness by 9 ins. to under 11 ins. in width. Thicknesses less than this are termed boards.

Battens.—Pieces of square-sawn softwood timber 2 ins. to 4 ins. in thickness by 5 ins. to 8 ins. in width, inclusive.

Boards.—Pieces of square-sawn softwood timber under 2 ins. in thickness by 4 ins. or over in width.

Scantlings.—Pieces of square-sawn softwood timber 2 ins. to 4 ins. in thickness × 2 ins. to 4½ ins. in width, inclusive.

Squares.—Pieces of strictly equal-sided sawn timber of any stated square dimension.

Timber Measures.

BAULKS AND TIMBER.—Sold at per load of 50 ft. cube. Deals, planks, battens, and scantlings at per Leningrad standard. (One standard = 165 ft. cube.)

PREPARED FLOOR BOARDS.—These are usually sold at per square. This is a standard measurement which equals 100 ft. superficial. Till recently it was the trade custom to supply a specific number of feet according to the width of the board, which should approximate to the square. These were as follows :—

4-in. boards	300 ft.	6-in. boards	200 ft.
4½ „	270 „	6½ „	190 „
5 „	240 „	7 „	180 „
5½ „	220 „		

This practice, which was always unsatisfactory owing to the inaccuracy of the figures, has now been discontinued.

LUMBER (see above) AND AUSTRALIAN WOOD.—Sold at per 1,000 ft. of 1-in. superficial measure for all thicknesses of 1 in. and over. Under 1 in. at per 1,000 ft. superficial of their thicknesses. Teak at per load of 50 cub. ft.

Descriptions of Timbers.*

(For specific quantities and weights per cub. ft., see Section V, Part II, pp. 123–124.)

ALDER, COMMON or BLACK (*Alnus glutinosa*).—Europe, including British Isles. A soft non-durable timber closely resembling birch. Light reddish-brown. Imported in the form of plywood; also used for turnery.

APITONG or BAGAC.—For description see GURJUN.

ASH, EUROPEAN (*Fraxinus excelsior*).—Europe, including British Isles. A straight-grained wood nearly white in colour, chiefly remarkable for its outstanding toughness and resistance to shock loads. A good bending timber. Used for motor vehicle framing, under-framing and bent work; aircraft construction; shafts and agricultural implements; handles of picks, shovels, etc.; sports goods.

ASH, AMERICAN WHITE (principally *Fraxinus americana*).—North America. Similar to English ash but generally considered inferior for aircraft construction, sports goods and other work where bending properties of a high order are required.

ASH, JAPANESE (*Fraxinus mandshurica*).—Japan. Similar to European and American white ash but not so strong. Used mainly for interior fittings, cabinet work and plywood.

BAGAC or APITONG.—For description see GURJUN.

BALSA (*Ochroma lagopus*).—Central and South America. The lightest timber in general use, varying from as little as 2½ lb. per cub. ft. to 20 lb. or more. The lighter grades are very soft and spongy. Nearly white in colour. Used for model aeroplanes, fairings in certain types of aeroplanes, floats, sound and heat insulation, etc.

BASSWOOD (principally *Tilia americana*).—North America. A soft, non-durable timber, nearly white to pale brown in colour. Used for turnery, cabinet work and especially pianoforte manufacture.

BEECH, EUROPEAN (*Fagus sylvatica*).—Europe, including British Isles. A straight-grained wood with a fine even texture. The natural colour is a light reddish-brown; the wood is often steamed, giving it a darker reddish colour. Comparable to oak in strength but not durable in exposed situations. A good bending timber. Used for a great variety of purposes, including furniture and cabinet making; automobile bodies; general turnery; bent work; parts of textile and other machinery; pianoforte manufacture.

BIRCH, EUROPEAN (*Betula pubescens* and *B. pendula*).—Europe, including British Isles. A fairly straight-grained, fine-textured wood, white to light brown in colour. Large quantities are imported in the form of plywood. It is also widely used for turnery.

BIRCH, CANADIAN YELLOW (principally *Betula lutea*).—North America. Somewhat heavier than European birch and darker in colour, light to dark reddish-brown. Extensively used for chair-making, furniture parts, framing for upholstered work, kitchen utensils, tool handles and general turnery; also for automobile bodies; flooring and general utility work.

BLACK BEAN (*Castanospermum australe*).—Australia. A handsome decorative timber, greyish-brown in colour. Used for cabinet work and panelling.

BLACKWOOD, AUSTRALIAN (*Acacia melanoxylon*).—Australia. A handsome reddish-brown timber marked with darker streaks. Used for interior decorative work.

BOXWOOD (*Buxus sempervirens*).—Europe (including British Isles) and Asia Minor. Exceedingly hard and fine-textured. Used largely for blocks for wood engraving, turnery and mathematical instruments. Other commercial boxwoods are West Indian boxwood (*Gossypiospermum praecox*), Knysna or Kamassi boxwood (*Gonioma kamassi*), and Cape boxwood (*Buxus macowani*), both from South Africa.

CAMPHORWOOD, BORNEO or KAPUR (various species of *Dryobalanops*).—Borneo and Malaya. A light reddish-brown constructional timber, closely resembling gurjun (*q.v.*) and used for similar purposes.

CAMPHOR, EAST AFRICAN (*Ocotea usambarensis*).—East Africa. A cabinet timber of pleasing appearance, darkening on exposure to a deep brown colour. Used for interior decoration work and fittings.

CEDAR, BORNEO.—See SERAYA.

CEDAR, CENTRAL AMERICAN (principally *Cedrela mexicana*).—Central America and West Indies. A soft, reddish, fragrant wood, somewhat resembling the lighter grades of true mahogany. Used for cigar and cigarette boxes and also for boat-building, cabinet work and joinery.

* More detailed descriptions of most of these timbers may be found in the official publications of the Forest Products Research Laboratory (Department of Scientific and Industrial Research) entitled 'Home Grown Timbers' and 'Empire Timbers,' obtainable from H.M. Stationery Office, York House, Kingsway, W.C. 2, or through any bookseller.

A more complete list of timbers used in Great Britain, their trade names, botanical names, and sources of supply, may be found in British Standard No. 881—1939 (Nomenclature of Hardwoods) and British Standard No. 589—1935 (Nomenclature of Softwoods), obtainable from the British Standards Institution, Publications Department, 28 Victoria Street, London, S.W. 1.

CEDAR, PORT ORFORD (*Chamaecyparis lawsoniana*).—North America. A high grade softwood with a strong cedar scent. Durable in exposed situations and resistant to acids. Used for interior fittings, furniture (especially for lining clothes chests) and for battery separators.

CEDAR, WESTERN RED (*Thuja plicata*).—North America. A reddish-brown, non-resinous, light-weight softwood noted for its outstanding durability under all conditions. Used for roofing shingles, weather-boarding, glass-house construction, and also for interior joinery work and cabinet making.

CHESTNUT, SWEET or SPANISH (*Castanea sativa*).—Europe, including British Isles. Resembles oak, from which it may be distinguished by the absence of the silver-grain figure. Lighter in weight and not so strong as oak. Durable. Used for many of the same purposes as oak. Timber from old trees is often spiral-grained and liable to ring-shake.

CHUGLAM, WHITE, and INDIAN SILVER-GREY WOOD (*Terminalia bialata*) are two varieties of timber furnished by the sapwood and heartwood respectively of the same species. White chuglam is a general utility hardwood. Indian silver greywood has a fine ornamental figure and is used for interior decorative work and panelling.

CRABWOOD or ANDIROBA MAHOGANY (*Carapa guianensis*).—Tropical South America. Closely related to true mahogany and resembling a plain mahogany in appearance and general properties. Somewhat heavier and darker in colour than average Honduras mahogany. Used as a substitute for mahogany.

DEAL, RED or YELLOW.—See REDWOOD, BALTIC.

DEAL, WHITE.—See WHITEWOOD, BALTIC.

DOUGLAS FIR.—See FIR, DOUGLAS.

EBONY (various species of *Diospyros*).—India, Ceylon, East Indies, Tropical Africa. The different kinds of ebony vary from brown, streaked with grey and black, to jet black. They are all heavy, hard and close-textured. Principally used for turnery, and also in the form of veneer for cabinet work.

ELM, COMMON ENGLISH (*Ulmus procera*).—British Isles. Elm is inclined to be cross-grained and has a corresponding tendency to warp. High temperature steaming treatment is effective in reducing this tendency, and timber so treated can be used successfully for furniture and interior fittings. A fairly strong, tough timber, somewhat inferior to oak in all strength properties. Durable under water and excellent for piles or dock and wharf construction. Other typical uses are for coffin boards; ends of packing cases and boxes; carts, wheelbarrows and wagons; furniture, chiefly chairs; barge and boat-building; sea groynes; agricultural buildings in the form of weather-boarding.

ELM, ROCK (*Ulmus thomasi*).—North America. A tough, dense wood, strong and durable; especially useful in resisting abrasion. Chiefly used in dock and wharf construction and as fenders, ships' belting, and in the construction of rowing boats and other small craft. Also for bent work as in motor body and railway carriage roofs.

ELM, WYCH (*Ulmus glabra*).—British Isles. Superior to other species of home-grown elm, being straighter in the grain and not so coarse-textured. Bends well and approaches ash in toughness. Used in chair-making, boat-building, for shafts and agricultural implements.

ENG or IN (*Dipterocarpus tuberculatus*).—Burma. A constructional timber very similar to gurjun (*q.v.*) but appreciably heavier and correspondingly harder and stronger.

FIR, DOUGLAS (*Pseudotsuga taxifolia*).—North America. Also known as OREGON PINE and COLUMBIAN PINE. A general utility softwood, usually straight-grained, moderately resinous. Slightly denser than Baltic redwood. Its more than average strength, combined with the large sizes in which it is available, renders it eminently suitable for heavy constructional work. The dense grades compare favourably with the best pitch pine. It is also used for interior fittings, joinery and a great number variety of similar uses.

FIR, SILVER (*Abies alba*).—Europe, including British Isles. Similar to European spruce and marketed with that timber as WHITEWOOD (*q.v.*).

GABOON or OKOUMÉ (*Aucoumea klaineana*).—Gaboon and Spanish Guinea. Also known as Gaboon mahogany. Not a true mahogany, but widely used as a mahogany substitute, principally in the form of plywood and lamin-board.

GREENHEART (*Ocotea rodiaei*).—British Guiana. A timber of outstanding strength and durability, especially in sea water, straight-grained and remarkably free from knots and other defects. Eminently suitable for marine work, piles, dock-gates and wharf construction. Also a first-class ship-building timber.

GURJUN, KERUING, APITONG or BAGAC and YANG (various species of *Dipterocarpus*).—Gurjun is the usual trade name for the timber of this group of species from Burma and the Andaman Islands. The corresponding species from Malaya and Borneo are known as keruing. Apitong or bagac from the Philippine Islands and yang from Siam belong to the same class. The timbers of this group are nearly indistinguishable for practical purposes. They are useful constructional timbers obtainable in large sizes. Used in railway wagon and carriage construction, in buildings as a substitute for oak and for parquet flooring.

HEMLOCK, WESTERN (*Tsuga heterophylla*).—British Columbia. A non-resinous softwood timber, typically straight-grained and of fairly even texture, superior in these respects to Eastern hemlock (*Tsuga canadensis*). Similar in strength properties to Douglas fir but not quite so strong. Not durable in exposed situations. Useful as a building material and for interior work generally. Also for boxes and crates, especially for foodstuffs.

HICKORY (various species of *Carya*).—North America. Exceedingly tough, hard, smooth and straight-grained. Principally used for spokes and rims of wheels, tool handles, machine parts, etc. White and red hickory are respectively the sapwood and heartwood of the same tree.

HORNBEAM (*Carpinus betulus*).—Europe, including British Isles. A hard, strong, tough timber, superior to oak in all strength properties, equal to ash in resistance to shock. Turns well and takes a very smooth finish. Used for cogs, wood screws, mallets, tool handles and other small articles, also for piano work and for flooring.

HORSE CHESTNUT (*Aesculus hippocastanum*).—Europe, including British Isles. Creamy-white with a fine, uniform texture. Not strong or durable. Used for turnery, dairy and kitchen utensils, etc.

IN.—See ENG.

IROKO (*Chlorophora excelsa*).—West and East Africa. A useful constructional timber, similar to home-grown oak in strength. Fairly durable and of good appearance, being light to dark brown in colour. Suitable for joinery and building work.

JARRAH (*Eucalyptus marginata*).—Western Australia. A heavy, hard, dark red timber with high mechanical properties and unusual durability. Obtainable in large dimensions and used for heavy structural work, in railway wagon building and for flooring.

KAPUR.—See CAMPHORWOOD, BORNEO.

KARRI (*Eucalyptus diversicolor*).—Western Australia. A high class constructional timber very similar to jarrah in appearance and properties but slightly stronger and not so durable. Suitable for structural work where strength, long lengths and large cross sections are required. For underground work or in damp situations preservative treatment is necessary.

KAURI (various species of *Agathis*).—New Zealand, Australia, etc. A valuable softwood timber with a fine, even, silky texture and a lustrous surface. Very strong for its weight; durable. The best variety is from New Zealand. Queensland kauri is lighter and softer. Other species occur in the islands of the Pacific. Kauri is obtainable in large sizes and is used for vat-making; also for deck planking and high-class joinery.

KERUING.—See GURJUN.

LARCH (*Larix decidua*).—Europe, including British Isles. The most valuable home-grown softwood on account of its strength and durability. Used for gates and fencing, mine timber, and out-door work generally.

LAUAN.—For description see SERAYA.

LAUREL, INDIAN (*Terminalia alata*, *T. crenulata*, and *T. coriacea*, formerly known as *T. tomentosa*).—India and Burma. A handsome walnut-brown timber figured with irregular streaks of darker colour. Used for high grade interior decorative work, such as panelling, doors, staircases, etc.

LIGNUM VITÆ (principally *Guaiacum officinale*).—West Indies. One of the hardest and heaviest timbers in commercial use. Heartwood dark greenish-brown to nearly black in colour, sharply defined from the yellowish sapwood. Used as bearings for propellor shafts for steamers on account of its natural lubricating property; also for mallets and turnery.

LIME, AMERICAN.—See BASSWOOD.

LIME, COMMON EUROPEAN (*Tilia vulgaris*).—Europe, including British Isles. A fine-textured, white or pale yellow wood, soft yet compact, cuts cleanly without splitting. Not durable. Excellent for carving; also used for turnery and parts of musical instruments including pianos.

MAGNOLIA (various species of *Magnolia*).—North America. A fairly soft, fine-textured, white wood, used in cabinet work, for mouldings and interior fittings.

MAHOGANY, AFRICAN (principally *Khaya ivorensis*).—Tropical Africa. Commercial consignments are commonly classified according to the port of shipment or district from which they are derived, *e.g.*, Lagos and Benin (Nigeria), Axim, Half-Assinie and Takoradi (Gold Coast), Grand Bassam (Ivory Coast), etc. Colour varies from a light pinkish-brown to a deep reddish shade. Grain usually interlocked, producing the characteristic stripe or roe figure of quarter-sawn stock. Texture somewhat coarser than Honduras mahogany and the wood is not so stable under varying conditions of atmospheric humidity. Obtainable in large sizes.

MAHOGANY, ANDIROBA.—See CRABWOOD.

MAHOGANY, CUBAN or SPANISH (*Swietenia mahagoni*).—West Indies. The original mahogany noted for its handsome appearance and remarkable stability. Denser and finer-textured than other commercial species of mahogany. Rarely used nowadays except for the finest furniture and interior decorative work, having been largely replaced by Honduras and African mahoganies.

MAHOGANY, GABOON.—See GABOON.

MAHOGANY, HONDURAS and CENTRAL AMERICAN (*Swietenia macrophylla*).—Central America. The same or a closely allied species supplies the bulk of the mahogany imported from other parts of Central and South America, including Mexico, Nicaragua, Peru and Brazil. Lighter and softer than Cuban mahogany. Colour varies from light yellowish-brown to a rick dark shade practically indistinguishable from Cuban mahogany. Grain tends to be interlocked but there is a good proportion of plain, straight-grained timber. Remarkably stable and does not shrink and swell as much as most woods. Used for furniture and interior decorative work; also for instruments of precision, aeroplane propellors, turnery, mouldings, printers' blocks, and superior joinery.

MAHOGANY, SAPELE (*Entandrophragma cylindricum*).—Tropical Africa. A decorative wood of the mahogany family, with a characteristic regular stripe or roe figure. Used almost exclusively in the form of veneer for interior decorative work and furniture.

MANSONIA (*Mansonia altissima*).—Tropical Africa. Resembles American black walnut and is used as a substitute for that timber.

MAPLE, ROCK or SUGAR (principally *Acer saccharum*).—North America. A light-coloured wood of fine, even texture; hard and strong. One of the best timbers for flooring and widely used for that purpose; also for interior decoration and for a variety of industrial uses where its hardness makes it particularly suitable.

MATAI (*Podocarpus spicatus*).—New Zealand. Technically a softwood, but its texture and general properties place it in the hardwood class for many practical purposes. Used for flooring.

MERANTI.—For description see SERAYA.

OAK, AMERICAN RED (*Quercus borealis* and other species).—North America. Differs from American white oak in being on the whole coarser in texture, less uniform in colour, not so strong or durable and generally inferior.

OAK, AMERICAN WHITE (*Quercus alba* and other species).—North America. Similar to European oak in appearance and general properties but subject to more variation in quality. Considered inferior to European oak for high-class work.

OAK, EUROPEAN (*Quercus robur* and *Q. petraea*).—Europe, including British Isles. The two species are not separated in practice. English oak is unexcelled by other varieties for constructional purposes demanding a combination of strength and durability. Various grades of Continental oak differ as regards their hardness, ease of working and general quality. Uses too well known to be enumerated.

OAK, JAPANESE (principally *Quercus mongolica* var. *grosseserrata*).—Japan. Is characterised by the open, porous texture of the wood and easy working properties. Obtainable in large sizes. Used principally for interior work and furniture.

OAK, SILKY (*Cardwellia sublimis*).—Australia. Not a true oak but has a somewhat similar appearance. Used for furniture and interior decorative work.

OAK, TASMANIAN (*Eucalyptus obliqua*, *E. regnans* and *E. gigantea*).—Australia. Not a true oak but has a passing resemblance to plain oak. Used principally for flooring as a substitute for true oak.

OBECHE or AFRICAN WHITEWOOD (*Triplochiton scleroxylon*).—West Africa. A soft, light, nearly white wood, comparable to poplar in strength. Works easily to a smooth finish and takes stains and paint well. Obtainable in large dimensions. Used principally in the furniture trade and for joinery.

OKOUMÉ.—See GABOON.

OLIVE, EAST AFRICAN (*Olea hochstetteri*).—East Africa. A highly decorative wood, light brown marked with irregular dark grey-brown veins or streaks of varying width. Used for flooring and ornamental purposes.

PADAUK, ANDAMAN (*Pterocarpus dalbergioides*).—Andaman Islands. A distinctively coloured wood of a rich handsome hue. Very strong, durable and hard wearing. Formerly employed for constructional work; now principally used (in the United Kingdom) for cabinet work and interior fittings and panelling in banks, offices, etc.

PADAUK, BURMA (*Pterocarpus macrocarpus*).—Burma. Rather harder and heavier than the better known Andaman padauk and used for similar purposes. Yellowish-red to brick-red.

PINE, CORSICAN (*Pinus nigra* var. *calabrica*).—Widely planted in the British Isles in recent years. Yields timber similar to Scots pine but with a wider sapwood zone and usually somewhat coarser in texture. Generally similar to the lower grades of imported deal or redwood and used for the same purposes.

PINE, JACK (*Pinus banksiana*).—Canada. Similar to Canadian red pine and Baltic redwood but inferior to the best grades of those timbers. Used for similar purposes.

PINE, PARANA (*Araucaria angustifolia*).—South America. A close-textured softwood with some resemblance to kauri. Heartwood often streaked with red.

PINE, PITCH (various species of *Pinus*).—Supplies from the Southern United States consist principally of longleaf pine (*Pinus palustris*), shortleaf pine (*P. echinata*), and loblolly pine (*P. taeda*), of which the first-named is considered the best. The three species are often indiscriminately mixed. The term Rosemary pine refers to coarse, fast-grown timber of inferior quality. Honduras pitch pine is *P. caribaea*. Pitch pine is strong, hard and heavy and is used principally for constructional work and to some extent for interior fittings.

PINE, RED (*Pinus resinosa*).—Canada. Similar to Baltic redwood and used for the same purposes.

PINE, SCOTS (*Pinus sylvestris*).—British Isles. The same species as imported redwood. Used for similar purposes.

PINE, SIBERIAN (*Pinus koraiensis* and *P. cembra* var. *sibirica*).—Siberia and Manchukuo. A softwood of fine texture, generally similar to Baltic redwood but the best grades are superior to corresponding grades of Baltic redwood. Used for general joinery work.

PINE, SUGAR (*Pinus lambertiana*) and PINE, WESTERN WHITE (*Pinus monticola*).—Western North America. Similar to the yellow or white pine of Eastern North America but slightly harder and stronger and obtainable in larger sizes. Used for high grade joinery, pattern-making, etc.

PINE, YELLOW or WHITE (*Pinus strobus*).—Eastern North America. A fine-textured softwood, straight-grained, easy to work, cutting cleanly in all directions of the grain. Shrinks and warps less than most softwoods. Used for superior joinery work of all kinds, pattern-making, etc.

POPLAR (various species of *Populus*).—Europe, including British Isles. Comparatively light and soft, straight-grained, rather woolly, not durable. Fairly tough and withstands rough usage without splintering. Used for the bottoms of carts and wagons, brake blocks, etc.

PYINKADO (*Xylia dolabriformis*).—Burma. A very hard, durable timber, used for heavy constructional work including marine structures.

REDWOOD, BALTIC, or RED or YELLOW DEAL (*Pinus sylvestris*).—Europe. The standard timber for housebuilding, carpentry and joinery, railway sleepers, scaffold and transmission poles, etc. Quality depends largely on growth rate and knottiness.

REDWOOD, CALIFORNIAN.—See SEQUOIA.

ROSEWOOD (various species of *Dalbergia*). Various tropical countries. Very hard and durable, usually brown in colour with darker brown or black markings. Used for turnery and ornamental work.

SEQUOIA or CALIFORNIAN REDWOOD (*Sequoia sempervirens*).—North America. A high grade softwood, red in colour, of light weight outstanding durability. Used for out-door constructional work and for interior fittings.

SERAYA, RED, with RED MERANTI and RED LAUAN (various species of *Shorea*).—Red seraya or Borneo red cedar is the usual trade name for the timber of this group of species from Borneo. The corresponding timbers from Malaya and the Philippine Islands are known as red meranti and red lauan respectively. They are largely used for interior constructional work, joinery, panelling, and as substitutes for mahogany in furniture. They are obtainable in large sizes.

SERAYA, WHITE, with YELLOW or WHITE MERANTI and WHITE LAUAN (various species of *Parashorea* and *Shorea*).—White seraya or Borneo white cedar is the usual trade name for timber of this group of species from Borneo. Yellow or white meranti and white lauan are the names for the corresponding timbers from Malaya and the Philippine Islands respectively. They are obtainable in large sizes and are used for constructional purposes and also for ships' decking, joinery, and furniture.

SPRUCE, CANADIAN (principally *Picea glauca*).—Eastern Canada. An almost white, straight-grained softwood, without appreciable odour or taste and only slightly resinous, closely resembling European spruce (Baltic whitewood). Not durable in exposed situations, used for general construction, boxes and packing cases, ladders, etc.

SPRUCE, SITKA (*Picea sitchensis*).—Western Canada and Western U.S.A. A high class light-weight straight-grained, softwood, non-resinous, odourless and tasteless. Remarkably strong and tough in proportion to its weight and with high elastic properties. Not durable in exposed situations. Used in aircraft construction and for masts, spars, oars and paddles.

SYCAMORE (*Acer pseudoplatanus*).—Europe, including British Isles. A fine-textured, lustrous, white or yellowish white wood, often finely figured. Used for rollers in the textile industries and for laundry work, mangles, etc.; also for furniture and decorative work.

TEAK (*Tectona grandis*).—Burma, India, Java, Siam, Indo-China. Combines the properties of durability, strength, moderate weight and hardness with a pleasing appearance. Used for a great variety of purposes including ship-building, railway carriage work and house-carpentry.

TEAK, RHODESIAN (*Baikiaea plurijuga*).—Rhodesia. A handsome reddish-brown wood finishing with a smooth, hard surface. Used principally for flooring. Not a true teak.

TURPENTINE (*Syncarpia laurifolia*).—Australia. A strong, heavy constructional timber used principally in marine engineering work.

WALNUT, AFRICAN (*Lovoa klaineana*).—West Africa. A handsome golden-brown wood of the mahogany family. Not a true walnut. Used for chair-making, cabinet work, panelling and high class joinery.

WALNUT, AMERICAN BLACK (*Juglans nigra*).—North America. Purplish or greyish brown. Used for much the same purposes as European walnut.

WALNUT, EUROPEAN (*Juglans regia*).—Europe, including British Isles. Greyish-brown, often finely figured. Used principally for furniture, cabinet work and interior decoration; also for gun and rifle stocks, air-screws and turnery.

Walnut, Queensland (*Endiandra palmerstonii*).—Australia. An ornamental wood resembling true walnut in appearance and used for similar purposes, principally in the form of veneer.

Whitewood, American, or Canary Whitewood, or Yellow Poplar (*Liriodendron tulipifera*).—North America. Pale yellow or greenish, soft, light, easily worked, takes a good polish and stains well. Used for interior joinery, mouldings, furniture parts, etc.

Whitewood, Baltic, or European Spruce (*Picea abies*).—Europe, including British Isles. Used in Scotland and the north of England for housebuilding, flooring and general joinery work, Baltic redwood being generally preferred for these purposes in the south. Slightly lighter in weight and not so durable as redwood.

Willow (various species of *Salix*).—British Isles. A light-weight, fairly soft, perishable wood. Used for cricket bats, artificial limbs, flooring, cart bottoms, crates, etc.

Yang.—For description see Gurjun.

Yew (*Taxus baccata*).—British Isles. Reddish-brown, very hard, and exceptionally durable. Barely used on account of difficulty in working, but sometimes employed for furniture, gateposts and fencing, and turnery.

Number of Cubic Feet in 1 ton of Timber.

Wood.	Cubic Feet per Ton.			
	Air-dry (15%)	Shipping dry (20%)	Green.	M.C. %.
Ash, European	51	49	43	46

Durability of Timber.

Resistance of Fungal Attack.—Fungi are low forms of plant life, comparatively few of which attack wood. These are, however, responsible for the major part of the destruction of timber. Fungi grow by means of hair-like threads termed hyphae, which travel through the wood, ultimately reducing it to powder. Under certain conditions they may form fruiting bodies which liberate minute spores to be blown about by the wind and spread infection. Fungi require certain conditions for development. They will not attack dry wood (under 20 per cent. moisture content) nor will they attack wood which is completely saturated. Consequently, practically all timber, whatever species, is extremely durable if kept dry (*e.g.* furniture), or if kept submerged (*e.g.* pier foundations and submerged piles). The durability of timber can only be compared, therefore, when it is under conditions favourable to decay. Under such conditions the following approximate classification gives the resistance of various species to fungal attack. In all cases it applies to the heartwood, the sapwood generally being much less resistant to attack.

High Resistance or very Durable.	Moderate Resistance or Moderately Durable.	Low Resistance or Non-Durable.
Oak, European	Scots pine	Spruce
Teak	Redwood	Beech
Pitch pine (Longleaf)	Douglas fir	Sycamore
Yew	Pitch pine (Shortleaf)	Maple
Larch	Elm	Ash
Jarrah	Red pine (Canada)	Birch
Pyinkado		Western hemlock
Western Red cedar		Poplar
Sweet chestnut		Willow
Greenheart		
Sequoia		
Teak (Rhodesian)		
Turpentine		

Dry rot is the name given to the decay of timber in buildings caused by the attack of various fungi, but in the majority of cases it is due either to the fungus *Merulius lacrymans*, *i.e.* the true dry rot fungus, or to *Coniophora cerebella*, the cellar fungus, which is only capable of attacking wood that is definitely wet. Outbreaks of attack are nearly always due to excess moisture coming in contact with the wood, and the most efficient way to prevent dry rot is by proper design and construction. Unseasoned timber should be avoided and all timber should be protected from ground moisture by efficient damp-proof coursing. All under-floor spaces should be well ventilated. Where there is any risk of timber becoming damp, a preservative should be used.

For further details, see 'Dry Rot in Wood,' Third Edition, price 1*s.* net, published by H.M. Stationery Office.

Resistance to Insect Attack.—The Common Furniture beetle may attack most species of wood, but the damage to external structural timbers is not of economic importance. It is frequently found attacking rafters, joists, floor boards and other structural timbers in buildings, particularly in old outhouses, barns and sheds where it may cause considerable damage, and is of course the main source of damage to old furniture. The Death-watch beetle (*Xestobium rufovillosum*) will attack old hardwoods, such as oak, elm, walnut, chestnut, alder, and is mainly found in old oak roofing timbers. Softwoods are unattacked except where in direct contact with seasoned hardwoods. The *Lyctus* Powder-post beetle attacks the sapwood of freshly seasoned hardwoods, mainly oak, ash, walnut, elm and hickory, and never attacks softwood. It is the most serious economic cause of damage to such hardwoods during seasoning and storage. Termites are the most serious cause of insect damage to timber in tropical countries. They are not active in temperate climates, and do not exist in the British Isles. There are many different species of termites, varying in their powers of destructiveness. No timber is known to be absolutely immune from attack, although a few, such as teak, pyinkado and greenheart, are highly resistant. There are two classes of preservatives effective against termites—coal-tar creosote oil type and compounds containing arsenic. In both cases impregnation treatment is essential, brush treatment being of little value.

Resistance to Marine Borers.—There are two main organisms which attack timber in sea-water round Great Britain, the Teredo or Shipworm (*Teredo navalis*), and the Limnoria or Gribble.

The Teredo is a long worm-shaped bivalve mollusc which bores into the timber, forming tunnels up to ½-in. diameter and 24 ins. long. These tunnels are lined with a calcelareous deposit, and may be so numerous as to completely honeycomb the timber without very obvious sign of attack on the external faces. On the other hand, Limnoria only form tunnels about

½ in. deep, but these are so close together that the remaining wood is easily eroded by wave action, exposing a fresh surface to attack, and the action becomes continuous, resulting in the well-known 'waisted' appearance of piles at water level. A similar borer called Chelura is often found associated with Limnoria.

Very few timbers are immune from attack by marine borers, but the following are generally reputed to be highly resistant: pyinkado, greenheart, jarrah, teak, turpentine, opepe, ironbark.

Experiments carried out by the Sea Structures Committee of the Institution of Civil Engineers tend to show that the most satisfactory method of protecting timber in sea water is pressure creosoting, and that the efficacy of such protection is dependent on the depth of penetration of the creosote. Places of poor penetration and untreated surfaces exposed by cutting or drilling after treatment are nearly always attacked by Limnoria.

Resistance to Fire.—All woods will decompose when exposed to heat of sufficient intensity and duration, and most woods will commence to char rapidly at about 270° C. Some species are more resistant to the passage of fire than others, and generally speaking hardwoods are more resistant than softwoods, and resistance increases with the density of the wood. Teak and pyinkado are highly resistant timbers. The resistance to fire can be considerably increased by impregnation with various chemicals, and in fact with proper treatment timber can be rendered non-inflammable in that it will not flame or glow, but merely char, and will not, therefore, assist in the propagation of fire. Impregnation of the timber is necessary for such results, and surface treatment such as brushing or dipping has little value. The usual chemicals used for fireproofing timber are: aqueous solutions of ammonium phosphate, sulphate and chloride, borax and boric acid.

Some protection against the initial outbreak of fire is afforded by 'Fire-resistant paints.' Generally these consist of aqueous solutions of sodium silicate with an inert filler such as kaolin, asbestine, lithopone, mica, whiting, etc. An exception to this type is the class of fire-retardant coatings consisting mainly of calcium sulphate plaster. Fire-retardant paints are not suitable for timber exposed to the weather, and with the exception of some proprietary makes they are not compatible with ordinary oil paint.

Wood Preservatives.

Many chemicals have been suggested at one time or another for the purpose of preserving timber, but those which have found general application are remarkably few.

There are three main classes of wood preservatives, which can conveniently be described as the 'oil,' 'water soluble' and 'solvent' types.

Practically all commercial impregnation treatments are carried out with the oil or water soluble types, as the high cost of the solvent precludes the use of the third type for treatments involving high absorptions of liquid.

Coal tar creosote is the most important preservative of the oil type, having been in use for over 100 years without having been seriously challenged by any other preservative for the preservation of structural and other timbers used under the most severe and exposed conditions. Coal tar creosote for preservation purposes is usually purchased to the British Standard Specification No. 144, 'Creosote for the Preservation of Timber,' (revised and extended in 1936). In addition to the specifications, standard methods of test are also described. Three types, A, A_2 and B, are described representing the normal types of creosote produced in this country, and no superiority of any one type over another is implied. Naturally some users have preference for one or the other, but any creosote conforming to the specification can be regarded as a satisfactory preservative.

Type A oils are the heavy oils, the specification allowing a specific gravity range of 1·010 to 1·065 at 38° C. when compared with water at 20° C. As regards the distillation range not more than 78 gms. should distil over when 100 gms. are distilled under prescribed conditions up to 315° C.*

Type A_2 oils are lower in specific gravity, the range being from 0·995 to 1·065 at 38° compared with water at 20° C. The distillate up to 315° C. is allowed to reach 85 gms. When low temperature creosote is specially ordered, the lower limit for the specific gravity is given as 0·935.

Type B is the designation given to creosotes produced in Scotland, and the general requirements of the specification are the same as those for Type A_2. An extended specific gravity range is allowed for creosotes produced from Blast Furnace Tar, the range being 0·935 to 1·065 at 35° C. compared with water at 20° C. In all cases no upper limit for the tar acid content is specified.

Other substances used for the preservation of timber which come under the heading of 'oil type' preservatives include coal tar, wood tar creosote and petroleum oil.

Coal tar from a preservative point of view is by no means as efficient as the creosote derived from it. It is much less toxic to wood-destroying agencies, and being very viscous does not penetrate the wood deeply. When used alone it should be applied hot. Coal tar is sometimes mixed with ordinary creosote, and provided the mixture is not too viscous it is a satisfactory preservative for pressure treatments, although the surface of the treated wood is much blacker and dirtier than when creosote alone is used.

* Revised 1941.

Wood tar creosotes, though satisfactory preservatives, are not used to any large extent in this country, mainly because they are not produced in any quantity nor are they prepared to any standard quality.

Petroleum oils by themselves are not satisfactory wood preservatives, as they have but little toxicity. Crude petroleum or petroleum fuel oils are, however, used in admixture with creosote in the U.S.A. for the treatment of railway sleepers with satisfactory results. These oils, when used for preservative purposes, should be regarded rather as diluents than as preservatives.

Water soluble salts.—These have, in certain cases, advantages over the oil type. They are easier to transport (since the solid or concentrated form can be used) and the majority involve very little fire risk. The treated wood, after drying, can generally be satisfactorily painted with ordinary oil paint. They are also for the most part odourless. On the other hand, being water soluble they are more readily washed out of the wood, if this is used in contact with the ground, and are therefore not so suitable as the oil type for use under severe conditions of exposure. Recent developments in this type of preservative have indicated the possibility of fixing to a fairly high degree some of the salts in the wood. Potassium dichromate has generally been the chemical used for fixing purposes.

The common water soluble salts which have found application for the preservation of timber are zinc chloride, sodium fluoride, copper sulphate, mercuric chloride and arsenic compounds.

Solvent preservatives consist of toxic substances dissolved in volatile solvents, and in quite a number of these the toxic material is insoluble in water. The solvent is used as a vehicle for carrying the toxic material into the wood, where it remains after evaporation of the solvent. Being much more expensive than the water soluble type, these preservatives are usually applied by brush or other surface treatment.

Methods of Applying Wood Preservatives.

The efficient preservation of timber is dependent as much on the method of application as on the preservative itself. It is not always practicable, nor is it necessary in the majority of cases, to obtain complete impregnation of the timber, but for permanent protection it is essential to obtain sufficient penetration of the preservative to ensure that at no time will unimpregnated wood be exposed by splitting, mechanical abrasion or cutting, and to provide a sufficient reserve of antiseptic in the timber to allow for losses that take place owing to leaching, evaporation, etc. An impregnation treatment is essential in all cases where long life is required in timber exposed to conditions favouring decay (*i.e.* in all timber in contact with the ground, water or saturated air). For timber not in contact with the ground and exposed to ordinary atmospheric conditions, the environment is not so favourable to the growth of decay-producing fungi, and a surface treatment is often sufficient.

Surface Treatments.

Probably the best known and most widely used method of applying wood preservatives is a brush treatment. Except for the sapwood of the more absorbent timbers, such application results in little more than skin deep penetration. A certain amount of protection is, however, afforded to the timber, but such protection is very slight compared with that afforded by impregnation treatments, and in the case of timber kept continually under conditions favourable to decay, it is negligible. When applying an oil paint by means of a brush, it is usually applied sparingly and worked well into the timber. The same method should not be adopted with a toxic preservative. The liquid should be applied liberally and swilled over the surface, the timber being allowed to absorb as much as possible. Brushwork is not necessary except to ensure that the preservative penetrates all cracks and crevices. A long-handled tar-brush is the best type for the application of creosote.

Better penetration is effected in most cases if the preservative is applied hot, particularly in the case of preservatives of the oil type. Heating, however, is not essential, and most preservatives sold for surface application are reasonably penetrating at normal temperatures. Preservatives should not be applied while the surface of the timber is wet, and brush treating is best carried out in the summer or autumn, when the timber is in a dryer and more absorbent condition. The higher temperatures obtaining in summer also aid penetration and obviate any necessity of heating the preservative.

The covering power of a preservative depends on its viscosity and on the species and condition of the timber treated. In the case of non-absorbent timbers, such as Douglas fir or oak, a gallon of liquid will cover a larger area than in the case of absorbent timbers, such as Scots pine or beech, and a machined surface will absorb less than a sawn one.. It is of course not desirable to obtain maximum covering power with a toxic preservative. An approximate figure for one of the oil type applied at normal temperatures on machined redwood (*Pinus sylvestris*) is 400 square feet to the gallon. This is for the first coat, the covering power for a second coat applied within a few days being about twice as great. For sawn surfaces the covering power is approximately half that for machined surfaces.

Spraying is a convenient method of surface application, which probably results in a more effective covering of the timber than can be obtained by brush treatment in that the preservative is more likely to penetrate cracks and its application is more liberal. In all other respects spraying is similar to brush application.

Dipping the timber in a bath of the preservative is better than either brushing or spraying, and results in the effective coating of all surfaces of the timber.

Steeping.

By prolonging the duration of dipping, or steeping the timber, the absorption and penetration are increased, but at a very slow rate.

The penetration obtained by steeping varies considerably with the species of timber used. With resistant timber, such as the heartwood of oak, larch or Douglas fir, steeping for as long as 200 days only results in slight penetration, whereas with permeable timber, such as beech and the sapwood of Scots pine, practically complete penetration of 2–3 in. material can be obtained in this period.

An absorption of 10–12 lbs. per cub. ft. can be considered as giving sufficient protection even under conditions favourable to decay. With many species this can be accomplished in using creosote by steeping for periods varying from 1 to 20 weeks. The actual time required will depend mainly on the species and dimensions of the timber and without extensive trial no definite times of treatment can be laid down.

As a rough practical guide for steeping the more permeable species in creosote, one week per inch of thickness should give good protection. This should be regarded as only very approximate, and if steeping is practised to any appreciable extent, the time of treatment to give the desired absorption should be ascertained by trial for each individual case.

Open Tank Treatment.

In order to obtain effective impregnation by steeping, the timber must be allowed to remain in the liquid for long periods often extending into weeks. Similar, if not better, results can be obtained in 24 hours by what is known as the open tank hot and cold process. Although the apparatus used consists of a tank open to the atmosphere, the impregnation is effected by means of pressure just as if a force pump had been used, the only difference being that it is the pressure of the atmosphere which forces the liquid into the wood. This pressure is brought into effect by means of variations in temperature. Wood in an air-dry condition contains minute air spaces totalling say 40–80 per cent. of its volume. If this piece of wood is immersed in a liquid which is then heated, the air in the wood expands, and a certain amount is driven out and can be seen escaping as bubbles through the liquid. On cooling, the remaining air contracts, tending to form a partial vacuum, and the liquid is gradually drawn into the timber. In other words, during cooling the atmospheric pressure is greater than the air pressure inside the minute spaces in the timber. *Thus absorption takes place during the cooling period.* The greater the difference between the maximum and minimum temperatures the greater the difference in the pressure of the air inside and outside the timber, and consequently the greater the absorption. Immersion of timber in either hot or cold liquid maintained at constant temperature does not induce this pressure difference and, consequently, absorption is not by any means so great.

This principle can be applied to impregnate timber with preservative in a very simple manner. The method of treatment is essentially the same for all species, but the times and temperatures may be varied to obtain the required absorptions for the particular species and dimensions of the timber treated. Actual experience will determine which treatment is the most suitable. The general method is as follows:—

The timber is immersed in the cold creosote, which is then gradually heated up to 180°–200° F. and maintained at this temperature for about 1–2 hours, depending on the size and species of timber being treated. The creosote is then allowed to cool, care being taken that the timber is kept completely submerged during the cooling period, and if necessary, more preservative added to maintain the level. The timber is then removed and allowed to drain, after which it is ready for use. The total time taken depends on the size and species being treated, but it is usually found convenient to do one run every 24 hours. Heating is started in the morning and lasts 3–4 hours, after which steam is turned off or the fire drawn, and the whole left to cool until the following morning. Thus the operator need only be in attendance for several hours each day. It may sometimes be found possible to carry two runs during the 24 hours, but this depends on the rate of heating and cooling of the tank and the species of timber under treatment, and can only be decided by actual trial.

For the treatment of fence posts, efficient results can be obtained by what is known as the 'butt treatment.' In this case the lower end only of the post is given an open tank treatment, and the upper end is either brushed with, or dipped in, the creosote. Thus the part of the post most liable to attack by fungus, *i.e.*, at and below ground level, receives the heavier treatment. All the apparatus required consists of an iron drum which can be heated by a fire underneath.

Pressure Treatment.

The most effective method of impregnating timber with preservatives is by means of pressure, and this process is always used when the quantity of timber to be treated justifies the capital outlay of a pressure plant. It is much quicker than the open tank process, the treatment is more easily controlled and better impregnation is obtained with the more resistant species. Practically all telegraph poles and railway sleepers used in Great Britain are impregnated under pressure.

The process consists essentially of impregnating timber in closed cylinders with a preservative under pressure. The cycle of pressure differences both below and above atmospheric and the duration of the pressure periods may be and are varied considerably in order to obtain the desired results, but pressure treatments are generally classified under the following types:—

(1) Bethell or Full Cell Process.
(2) Rueping or Empty Cell Process.
(3) Boulton or Boiling under Vacuum Process.

The Bethell or Full Cell Process is the oldest process in use, having been introduced about 1838, and it is probably the most widely used pressure process at the present day. The timber is enclosed in a cylinder and subjected to a vacuum of 15 to 25 ins. of mercury for a period varying from ½ to 2 hours. The cylinder is then flooded with preservative and pressures of 100 to 200 lb. per sq. in. applied for a period of ½ to 5 hours, depending on the species of timber being treated and the results desired. The cylinder is then emptied of preservative and a final vacuum applied.

The Rueping or Empty Cell Process was introduced about 1904. It differs from the Full Cell Process in that pressure of the air in the cylinder containing the timber is increased and not diminished. The usual oil-pressure treatment is then applied and on release of the pressure the compressed air in the cell spaces expels the excess creosote, leaving a coating only on the cell walls. Thus a deep impregnation is obtained without a heavy absorption of creosote.

The Boulton or Boiling under Vacuum Process is really a seasoning process and is applied to green timber. The timber is immersed in creosote at a high temperature and a vacuum applied for the purpose of removing moisture from the wood. After 12 to 24 hours of this treatment an ordinary full cell or empty cell pressure treatment is applied.

The Full Cell Process is the most suitable for general purposes and for timber exposed to bad conditions and which is required to have as long a life as possible. The Empty Cell Process is only suitable for timbers which are very easily treated and where conditions of exposure are not too severe. It is not suitable for instance for marine timbers. The Boiling under Vacuum Process is suitable for timber which is difficult to impregnate and which is used in large sizes. Its particular application is for marine piling of Douglas fir.

Different species of timber vary considerably in their resistance to the penetration of liquids. Larch and oak heartwood are practically impervious, whilst beech and the sapwood of most species can be completely impregnated. Douglas fir and spruce are fairly resistant to impregnation, but the resistance of spruce seems to vary considerably in timber from different localities. Most of the non-durable timbers, such as sycamore, birch, and the sapwood of Scots and Corsican pines, are very easily impregnated either by means of pressure or by the open tank hot and cold process, and it is with these species that the economy of a preservative treatment is most pronounced.

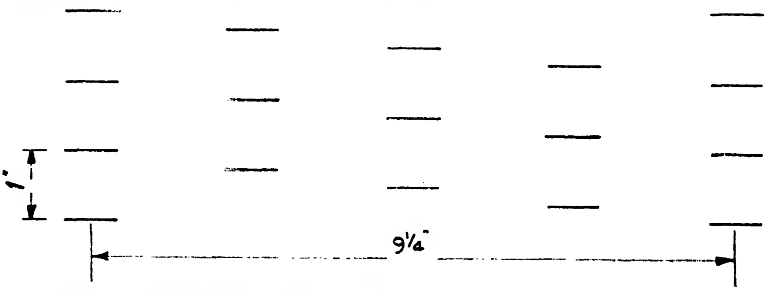
'Pressure Creosoting of Timber' is now the subject of British Standard Specification No. 913—1940.

Incising.

Some timbers, such as Douglas fir, are difficult to treat even under pressure, as not only do they absorb but small amounts of preservative, but the absorption during treatment is very irregular. Several methods have been suggested for improving the treatment of such woods, most of which entail perforating the longitudinal surfaces of the timber.

The method most commonly employed consists of making narrow incisions, usually about ¾ in. deep, over all longitudinal surfaces of the timber by passing it under a spring loaded roller from which project the incising knives. The knives are fairly thin, and are designed to part the fibres of the wood, rather than sever them, so that the strength is not seriously impaired by the process. The spacing of the incisions varies somewhat, but an average arrangement suitable for Douglas fir is shown in the diagram, fig. 1.

Such an arrangement allows the creosote to penetrate the ¾ in. depth of the incisions and then spread in each direction so that the wood is eventually uniformly penetrated to the depth of the incisions.



DEPTH OF INCISIONS 3/4" FIG. 1.

Diffusion Methods.

These methods of treatment are applied to timbers in green or damp condition, and their main use is for timbers already erected which cannot otherwise be treated. Several methods of application have been suggested, but they all rely on the diffusion of a water soluble preservative into the wood. One method consists of injecting the preservative as a paste into the wood through a hollow incising tool. A similar method is to bore holes in the timber, which are then filled with the preservative paste. Another but slightly different method consists of holding a quantity of the preservative in contact with the wood by means of a waterproofed bandage.

Seasoning of Timber.

Why Timber must be Seasoned.

Freshly felled timber contains a large quantity of moisture. In ash, for example, one-third of the total weight is water, and in the sapwood of some coniferous trees, only one-third of the weight is timber. If kept as logs, most timbers dry very slowly indeed, but if converted to scantlings, planks or boards and exposed to air in this form, they lose their moisture more freely, and sooner or later most, but not all, of the original moisture of the tree evaporates. This process is accompanied by shrinkage of the wood, hence if unseasoned timber is employed, the work for which it is used will lack stability. Floors and framing laid on such material will sink, joints in structures will become loose, and in pattern-making and decorative work, shrinkage will cause loss of shape and size, and the wood will probably split and crack.

Additional advantages of seasoning are that wood becomes lighter and stronger, more durable, better able to take preservatives, paints and polishes, and its machining qualities improve.

Shrinkage of Timber.

The difficulties caused by the shrinkage of timber during seasoning are intensified by the fact that the movement is not the same in all directions. The greatest shrinkage occurs in a direction tangential to the growth rings of the tree. In the radial direction of the tree the shrinkage is roughly only half as much, while along the grain, that is the longitudinal direction of the tree, the movement is relatively very small, say only 2 to 3 per cent. of that tangential to the rings. The magnitude of the average shrinkage of timber can be seen from the chart on p. 290. The differences in directional shrinkage are the main cause of distortion which occurs in drying. The square cross-section of a piece of wood cut from a log tends to become diamond shaped in drying if the growth rings are not roughly parallel to the faces of the square. A board or plank cut other than diametrically from the log tends to cup or curve across its width in drying. A board cut along a radius or diameter of the log, that is a quarter-sawn board, remains flat in drying. Such a board tends to shrink in width least in drying and to move least in subsequent service and is thus most suitable for use where dimensional variation is undesirable as in large panels, etc.

Moisture Content.

The only satisfactory way of expressing the degree of seasoning or dryness of timber is by moisture content. Terms such as ' air-seasoned ' or ' kiln-seasoned ' may bear some conventional meaning, but they are too loose to use as specifications. The phrases ' thoroughly seasoned,' ' well seasoned ' and ' bone dry ' are strongly to be deprecated.

Moisture content is the amount of water in a piece of timber expressed as a percentage of the weight of dry wood substance. It is generally determined as follows :—

(1) Cut a full cross-section from the board, ½ in. long in the direction of the grain and at a distance of 9 in. from the end.

(2) Weight this sample as quickly as possible. This is the Initial Weight W.

(3) Dry in a ventilated oven at 100° C. (212° F.) until constancy of weight is attained. This is the Dry Weight D.

(4) Moisture content $= \frac{W - D}{D} \times 100$ per cent.

Where it is inconvenient to cut the timber (as in large baulks, sleepers, etc.) a sample can be obtained with an auger or bit, but it is advisable to collect the chips in a bottle to guard against loss of moisture before they can be weighed.

Electrically operated machines are on the market that indicate moisture contents from about 6 per cent. to 25 per cent. If used with intelligence and a knowledge of their limitations, they are sufficiently accurate for commercial work.

Moisture Content of Timber for Various Purposes.

The degree of seasoning desirable in timber depends on the use to which the timber will be put, and as a practical issue, upon the amount of shrinkage permissible in the finished article. For marine piling, and generally where timber is to be in contact with water, there is obviously no point in drying before use, unless it has first to be creosoted, and even then, only a sufficient thickness of seasoned wood is necessary for the required penetration to be obtained.

Fig. 2.

The diagram on p. 290 shows the moisture contents that obtain in various environments, and for important work, the timber should first be dried to the appropriate figure. The diagram also gives data from which specifications may be framed. For general joiners' uses, as an example, a moisture content of 15 per cent. is satisfactory, but for furniture and decorative woodwork, 12 per cent. is a more suitable figure. Shrinkage consequent upon moisture change can be estimated from the scale on the right.

An important point in builder's work is immunity from dry rot and other wood-destroying fungi. Unless the moisture content in the timber exceeds 20 per cent. these will not attack the wood, and if the joists, etc., are seasoned to this figure or less prior to installation in adequately ventilated buildings, safety is ensured.

Methods of Seasoning Timber.

Air Seasoning.—Round timber for telegraph poles, pit props, etc., should have the bark removed to accelerate the seasoning, and be stacked in some open form such as self-crossing, with spaces between adjoining pieces in each row.

Timber sawn into boards, planks, etc., is piled in the open or in a ventilated shed so that air can circulate freely over its surfaces.

The stacks should be raised about 12 ins. off the ground by level foundations, and for rapid drying the pile should not exceed 6 ft. in width; length and height, consistent with convenience and safety, are immaterial. Between individual piles a space of 9 in. to a foot will ensure adequate air movement, and it has been found that special orientation of the yard with respect to the prevailing wind is unnecessary.

Within the stack the boards should be laid with slight gaps between them, and the rows should be separated by piling sticks about 1 in. square. Certain refractory timbers such as oak will benefit if the sticks are only ½ in. thick, but there is little advantage in increasing the thickness beyond 1 in. even with free-drying softwoods. The distance between the sticks depends on the timber, and as a guide, these may be taken as 9 to 18 ins. with ½ in. timber; 1 ft. to 2 ft. with 1 in.; 1 ft. 6 ins. to 2 ft. 6 ins. with 2-in. stocks and 2 to 4 ft. with thicker material.

If the timber is stacked in the open, it is advisable to fit a good roof to prevent rain penetrating to the middle of the pile. It is very necessary that the ground beneath the stacks be kept clear of weeds and odd scraps of wood. These latter may decay and may infect the timber with wood-destroying fungus.

The moisture content attained by timber in air-drying in the open varies with the season, 20 per cent. being a fair average with upper and lower limits of about 23 per cent. and 17 per cent. Whilst the drying times depend on the time of year at which the timber is piled, the table gives approximate data for freshly-cut 2-in. material of a few common species under favourable conditions.

Species.	Time (Months).	Species.	Time (Months).
Oak	18	Ash	6
Beech	9	Elm	6
Pitch pine	6	Scots pine	2

Kiln Seasoning.—The relative merits of air seasoning and kiln drying are frequently contrasted, and there are many misconceptions regarding both methods. It can be stated definitely, however, that seasoning and drying are synonymous terms for all practical purposes and the manner in which moisture leaves the wood is the same in the two methods, the difference being merely one of speed and temperature. There virtually is no way of distinguishing between air-dried stock and that which has been seasoned in a kiln under correct conditions and proper control, assuming the degree of seasoning, that is the moisture content of the timber, is the same.

There is no strict line of demarcation between the methods, for the two are frequently combined. Thus, freshly-converted timber can be dried directly in a kiln to say 12 per cent. moisture content, or it can be partly air-seasoned first and then finished off in a kiln or in a warm store, which is virtually a low temperature kiln.

One point must always be remembered; air-seasoned timber is insufficiently dry for interior uses, and if shrinkage is to be avoided, it must be given further treatment.

Essentials of a Timber Drying Kiln.

The three essentials of a kiln are: *Heat, Humidification* and *Circulation*, the terms applying to the air, which is the medium with which most dryers operate.

Heat is needed to evaporate the moisture from the timber, and the use of high temperatures increases the rate of movement to the surface from the interior.

Humidification of the air is necessary to effect a balance between evaporation at the surface of the wood and the internal transfusion of moisture to that surface.

Circulation is required to move air continuously over the surfaces of the boards. If it remained stagnant in contact with the undried timber, the air would soon become too humid and drying of the timber would cease.

In most kilns, a large proportion of the air after passing once through the timber is recirculated, but some fresh air is constantly introduced for ventilating the kiln, otherwise the air as a whole would become too humid. The volume introduced for ventilation is, however, small.

Temperature and humidity should be under the complete control of the operator, and the air movement should be adequate and uniform.

Types of Timber Drying Kiln.

Progressive Kilns.—The progressive kiln usually consists of a tunnel from 60 to 300 ft. or more in length along which the timber, which is piled on trucks, is moved by stages. Below the trucks in a basement, steam heated coils run for about two thirds the length of the kiln, and there are generally steam sprays for humidification purposes.

Heated air rises from the coils at one end of the kiln, passes in a more or less horizontal direction along the kiln through the timber stacks, and falls back into the basement at the opposite end. It then returns along this basement and is again heated for recirculation. As the air passes through the piled timber, it becomes cooler due to the heat given up in evaporating moisture and more humid owing to the moisture taken from the wood.

At one end of the kiln therefore, the air is hot and relatively dry and in passing from one end to the other it gradually becomes more humid and cooler. The timber is put in the kiln at the wet or cold end, and is moved by stages to the other, by which time, if the conditions are suitable, it will have dried. The air movement can be accelerated by fans and the drying rate thus speeded up.

Progressive kilns depend for their efficient working on a continuous supply of timber of the same species and thickness, and will not work satisfactorily if only partly full. Generally speaking, production conditions are on too small a scale in England to lend themselves to the efficient use of progressive kilns.

Compartment Kilns.—In the compartment kiln, the load is not moved until drying is completed, and the air temperatures and humidities are varied to suit the current moisture content of the stock. Such dryers are under more exact control than progressive kilns, and whilst it is not good practice to mix species and dimensions in any one charge, these kilns can be used to dry a wide variation of timbers and sizes.

Kilns are usually built of brick, but concrete, timber, asbestos sheeting or non-corrosive metals have been successfully employed. The walls must be reasonably heat- and damp-proof.

Compartment kilns are classified according to the means by which circulation is produced. In natural draught dryers, air movement is induced by convection currents. The type is not efficient for handling very wet timber, but in some of its forms, is suitable for completing the seasoning of partly-dried stock.

Forced circulation kilns are fitted with fans for moving the air, and are designated by the type and disposition of these parts. The external fan pattern has a centrifugal blower that forces the air into the stacks through a duct and exhausts it for re-circulation through a second trunk. In the internal fan kiln, propellers are used to keep the air in motion. The fans are carried either on one shaft running lengthwise or on several spindles placed across the kiln, and the air is deflected into the stack by baffles or grids. The general practice is to use steam-heated coils for heating and steam sprays to control humidity, and in the case of external fan kilns, these are usually in unit form embodied in the fan casing or in the ducting.

Internal fan kilns can be arranged with the fans, heating coils and humidifying sprays in a basement below the timber or they can be placed above the piles. The latter is generally preferable, since the timber can be piled on a solid floor and the expense of excavating a basement is obviated. The return of condensate from the heating pipes is facilitated by the overhead construction.

The essential of a fan kiln is that the air blown into the stack should be uniform in rate of flow, temperature and humidity along the whole length and subject to this proviso, the methods employed are unimportant.

Kiln Operation.

Air conditions in a kiln should be regulated according to the species being dried, the thickness of the stock and the moisture content of the timber. An operation schedule based on time alone is unsound and may lead to disastrous results. Such a method can sometimes be evolved after long experience with a particular class of timber, but where the loads vary in species and moisture content, it is strongly to be deprecated.

Successful kiln operation depends on a sound knowledge of the principles of drying, and should never be regarded as a rule-of-thumb process.

KILN DRYING TIMES.

The times given in the table are for drying 2-in. timber from the freshly felled state to a uniform moisture content of 12 per cent. in a moderately efficient fan kiln, the timber being then in a fit condition for immediate use for any purposes including resawing or moulding. Where the needs are not so exacting, or where uniformity of moisture content and stress-free state are unimportant the times can be reduced appreciably.

Species.	Time (weeks).	Species.	Time (weeks).
Oak	10–12	Ash	4–5
Elm	4–5	Pitch pine . . .	3–4
Beech . . .	5–6	Scots pine . . .	1–2

STEAMING OF TIMBER.

The steaming of fresh timber is commonly practised in the belief that it accelerates seasoning. In practical terms, this is erroneous, although the process is frequently of value in sterilising the wood and in producing a more pleasing colour.

Timber attacked by wood-destroying beetles and fungi can be sterilised by a suitable short kiln treatment. This kills all insects, grubs and eggs or spores, but does not necessarily render it immune from re-infestation.

STORAGE OF LOGS AND TIMBER.

The storage of timber in log form is common practice, and in broad terms is fairly safe. Certain non-durable woods such as beech, ash, poplar, etc., are liable to fungus attack, whilst in valuable logs, end-splitting may seriously reduce their value. The use of a water-proof end coating will reduce splitting, and if the paint has toxic properties, the danger from fungus is lessened. Both dangers are eliminated by keeping the logs under water. Where water storage is impracticable, the timber should be placed on skids and not allowed to lie on the bare ground.

On no account should wet sawn timber be closely stacked for any appreciable time, for such conditions may lead to staining and to the growth of wood-destroying fungi.

Boards that have been air-seasoned (*i.e.* to a moisture content of about 20 per cent.) may safely be bulk-piled, but the ingress of rain must be prevented. Material dried to 15 per cent. or less will absorb moisture if stacked in the open air, and should for preference be stored in a warmed shed. Where this is impracticable, the absorption rate can be greatly reduced by bulk piling and covering the stack with tarpaulins.

Strength Properties of Timbers.

In addition to wide natural variation the strength properties of timber are sometimes considerably influenced by its moisture content, by the conditions under which it is tested and by knots, cross grain and other features, as found in any particular piece. In consequence, for the derivation of basic data for comparing the strength properties of various species of timber the conditions of test are standardised, the timber is tested at a specific moisture content, and, owing to the impossibility of matching defects, the tests are made on clear specimens of timber, *i.e.* pieces cut straight with the grain and selected free from knots, splits, etc. The standard test pieces are cut from planed sticks 2 ins. square in cross section, and the tests are, briefly, as follows:—

STATIC BENDING.

The test piece is 30 ins. long and is supported over a span of 28 ins. and centrally loaded, the rate of increase of deflection at the centre of the span being 0·105 in. per minute. Readings of load and deflection are continued past maximum load, until either the load has fallen to 200 lb. or a deflection of 6 ins. has been reached. The quantities computed are equivalent fibre stress at maximum load (sometimes referred to as Modulus of Rupture), modulus of elasticity and work expended in bending (*a*) to the point of maximum load (*b*) over the whole range of deflection. The work expended in bending is a measure of the resilience of the timber.

IMPACT BENDING.

The 30-in. specimen on the same span of 28 ins. is broken by a weight of 50 lb. falling, in vertical guides, on to the specimen at the centre of the span, from heights starting with 2 ins. and increasing 1 in. at a time to 12 ins. then by 2 ins. at a time until failure occurs. The maximum drop of the 50 lb. weight required to break the specimen is a measure of the strength of the timber to resist suddenly applied loads.

STRENGTH PROPERTIES OF SMALL CLEAR SPECIMENS OF TIMBER.

COMPRESSION PARALLEL TO GRAIN.

The specimen is 8 ins. long and is crushed between parallel plates. The maximum load is recorded and the maximum crushing strength computed therefrom.

SHEAR.

The specimen is 2 ins. long (*i.e.* a 2-in. cube) and is loaded so as to produce shear along the grain, tests being made with the plane of shear parallel to the growth rings and at right angles to them.

HARDNESS.

Measurement is made of the load required to indent the timber by means of a hemispherically headed plunger 0·44 in. diameter to a depth equal to the radius of the head.

CLEAVAGE.

The specimen is 3¾ ins. long with a notch ⅜ in. deep across one end. Hook grips inserted on the opposite sides of the notch enable the specimen to be subjected to a tensile force at right angles to the grain which is increased until the specimen splits. The splitting load is recorded.

For full details regarding these tests see 'Project I. Mechanical and Physical Properties of Timbers. Tests of Small Clear Specimens' by C. J. Chaplin, published by H.M. Stationery Office.

Above approximately 26 per cent. moisture content the strength of wood is uninfluenced by moisture changes. Below this value most strength properties vary inversely with the moisture content, the relationship being approximately logarithmic. The practice is, therefore, to record the strength of timber under two standards conditions: (i) as near as possible freshly felled (moisture content between 50 and 100 per cent., depending on the species) and (ii) at 12 per cent. The former relates in practice to all timber exposed to the weather and the latter to timber in a centrally heated building. From these data the strength at other moisture contents may be calculated.

The accompanying table gives the average values of strength and shrinkage of a few important timbers. Many other species have been tested by various authorities under the same system of standardised tests, the results of most of these tests will be found in the following publications:—

'A Handbook of Home-Grown Timbers," H.M. Stationery Office, London.

'A Handbook of Empire Timbers.' H.M. Stationery Office, London, 1939. Price 3*s.* 6*d.*

'Strength and Related Properties of Woods grown in the United States.' Technical Bulletin, No. 479. U.S. Dept. of Agriculture, Washington, D.C. Price 25 cents.

'Mechanical Properties of Canadian Woods.' Forest Service Bulletin No. 82, Dept. of the Interior, Ottawa, Canada.

'The Physical and Mechanical Properties of Woods grown in India.' The Indian Forest Records, vol. xvii, part 10. Govt. of India, Delhi. Price 7*s.*

It is emphasised that these figures are the ultimate strengths and other properties of small clear specimens, and as such are not to be confused with safe working stresses for which see p. 296.

THE EFFECT OF SEASONING ON THE STRENGTH OF WOOD.

The influence of seasoning on the strength properties of wood is shown by the difference between the values of each property at the two moisture contents in the table of mechanical and physical properties. The effect is most pronounced in the case of the crushing strength parallel to the grain, which is increased by approximately 100 per cent. in drying from 26 to 12 per cent. moisture content. Other properties are increased by less amounts and in certain cases, notably the strength in impact bending, the property is sometimes slightly reduced by seasoning. This latter irregular behaviour is because ability to withstand impact loads depends not only on strength but also on ability to absorb the energy of the blow by deflection. Timber at low moisture contents is stiffer and therefore not capable of yielding so far without breaking. These progressive changes in strength have been found to continue to moisture contents as low as 5 per cent. and probably also continue to zero moisture (oven-dry).

Providing the timber is dried to the same moisture content and as long as the drying schedule employed in the kiln is suitable for the timber, these changes in strength are the same whether drying takes place in the open air or under controlled conditions. The employment of an ununsuitable seasoning schedule involves the risk of impairing the resilience or toughness of the timber, and also, with certain species, of developing honeycombing, case hardening or collapse.

SAFE WORKING STRESSES.

As the strength of structural timber is largely influenced by knots and other defects it is necessary to define the extent to which these may be permitted before safe working stresses can be evaluated. It follows that the derivation of safe working stresses is greatly facilitated if timber is marketed in definite grades based on defects (as distinct from blemishes). Such is the position in America where the practice has been adopted of grading timber according to stated schedules of defects and evaluating safe working stresses for each grade. British Standard Specifications (B.S. 940, Parts I and II) have been published detailing stress grades for the species of timber commonly used for structural purposes in this country. So far, however, timber graded to these specifications has not been available through normal trade channels.

The Strength of Poles.

Poles in the line are subjected to overturning moments arising from (1) the load at the top due to the pull of the wires, or the wire pressure due to snow on the wires, and (2) wind pressure causing a load distributed along the length of the pole and on sleet-covered wires. Theoretically the maximum bending moment occurs either at the ground line, or, if the taper on the poles is sufficiently acute, at the section at which the diameter is 1½ times the diameter of the top. In practice poles more often fail a little way above the ground line, which suggests that the stresses set up differ slightly from the theoretical.

In testing poles for their ultimate strength the theoretical stress distribution of service conditions is obtained approximately by supporting the pole at each end and applying a single concentrated load at the point corresponding to the ground line. As the load on a pole is greatest at the wettest time of the year, when, consequently, the pole in, and just above, the ground is saturated with water, it is necessary, in order that test results shall indicate the strength of the pole under the worst conditions, that the poles should be soaked in water prior to test.

The following results have been obtained from tests of creosoted and uncreosoted poles carried out under the above conditions at the Forest Products Research Laboratory :—

Species.	Ultimate Stress in Bending, Lb. per Sq. In.	Weight, Lb. per Cub. Ft. at 30% Moisture Content.
1. Redwood (Scots pine, *Pinus sylvestris*) . .	7,980	37

SECTION IX

PART II

ROOFS — FLOORS — PARTITIONS — STAIRS — BRICKWORK — LONDON BUILDING ACTS — FOUNDATIONS — MASONRY

ROOFS.

The Ministry of Health's Model Byelaws, Series IV, Buildings (1938), Clauses 78 to 79, relating to roofs are compulsory in many localities. Obtainable from H.M. Stationery Office, London, price 1*s.* 6*d.* net.

ROOFING MATERIALS.

The chief roofing materials are :—

(I) *Slates.*—The following terms are used as in slaters' work :—

Head : the upper or edge top of slate. *Back* : the upper or exposed surface of slate when laid. *Bed* : the lower or under surface of slate. *Tail* : the lower or bottom edge of slate. *Margin* : the part of each course of slates exposed to view (*a–b*, fig. 1). *Gauge*: the distance battens are apart from centre to centre ; required to determine the position of battens to receive the nails by which the slates are secured. *Bond.*—When a joint of two adjacent slates is immediately in the centre of the slate, the tail end of which rests upon them, the slates are said to bond. *Lap* : the distance the tail of one slate overlaps the head of second course below, when slates are nailed near the centre, or the distance the tail of slate overlaps the nail-hole of second course below when slates are nailed near the head. The lap, in practice, ranges from 2½ inches to 4 inches, and averages as 3 inches. *Holeing* : the piercing of slates to receive nails. *Sorting.*—When roof is to be covered by slates of different lengths, they are regulated to proper dimensions, so that the largest slates may be nailed near the eaves, and the smallest at the ridge. *Eaves* : the lower part of slating hanging over a wall.

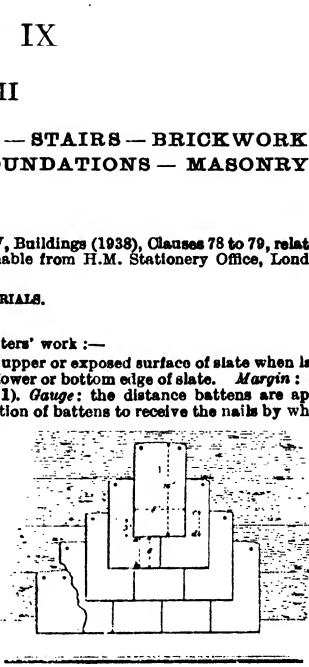

FIG. 1.

See British Standard Specification No. 680.

SIZES OF SLATES.

The sizes of slates in common use are as follows :—' Duchess ' slates, 24 inches by 12 inches, for moderate flat roofs of ⅙ pitch ; ' Countess ' slates, 20 inches by 10 inches, for roofs of ¼ pitch ; and ' Ladies,' 16 inches by 8 inches, for roofs of ⅓ pitch, the rule being, the steeper the pitch, the smaller the slate, and the more exposed the building, the greater the pitch of the roof.

Slates are laid on *boards* (fig. 1) or *battens* (fig. 2), the latter being the cheapest. Boards, ¾ inch thick for Countess slates, and rafters not more than 18 inches in the clear, 1 inch or thicker, otherwise. Battens, 2 inches by ¾ inch for Countess, with rafters 12 inches interval ; 3 inches by 1 inch for Duchess. Slates are often *holed* 1 inch or 1½ inch from the head, as in fig. 1, but are better centre-holed, i.e. just clear of head of slate below, as in fig. 2.

If a *good slate* is stood half its depth in water for several hours the moisture should not rise to the top.

Composition nails are recommended for all good work; they are stiffer than copper or zinc, present a brassy appearance, and are cheaper than copper nails. If iron nails are used, they should be galvanised, or boiled in linseed oil. Two to each slate, 1⅜ inch long for small slates, 1½ inch long for Countess, and 1¾ for Duchess slates.

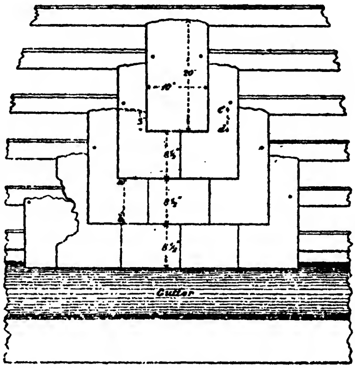

FIG. 2.

Zinc and Copper Clips.—**When a slate that is nailed to boarding gets broken and has to be repaired, narrow clips, about ½ inch wide, are pushed between the slates to catch the head of slate below. The new slate is then inserted, and the end of clip turned as a hook over the tail of the slate. When slates are nailed to battens, and the interior is accessible, they may be repaired by means of a piece of copper wire which is pointed at one end and driven into the batten or boarding at the head of under slate, passed between the side-joints of slates immediately above it, and lapped over the tail of the next slate but one above it. A man under the battens will secure a piece of copper wire to the battens, and then push the wire between the slates for the man above to clip over the tail of the new slate.**

SIZE AND WEIGHT OF SLATES.

A thousand slates means 1,200. A square is 100 super feet.

Name.	Size.	Gauge for 3-in. Lap Nailed in Centre.	No. of Squares covered by 1,000 of 1,200.	Weight per 1,000 of 1,200.	Weight* per Square.	No. to Cover One Square.	Nails required per Square.	
							Iron.	Copper.
	Ins.	Ins.		Cwts.	Cwts.		No.	Lbs.
Smalls . . .	12 × 8	4½	2·8	17½	6¼	430	860	5
Doubles . . .	13 × 6	5	2·5	18	6	480	960	6
Ladies . . .	14 × 12	5½	5	31	6¼	240	480	3¼
" . . .	16 × 8	6½	4·5	25	5·5	300	600	3½
Viscountesses . .	18 × 10	7½	6	36	6	200	400	2¾
Countesses . .	20 × 10	8½	7	40	5·7	171	342	4
Marchionesses . .	22 × 12	9½	9·4	55	6	130	260	3½
Duchesses . . .	24 × 12	10½	10	63	6	125	250	3
Imperials . . .	33 × 24	13½	25	..	..	48	96	3
Rags	36 × 24	16½	30	..	..	40	80	3½
Queens . . .	36 × 24	16¼	30	..	..	40	80	2

*** The weights are for first quality Penrhyn or Bangor; second quality weigh about one-third more. As the sizes of slates of the same name sometimes differ slightly, the size required should be given as well as the name, when of importance. This Table allows about $\frac{1}{20}$th for waste.**

See Brit. Stand. Specific. for No. 680—1936, Welsh slates; No. 690—1940 for Asbestos slates.

(ii) *Asbestos-cement* in the form of sheets (often known as 'slates') of rectangular, honeycomb, and diamond shape.

These slates are made rectangular, honeycomb, and diamond in pattern. They may be obtained in five rich colours, red, blue, grey, russet-brown, and brindled.

The original weather-resisting qualities of some Asbestos Cement Slates are guaranteed for twenty years.

These slates can be cut to fit hips, valleys, verges, round chimneys, and roof lights, etc.

Rectangular sizes, 24 ins. × 12 ins. and 16 ins. × 8 ins. Diamond and honeycomb sizes, 15¾ ins. × 15¾ ins. and 11¾ ins. × 11¾ ins.

The lap to be given is determined by the pitch of the roof, position and building, and prevailing weather conditions.

British Standard Specification No. 690—1940 relates to asbestos-cement slates and also to unreinforced flat sheets and corrugated sheets.

(iii) *Roofing Tiles.*—Roofing tiles may be *plain* (i.e. rectangular and almost flat), or they may be wavy, as *pantiles*, or they may have grooves or other structures which enable them to *interlock* with one another. Interlocking tiles are much heavier than plain tiles, but form a more weather-proof roof. (See also pp. 367 and 369.)

The unit of measure for roofing tiles (when fixed) is a 'square' having an area of 100 sq. ft. Thus, if 4 in. is to be exposed on a *plain tile*, 600 such tiles will form a 'square,' but in flat roofing, where the overlap is much less, only 210 tiles will be required for a square. 1 square weighs about 15 cwt. 100 plain tile laths 5 ft. long = 1 bundle.

For *pantiles*, 180 to a 10-in. gauge, 164 to an 11-in. gauge, and 150 to a 12-in. gauge. The lap of the tile over the one below it will be just the difference between its length and the length of the gauge. 1 square weighs about 8 cwt. 12 pantile laths 10 ft. long = 1 bundle. Fir tiling laths are 1¼ in. by 1 in.; and oak tiling laths, 1¼ in. by ½ in. 1 square of tiling requires 1 bundle of laths, 150 nails, 1 peck of tile-pins and 3 hods of mortar. (See p. 367.)

Wall and Floor Tiles are usually glazed; they are not very suitable for external use.

See also British Standard Specification No. 1281.

Roofing tiles are also made of concrete (see p. 350).

(iv) *Corrugated Iron Sheets.*—See pp. 236 and 301.

(v) *Zinc.*—Roofs are not covered with zinc, but with galvanised iron, *i.e.* zinc-coated iron.

The gauges of zinc recommended for roofing purposes are Nos. 13, 14, 15, and 16, the weights per sq. ft. of each gauge being respectively 16 ozs. 15 drs., 18 ozs. 12 drs., 21 ozs. 12 drs., and 24 ozs. 12 drs. The sheets usually measure 8 ft. × 3 ft. See also p. 86.

(vi) *Lead.*—Sheets of lead are used for some flat roofs (see p. 132).

(vii) *Wood.*—Wooden roofs are preferably covered with felt or mastic which are easily renewed (see also Table on p. 301).

(viii) *Felt.*—Usually impregnated with tar, asphalt, bitumen, or other impervious material (see Mastic). The felt is laid over matchboard, sometimes with a prepared paper between. (See British Standard Specification No. 747.)

(ix) *Mastic.*—The mastic compositions generally used for roofing are a form of asphalt, *i.e.* mineral grains (grit) embedded in a plastic binder, such as bitumen. The material may be 'natural' or 'synthetic.'

The mastic may be applied direct to concrete roofs, but for wooden roofs it is applied to a layer of felt impregnated but not coated with bitumen. Expanded metal or wire netting is sometimes laid over the felt. A paper underlay is often advantageous.

Mastic asphalts tend to creep in warm weather so some form of 'key' to hold them in position is desirable.

See British Standard Specifications Nos. 988 and 1162.

Heat-Insulating Value of Roofing Materials.*

A National Physical Laboratory test of roofing by measuring the heat lost from a heated room leads to the remarkable conclusion that the rate of emission of heat by radiation from the covering surface has more effect on the inside temperature than the rate of conduction of heat through the material. This result is of importance in the roofing of large factories of

* W. M. Thornton, D.Sc., D.Eng., Armstrong College, Newcastle-on-Tyne; *Engineering*, October 19, 1917.

a semi-permanent nature, where the temperature depends more upon the covering than in the case of buildings having a closed air space under the roof.

Old galvanised iron allows more heat to pass than glass, a remarkable result. Slates are good, but in proportion heavy. Deal boarding covered with asphalted felt, though thick, is not so heavy as Welsh slate, and is one of the best insulators. In this case its poor conductivity is evidently not negligible, and in all thick roofing materials it is probably of importance. (See also British Standard Specifications Nos. 1304 and 1334.)

Heat Transmitted through Roofing Material Exposed to Strong Radiation.

Material.	Rise of Temperature in Testing Chamber Deg. C. per Minute.	British Thermal Units per 10 sq. ft. per Hour.	Thickness in Inches.	Weight in Pounds per Square Foot.
1. Bright galvanised iron sheet	0·268	111	0·04	1·6
2. Galvanised iron, blackened below	0·40	108	0·04	1·6
3. Galvanised iron, blackened above	0·93	385	0·04	1·6
4. Galvanised iron, blackened above and below	1·40	581	0·04	1·6
5. Galvanised corrugated iron after one month's exposure to the weather	0·75	310	0·033	1·28
6. Do. one year	1·02	422	0·033	1·28
7. (6) painted black above	1·13	472	0·033	1·28
8. Roofing glass, serrated	1·10	453	0·22	2·25
9. Welsh slate	0·81	337	0·17	2·9
10. Westmoreland slate	0·60	248	0·25	4·8
11. ¾-in. T.G. deal covered with asphalted felt	0·30	124	1·0	2·6
12. Corrugated fibrocement after one month in use	0·78	325	0·2	1·8
13. Do. after one year in use	0·80	334	0·2	1·8
14. Do. painted dead black	0·82	341	0·2	1·8
15. Do. 'aluminium-finished' outside	0·50	207	0·2	1·8
16. Do. laid on top of thin asphalted felt	0·51	211	0 25	2·0

A suggestion was made in a National Physical Laboratory Report that air spaces in roofing materials might be advantageous. A satisfactory means of doing this is to lay corrugated asbestos-cement plates on the thinnest asphalted felt or other light sheet material supported by the roof frames. The effect of this is shown by the table to be equal to that of an aluminium surface, and where heat insulation and lightness are of the first importance a strong and efficient roofing can be made in this way at a reasonable cost.

Load on Roofs.

Description of Covering.	Per Square of 100 Superficial Feet.	Minimum Slope.	Description of Covering.	Per Square of 100 Superficial Feet.
	Lbs.	Degrees.		Lbs.
Lead covering weighs	784	4	Timber framing for slated or tiled roofs	560 to 672
Zinc	168	4		
Corrugated iron	336	4		
Slates	840 to 1,008	25½ to 30	Additional load for pressure of wind	4,032
Tiles	896 to 1,680	26½ to 30		
Boarding ¾ inch thick	290	25	Ditto for Hurricanes, say	8,960
Boarding 1½ inch thick	580	25		

The angle of Gothic roofs should not exceed 60°.

Corrugated-Iron Roofing.

B. Wire Gauge.	Size of Sheets.	Weight per Square.	Square Feet per Ton.	B. Wire Gauge.	Size of Sheets.	Weight per Square.	Square Feet per Ton.
No.	Feet.	Lbs.		No.	Feet.	Lbs.

10	3½ × 2	7 × 1½	5 × 2	16	5 × 2	8 × 1½	8 × 2
12	4 × 2	7 × 1½	6 × 2	18	5½ × 2	8 × 1½	9 × 2

Collar-beam Roof.

Ceiling carried on under side of rafter and collar; collar best placed half-way up rafter; used for roofs up to 18′ span, under the same conditions as to wind, walls, and ties as given for couple roofs (fig. 4).

The rafters are nailed to ridge-piece and bird's-mouthed over wall-plate, 1′ apart in the clear, or from centre to centre on very exposed sites.

Ridge piece 7″ × 1½″.

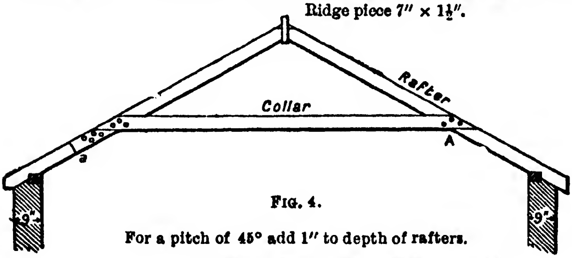

FIG. 4.

For a pitch of 45° add 1″ to depth of rafters.

SCANTLINGS FOR COLLAR-BEAM ROOFS.
Pitch up to 30°. If 45°, add 1″ to depth of rafters.

Span in Feet.	Rafters. For Countess Slates on ¾″ Boards, 1′ clear apart, or centre to centre if very exposed Site.				Collars.	
	† Thrust taken by Walls or Ties, Collars ½ way up.		‡ Tied by Collars ¼ way up to prevent Walls spreading.		From ¼ to ½ way up.	At any Height.
	No Ceiling.	Ceiled to Collars.	No Ceiling.	Ceiled to Collars.	No Ceiling.	Ceiled to Collars.
	Inches.	Inches.	Inches.	Inches.	Inches.	2″ wide × ½″ added to ½″ for every foot run of clear length of underside of collar.
8	1½ × 2½	1¾ × 3	2¼ × 3½	2¼ × 3¾	1¾ × 2½	
10	1¾ × 2½	1¾ × 3	2¼ × 4	2¼ × 4½	2 × 2½	
12	1¾ × 2¾	1¾ × 3¼	2¼ × 4½	2¼ × 5	2 × 2¾	
14	1¾ × 3	1¾ × 3½	2½ × 5	2½ × 5½	2 × 3	
16	2 × 3¼	2 × 3¾	2½ × 5½	2½ × 6	2 × 3½	
18	2 × 3¾	2 × 4¼	2½ × 6	2½ × 6½	2 × 4	

* When used they act as ties, B (fig. 3), but without K.
† Halve these collars on to rafters without cutting into latter.
‡ These rafters allow of the tension joint. If the collar is required halfway up, about one-fourth must be added to both breadth and depth of rafters, and ¼ in. to depth of collars. But with unstable walls, ties are far cheaper, and may be at long intervals if secured to wall-plates of sufficient width to take the thrust between the ties.

King-Post Roof.

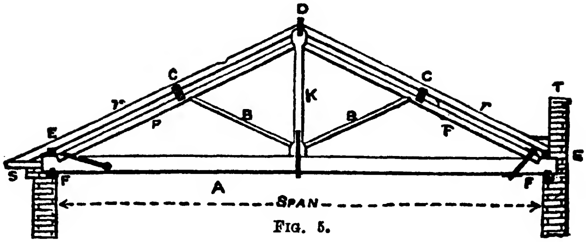

FIG. 5.

Used for spans from 20' to 30' (fig. 5).

A, tie-beam; B, braces or struts; C, purlins; D, ridge-board; E, pole-plate; F, wall-plate; K, king post; P, principal rafter; r, small or common rafter; S, eaves boarding; T, parapet.

Trusses, 10 apart ; pitch of roof. 26° 33′, or ¼ ; countess slates : timber, Baltic pine.
Wall-plates, F, 5″ × 4″ to 6″ × 4″ ; more if trusses are over openings.

Common Rafters.

12″ from centre to centre, or apart if not very exposed site.

Bearing in Feet.	Breadth in Inches.				
	1¾	2	2¼	2½	3
	Depth in Inches.	Depth in Inches.	Depth in Inches.	Depth in Inches.	Depth in Inches.
5	3	2⅞	2¾		
6	3¼	3½	3¼	3⅛	
8	4¾	4⅝	4⅜	4¼	4
10	6	5¾	5½	5⅜	5
12	7	6¾	6¼	6⅜	6
14	8¼	8	7¼	7½	7
16	9½	9¼	8¾	8½	8
18	10½	10¼	10	9½	9
20	11¾	11½	11	10½	10

Thin and deep rafters most economical; should not be thinner than 1¾″ to 2″, or may split when boards are nailed to them. For stone or tile covering should be one-third stronger.

Pressure of Wind and Weight of Snow on Roofs.

The *Wind Pressure* is usually assumed to be equal to 40 lbs. per foot in cases where the inclination of the roof is 60° ; for less angles than this the pressure is taken as follows :—

Inclination . . .	5°	10°	15°	20°	25°	30°	35°	40°	45°	50°	55°	60°
Pressure in lbs. per sq. ft.	5·1	9·6	14·2	18·4	22·6	26·5	30·1	33·3	36·0	38·0	39·4	40·0

The *Weight of Snow* in Great Britain varies from 5 to 11 lbs. per cubic foot. It is not likely to accumulate on roofs to a greater depth than 6 inches ; 5 lbs. per superficial foot of horizontal surface covered seems a quite sufficient allowance to make.

In Canada and the United States snow has been found in some instances to weigh as much as 30 lbs. per cubic foot some hours after it has fallen, and an allowance of at least 12 lbs. per superficial foot of horizontal surface covered should be allowed for it.

FLOORS

Wooden Floors.

Wooden floors are of three chief types, (i) single-jointed floors, (ii) double floors, and (iii) framed floors. They are described in architectural text-books. (See also British Standards Nos. 1018 and 1297.)

Jointless Floors.

Various bitumastic and other materials are used for *composition floors* or jointless floors, but the chief material used for this purpose is a magnesium oxychloride cement heavily loaded with a fibrous or other organic filler such as wood-fibre or sawdust. This can be finished with a denser, hard wearing surface, to produce a warm, comfortable, and durable floor. As the material is laid in a plastic condition it can be used in large uninterrupted areas and worked as a curved skirting to walls—a matter of some importance in hospitals and similar buildings. An excess of absorptive filler must not be used or the floor may 'sweat.' Magnesium oxychloride floors need protection by oiling or waxing to protect them against humidity and against decomposition by atmospheric carbon dioxide. They should be polished, but not washed or scrubbed (See p. 307).

Fire-resisting Floors.

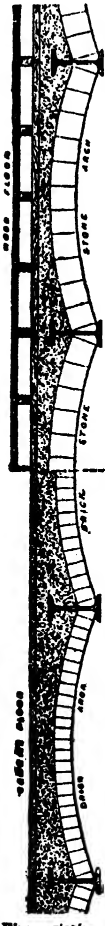

FIG. 7.

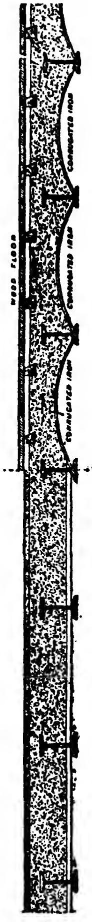

FIG. 8.

FIG. 9.

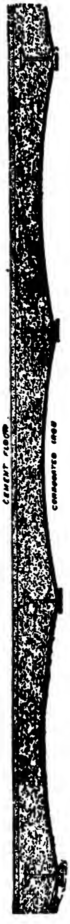

FIG. 10.

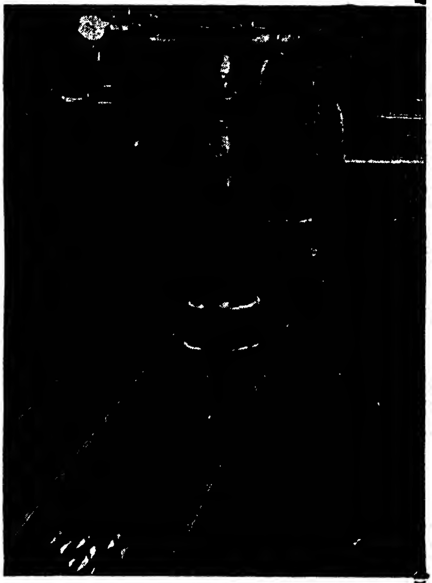
Fire-resisting floors are made of :—

(i) Reinforced concrete throughout.
(ii) Reinforced concrete between iron girders or rolled joists (figs. 8, 9).
(iii) Arches of corrugated iron or steel supported by rolled joists or girders (fig. 10).
(iv) Arches of brickwork or stone surmounted by concrete (fig. 7).
(v) Hollow blocks of burned clay (terra-cotta) between rolled joists, surmounted by just sufficient concrete to produce a smooth level surface without apparent joints. This type of

'SAFETREAD'

WELDED MESH STEEL FLOORING



Ideal for all types of Floors, Platforms, Gangways, Screens, Stairway and Ladder Treads, where strength, durability, economy and penetration of light are essential factors

Installations for Power Stations, Factories, Aerodromes, Works, etc., are a speciality, Light Supporting Steelwork, Stanchions and Handrailing also supplied at lowest prices

Manufactured by

ALLAN KENNEDY & CO. LTD.

MARITIME STREET, STOCKTON-ON-TEES

Phone, Stockton-on-Tees 67706. Grams, 'Grating, Stockton-on-Tees.'

floor is the most modern: it is the most resistant to heat and is relatively inexpensive. Many different shapes of hollow blocks are used.

See also 'Fire Resistant Construction,' ***Building Research Board Report No.*** **8 (1927), published by His Majesty's Stationery Office, York House, Kingsway, London, W.C. 2; price** 1*s*. 6*d*. net, and British Standard Specification No. 476.

The Ministry of Health's Model Byelaws, Series IV, Buildings, 1938, Clause 77, relating to floors is compulsory in some localities. Obtainable from H.M. Stationery Office, price 1*s*. 6*d*. net.

Factory Floors.

Floors used in some industrial buildings are particularly liable to corrosion in addition to ordinary wear and tear. Such floors should not undergo changes in volume or form shrinkage-cracks (produced in drying); for the sake of comfort, the floor should not be too hard, or too cold, slippery or noisy and should also look well and be easy to clean.

To resist very severe abrasion, paving brick, dense concrete, or heavy asphalt, reinforced with steel or iron grids are often used. Dust is highly objectionable in certain trades, for example, in painting shops and in food-manufacture. Concrete floors are liable to be dusty unless suitably treated. Wear is greatly reduced if factory trucks are fitted with rubber tyres with ball bearings and some means of steering; they also economise human effort, and are quieter in service.

In cheese factories, dairies, etc., where the destructive agents are mainly organic acids and fats, and abrasion is caused by the rolling of heavy churns, the best construction appears to be a hard, acid-resistant granitic asphalt-mastic, with cast-iron grids laid to form paths for churns; the provision of rubber mats at unloading points reduces wear, and prolongs the life of the churns.

In factories handling animal and vegetable fats or sugar, jams or fruit juices, quarry-tiles with a thin, neat Portland cement joint, or 'blue bricks' set in and jointed with aluminous cement mortar, is advisable. Timber is not likely to be attacked chemically, but will absorb fats, etc., and be liable to become very slippery and unhygienic.

In bacon, hide-tanning and other curing factories, the washing water contains salt which makes it necessary to protect a reinforced concrete sub-floor by an impermeable surface, such as asphalt.

The following British Standards may be helpful: Mastic asphalt Nos. 1076 and 1410. Magnesia compounds No 776. Pitch Mastic Nos. 1093 and 1177. Coloured Mastic No. 1375.

Sound-proof Floors.

The transmission of sound through floors can be minimised and in some instances prevented by providing a floating floor isolated from the walls, by the use of an isolating material of non-homogenous nature between the floor-covering and the floor proper, by massive and rigid construction of the floor itself, and by the use of a suspended ceiling. The suspended ceiling can be dispensed with in ordinary buildings if the floor-surface floats upon a resilient layer and has sufficient mass to absorb the energy of impact vibrations.

In converted flats and other locations where existing floors are to be made sound-proof a good result may usually be obtained by packing the space between the ceiling and the floor lightly yet fully with slag-wool. If the floor-boards are taken up in order to do this, strips of rubber or hair felt should be laid on the joists before refastening the boards and joists. Prior to using slag-wool, precautions should be taken to ensure that the ceiling will carry the additional weight which may be 80–90 lbs. per sq. yd.

See also 'Pugging' on p. 314.

Fire-resistant construction in floors normally provides adequate insulation against air-borne sound, but satisfactory insulation of the noise of footsteps and similar impact sounds can only be secured by the installation of a floor surface weighing some 20 lbs. per sq. ft. and floating upon a resilient medium. Normally this involves an increase of several shillings per square yard.

See also *Sound-proof Partitions* (p. 309) and *Sound Insulation* (p. 311).

Safe Loads on Floors.—**see p. 318 and 437.**

Partitions.

Partitions for internal use may be made of:—

(i) Deal boards—usually 2 ins. × 1 in. or 2 ins. square—placed about 2 ft. apart and covered with cheap canvas or calico, stretched tightly before nailing. The canvas may afterwards be covered with wall-paper applied in the usual manner. Such partitions are easily damaged, but are quite satisfactory for many purposes.

(ii) Slabs of highly porous concrete, sorel cement and sawdust, terra-cotta, plaster, or anhydrite, each slab being of a size convenient to handle, and fitted with a tongue and groove at opposite ends and sides so as to make a thin strong joint. (See British Standard No. 492.)

Lightness may be secured by mixing kieselguhr, diatomite, slag-wool, or sawdust with the clay of which terra-cotta slabs are made or with the plaster or sorel cement for other kinds of slabs. Alternatively, the plaster may be mixed with some substance which produces a foam or lather when wetted and so introduces a large volume of air-cells into the wet plaster.

Plaster-board is the most suitable form; *plaster-base* is a cheaper product which is satisfactory for rougher work. (See British Standard Specification No. 1230.)

The slabs may be simple (*i.e.* 'all in one piece') or they may be built up of two thin slabs of plaster, concrete, or terra-cotta with a different highly porous material, such as spun-glass.

(iii) Wooden panels, though these are usually expensive and are not sufficiently sound-proof.

(iv) Wooden laths nailed on to timber are cheap, but not sound-proof. The laths are usually covered with plaster in the same manner as ceilings. This kind of partition is stronger than (i) and is extensively used for bedrooms. In recent years, slab partitions (ii) have been much more popular as, though the slabs are more expensive than timber, the total cost of the partition is less and less skill is required in fixing.

(v) Multicellular glass has been reported upon favourably.

One of the lightest partitions on the market consists of very thin sheets of wood about an inch apart, with the intervening space filled with compressed wood fibre or wood-wool. It is extremely light and easy to fix, but very inflammable.

It is usually essential to avoid unnecessary weight in partitions, particularly when they are used in buildings not intended for them.

Where additional resistance to sound is required, two partitions about 2 ins. apart, with the intervening space packed with some light fibrous material, is usually satisfactory, but may form a home for mice.

When partitions are made of wood covered with canvas or other textile material they may be constructed as shown in figs. 11, 12 or 13.

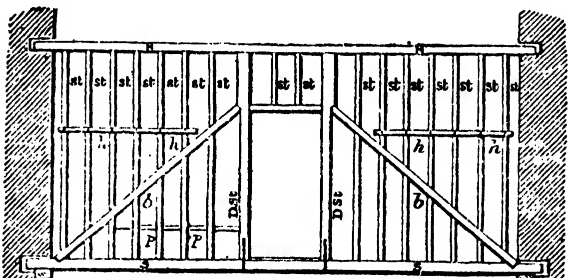


FIG. 11.

Partitions (fig. 11) should be framed so as to be supported only by the walls. *b* braces, H head, S sil, *st* studs, D*st* door-studs.

Dimensions of principal timbers, *b*, H, D*st*:—

4 ins.	× 3 ins.	for a bearing	not	exceeding	20 feet.
5 ,,	× 3½ ,,	,,	,,	,,	30 ,,
6 ,,	× 4 ,,	,,	,,	,,	40 ,,

The filling-in pieces, 'studs,' or 'quarterings,' need not be thicker than 2 ins., or just sufficient to nail the laths to. They are tennoned to the top and bottom plates, but butted and nailed on to the braces. If they exceed 3 ft. or 4 ft. in length they should be strengthened by short struts or horizontal pieces, as at *p*, *p*, called 'nogging pieces,' or, what is better, by a continued rail, *h h*, notched across the uprights and nailed to each. In a brick-nogged partition the nogging pieces are essential. They are much thinner than in a lath-and-plaster partition, being about ¾ in. thick and 2 ins. wide, placed at every fourth course of the brickwork in height.

The studs or quarterings for a lath-and-plaster partition should be spaced at from 12 ins. to 18 ins. from centre to centre; in a brick-nogged partition they should be 18 ins., 2 ft. 3 ins., or 3 ft. apart. If a partition is not well framed, or is made with unseasoned timber, the plastering will crack. Weight of a square (100 feet super) of partioning may be taken at 1,480 to 2,000 lbs.

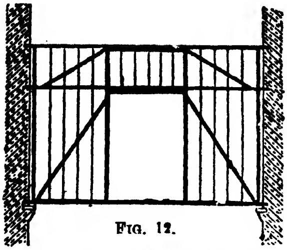

FIG. 12.

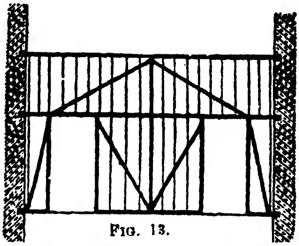

FIG. 13.

Figs. 12 and 13 show arrangements for partitions having doorways; in both cases the main portion of the partition is suspended from the truss forming the upper part of it.

Concrete Partition Slabs.

British Standard Specification No. 492—1933 requires that pre-cast solid concrete partition slabs shall be made of a specified aggregate (clinker, coke-breeze, pumice, or granulated blast-furnace slag) and Portland cement. The slabs must be matured for at least four weeks. The slabs shall be 17⅞ or 23¼ (±⅛) ins. long, 8⅞ or 11⅞ (±⅛) ins. high, and 2, 2½, 3, or 4 ($\pm\frac{3}{32}$) ins. thick, with bedding surfaces at right angles to the face. The edges forming the vertical sides shall be provided with tongues and grooves of specified radii. The slabs shall conform to the following:

For hollow concrete partition slabs, see British Standard Specification No. 728—1937.

Transverse test of six saturated slabs each supported on rods 15 ins. apart to correspond to a modulus of rupture of 100 lb. per sq. in.

Shrinkage on Drying not to exceed the following:

Type of Aggregate.	Linear shrinkage. Per cent.	Type of Aggregate.	Linear shrinkage. Per cent.
Clinker	0·08	Pumice	[illegible]
Coke-breeze	0·09	Granulated blast-furnace sla[illegible]	[illegible]

Moisture Movement or linear expansion after three days soaking in water [illegible]

Type of Aggregate.	Linear expansion. Per cent.	Type of Aggregate.	Linear expansion. Per cent.
Clinker	0·08	Pumice	[illegible]08
Coke-breeze	0·09	Granulated blast-furnac[illegible]	0·08

Loss of Ignition of slabs made with clinker and crushed to pass Stand[illegible] Sieve No. 72 not to exceed 28 per cent.

Density of the dried slabs not to exceed:

Type of Aggregate.	Average weight. Lbs. per cub. ft.	Type of Aggregate.	Average weight. Lbs. per cub. ft.
Clinker	90	Pumice	70
Coke-breeze	70	Granulated blast-furnace slag	90

A method for testing the suitability of clinker for use as aggregate is included in an Appendix to the Specification.

For Precast Concrete *Hollow* Partition slabs, see British Standard Specification No. 728—1937.

Sound-Proof Partitions.

The most effective sound-proofness of walls is obtained by a hard reflecting surface on the outside of the wall, by a non-homogeneous structure containing inert air-cells, by an air gap to prevent continuity, by a layer of insulating material, by a sound-absorbent surface facing the other room, and by massive and rigid construction: this is too costly for general use.

Other suitable sound-insulating materials are:

Rigid Acoustical Materials: boards of compressed straw and reeds, synthetic wood and other fibre boards, wood-wool boards made up with cement or plaster, and porous slabs of terra-cotta, stone or concrete.

Flexible Acoustical Materials: acoustic felts, eel grass blankets, slag-wool and vegetable fibre quiltings, glass silks, and sponge rubber.

Plastic Materials: sprayed asbestos, and acoustic plasters.

Tiling: porous tiling, perforated tiles with absorbent interiors, cork slabs, and fibre-board tiling.

Filling Materials: slag-wool and eel-grass, kapok, asbestos fibre, granulated cork, exfoliated mica, etc.

No partition is perfectly sound-proof, but sufficiently good results for most purposes may be obtained by using partitions of type (ii) on p. 307.

Partitions between rooms and flats and offices are commonly made of breeze two ins. thick and plastered both sides, but a minimum thickness of three ins. is required for adequate sound insulation, which thus entails a possible increase in cost. 'Party' walls between flats and offices are commonly made of two 2-in. thicknesses of breeze plastered both sides, but a more satisfactory sound insulation is obtained by the use of two 4½-in. brick partitions plastered on their outer faces or by some equivalent construction, but it is much more expensive.

Large cavities or plain spaces between a pair of walls do not produce good sound-proof partitions. The space should be filled with some porous or fibrous material so that a very large number of small separate air-cells is formed. It is important that as many as possible of the air-cells should be separate, as connecting cells are not nearly so sound-proof as are separate ones.

The smaller the cells the better, provided the 'walls' between them are sufficiently thin.

The larger the number of cells in a given volume (or weight) of partition the better will be the power of suppressing sound.

It is also important to use fibrous packing between a partition and the walls or floor with which it comes in contact.

'Solid to solid' fastenings destroy much of the value of an otherwise sound-proof partition. Hence, nails and screws should have rubber or other sound-insulating buffers.

Sound Insulation.

When a chamber is to be constructed so that no sound produced within it can be heard outside, or no externally produced sound can be heard in the chamber, it is seldom sufficient to make the walls, floor and ceiling merely sound-proof in the sense in which this word is applied to partitions. It is usually necessary to surround the chamber completely by a larger one with a space at least 4 ins. wide between the two and to make the walls, ceiling and floor of this external chamber also of sound-proof materials.

It is particularly important to avoid direct (hard) contact between solid materials, so fibrous or highly porous buffers must be used to prevent this. For some purposes rubber or asbestos cubes may be used as buffers, though they are neither porous nor highly fibrous. Metal-work should be avoided as much as possible as it is a good conductor of sound, and so is concrete unless it is sub-di[illegible]d with porous rubber, bituminous, or other sound-deadening materials between each sectio[illegible]

Vent[illegible] often a very difficult problem and much ingenuity is usually needed if adequate ventilat[illegible]e secured. Usually some form of forced draught, such as that created by an electri[illegible]tial.

A[illegible] principles just mentioned, there are no general rules for insulating buildings so tha[illegible] enter or leave them as this subject is still in an early stage of development.

See also S[illegible] *of Partitions* (p. 309), and *Sound-proof Floors* (p. 307).

Thermal Conductivity and Heat Transference.

The ready passage of heat through materials is sometimes of great importance, e.g. the plates of boilers, the tubes of recuperators and the sides of retorts and crucibles. The ability to transfer or conduct heat is a function of the material itself (metals being the best conductors and air and other gases the worst), of its density, and of its temperature. The denser the material the more readily will it transmit heat, whilst the more porous a material the lower is its conductivity.

Most inorganic building materials have a greater thermal conductivity when hot than when cold, but magnesian bricks are an exception. Carborundum has a much greater conductivity than fireclay, terra-cotta, silica or stone.

The following Table shows the thermal conductivity in gram-calories transmitted in one second through a plate of one square centimetre area and 1 cm. thick, the difference in temperature between the two faces being 1° C. (these figures can be converted into the British unit, viz. :— B.Th.U. per sec. per lin. cube for a difference of 1° F. by multiplying by 8·672).

Material.	Thermal Conductivity.
Stoneware	0·0045
Calais sand	0·0026
Carborundum	0·0145
Fused quartz	0·0039
Fireclay brick	0·0030
Silica brick	0·0020
Kieselguhr	0·0018
Slag-wool	0·0006
Calcined magnesia	0·0034
Porcelain	0·0043
Asbestos	0·0024
Graphite	0·0250

A valuable series of Reports on the transference of heat through walls of various kinds has been made by the Building Research Board, Watford, and published by H.M. Stationery Office. Kingsway, London, W.C. 2.
See also the Table on p. 300.
A valuable paper on Heat-conductivity by R. H. Heilman appeared in *Trans. Amer. Inst. Chem. Eng.*, 1935, 31, 165.
The *prevention* of heat-transference is effected by the use of *Heat Insulating Materials* (p. 375).

JOINTING BEAMS

Fishing.

To resist Tension.—For lengthening ties a plain fished joint is most economical for labour and material. The two ends of the beams are butted together, and secured on each side by means of bolts, as shown by fig. 14, which shows the fishing of a 6-in. × 4-in. beam with an iron plate on one side and a wooden plate on the other, the bolts being 1 in. in diameter with $1\frac{1}{2}$-in. heads, and the washers $2\frac{1}{2}$ ins. × $\frac{1}{4}$ in.

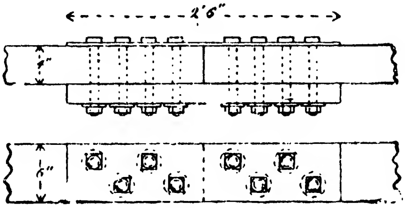

FIG. 14.

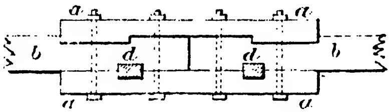

FIG. 15.

Another method is shown by fig. 15.
In this method, in order to relieve the strain on the bolts, the beam is indented or tabled as shown on upper side, or joggles or keys, *d*, *d*, are inserted. In either case the effective area is reduced by the indents or keys. The joint sectional area of the fish pieces, *a*, *a*, should equal that of the beam, *b*. The joint sectional area of bolts should be at least one-fifth that of timber minus bolt-holes. Bolts are better square than round. Large washers should be under bolt-heads and nuts; for oak the washers should be $2\frac{1}{2}$ times diameter of bolt, and for fir $3\frac{1}{2}$ times.

Scarfing.

To resist Compression (fig. 16).—The bearing surfaces, *e*, *e*, should always be perpendicular to compressing force. Fig. 17 is a more elaborate form.

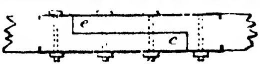

FIG. 16.

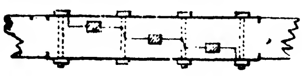

FIG. 17.

The lengths of scarfs should bear the following proportions to the depth :—

Wood.	Without Bolts.	With Bolts.	Bolts and Indents Combined.
Hard wood (oak, ash, elm)	6	3	2
Fir and straight-grained woods	12	5	4

The sum of the depths of the indents should equal 1½ depth of beam.

If assisted by fish-plates, it may be equal to the strength of a simple fished joint, which is as strong as the tie itself, less one rivet hole; and no advantage is gained by making the joint complicated, but it should be formed similar to that shown by fig. 16.

To resist Tension.—Fig. 18. is often used. It will hold without bolts or straps. At *c* a key or joggle of hard wood is inserted, wedged in so as to tighten the joint moderately; depth of key one-third depth of beam. This joint has only one-third the strength of solid timber tie; it may be increased by bolting an iron fish-plate on each side, as in fig. 19.

FIG. 18.

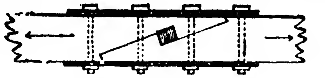

FIG. 19

To resist Compression and Tension.—Fig. 20 is suitable. The wedges at *c* are only required when bolts are to be added, in which case they are used to bring the parts together before the bolts are inserted, in order to prevent violent strains on the latter.

FIG. 20

To resist Cross Strains.—Fig. 21 is the best. The joint at *a*, being in compression, should be kept square; the lower, having to resist tension, may be oblique. There should be as great a thickness as possible at *b c*. To resist cross-strain, the scarf is strongest when made vertical, *i.e.*, the pressure in the figure being at right angles to the paper.

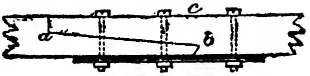

FIG. 21.

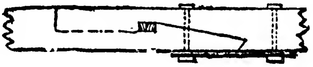

FIG. 22.

To resist Cross Strain and Tension.—The resistance to tension is given by indenting the beam and inserting wedges, as shown in fig. 22.

T Joint.

A very effective method of securing two pieces of wood, A and B, at right angles to each other, is to insert in a mortice hole in B a piece of aluminium *a* which has been drilled with a hole into which an ordinary wood screw *s* is forcibly screwed. The aluminium being comparatively soft enables the wood screw to readily work its way through the hole, whilst it forms a nut which enables the screw to be very tightly screwed up as shown in fig. 23.

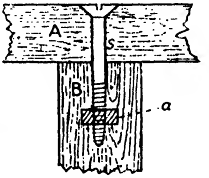

FIG. 23.

Building-up.

For building-up or joggling beams the method shown by fig. 24 may be adopted. This figure shows a portion of a 9 × 18-inch beam, 22 feet long, formed of two 9 × 9-inch beams secured

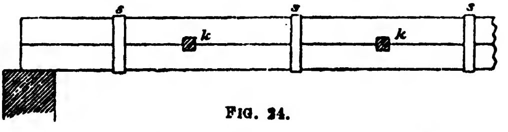

FIG. 24.

by wrought-iron straps, *s*, *s*, *s*, each 2 × ¼ inches; keys, *k*, each 2 × 2 inches, prevent the two pieces of which the beam is formed from sliding on one another.

Fig. 25 shows a similar beam with the two halves indented the one into the other so as to prevent sliding.

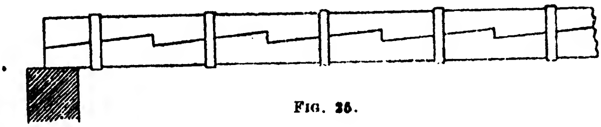

FIG. 25.

Mortise and Tenon.

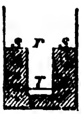

FIG. 26.

Mortising Upright into Horizontal.—The tenon, T (fig. 26), is usually one-third breadth of vertical. The pin-hole, if any, is generally placed at one-third length of tenon from shoulder, *s s*, and its diameter=one-fourth thickness of tenon. The mortise is made a little deeper, so that the shoulder may bear well; *r* is the *root*; C, C are the *abutment cheeks*.

Mortising Horizontal Beams.—The tenon is a projection from the end of the cross-beam, fitting closely into a mortise cut in the side of the main beam. It should be at the middle of its depth, so that the centre of the mortise may be at the neutral axis. Practically its lower edge is generally *on* the neutral axis.

Shouldered or Tusk Tenon.

To keep a cross-beam steady in its position a tenon requires length; to bear its share of load it requires depth; but a tenon long and deep would weaken the main beam too much. To avoid this a shouldered tenon is used. G (fig. 27) is the girder of a floor, B the binding joist, *a* the shoulder, *b* the tenon. The shoulder penetrates the girder about one-sixth depth of joist. Depth of tenon about one-sixth depth of joist; length about twice its depth, or it may be carried right through a thin girder and pinned, as in the case of a trimmer running into a trimming joist. Care should be taken that both tenon and shoulder bear exactly. Tredgold says the tenon should be one-third depth of joist above its lower edge. It should be, however, in the neutral axis.

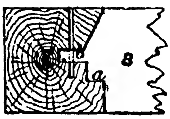

FIG. 27.

Post and Beam Joints.—To frame a horizontal beam into the side of post the 'shouldered tenon' is used, but the long tenon should be on edge or have its narrowest dimensions horizontal.

When the beam rests on the top of the post, a small tenon in centre of post may fit into mortise on the under side of the beam. Or the post may fit into a shallow rectangular notch in beam, the notch being divided into two parts by a *bridle* left uncut in the middle of the notch. about one-fifth breadth of beam.

Wedges.

When the end of the tenon is seen, it is kept tight by driving wedges of hard wood dipped in glue or white-lead between tenons and sides of mortise. When end of tenon is not seen, small wedges, called *fox wedges* (fig. 28), are inserted in saw cuts in end of tenon; when tenon is driven home, they enter and expand it. The mortise is dovetailed or made slightly wider at bottom This joint, when properly made, has the advantage that the post or style shrinks towards the shoulder and not away from it, and for this reason is sometimes employed for first-class work.

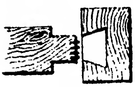

FIG. 28

Joint of Straining-Beam.

In oblique joints under compression the joint should be either perpendicular to one piece, as at *a* (fig. 29), or bisect the angle, as at *b*; the latter is the best in the case given in the figure. With a thicker strut at *b* it would be as shown by the dotted line.

Joints in carpentry should have white-lead applied with a brush over the surface forming the joint

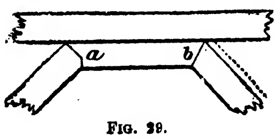

FIG. 29.

Strutting.

Joists laid with boards on top, and lath and plaster underneath, are not found to be sufficient to prevent bending and vibration under pressure. To remedy this, which is injurious to walls and to timber, strutting is placed in straight, continuous rows, at intervals not more than 4 feet apart, which reduces to a great extent the defect.

The following are three methods of strutting :—

Herring-bone Strutting.—This consists of pieces about 2 inches square fixed as shown in fig. 30.

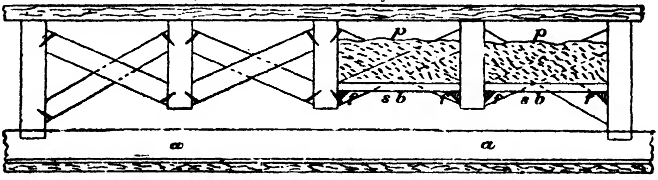

FIG. 30.

It is usual, instead of boring holes for nails, to make a saw cut at ends, and through this channel to drive the nail. By doing this any danger of splitting is avoided. This method has the recommendation that it acts where its leverage to prevent bending is greatest, viz., at the edges of joists, and is used largely in dwelling-houses.

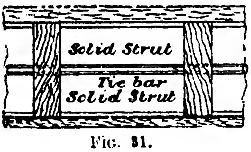

FIG. 31.

Solid Strutting.—1 or 1¼-inch boards, nearly the same depth as joists, are cut in tightly, and nailed between joists, as in fig. 31. This method is largely used for floors of factories and heavy buildings; and if cut so that the entire shoulder butts against the joists, is undoubtedly the firmest method; but unless care is exercised, the shoulders are apt to bite on the centre only. Sometimes long bolts, either of round bar or gaspipe, are passed through all the joists, and the strutting squeezed together with the joists and held tightly.

Key Strutting.—In this method struts are tenoned at their ends, and pass through mortises cut in the joists, and are secured with wooden keys. The method is expensive, weakens the joist, and altogether is a defective and unsatisfactory arrangement.

Pugging.

To prevent sound, sound-boarding, *s b* (fig. 30), is supported by fillets, *f*, *f*, cut diagonally out of 2-inch × 1¼-inch stuff nailed to bridging joists half-way between floor-boards and ceiling joist, *a*, *a*: over these pugging, *p*, *p*, of coarse plaster about 1½ inch thick is put. Dry moss or a mixture of lime mortar, earth, and smith's ashes, or chopped straw, is sometimes used instead of plaster. Strips of felt are sometimes placed between the joists and boarding to deaden sound.

See also p. 307.

Stairs.

Stairs (fig. 32) are described according to their form in plan, viz. :—

1. *Straight*—*a*.
2. *Dog-legged*—*b*; when the flights rise alternately in opposite directions with no interval between the flights.
3. *Open newel*—*c*; when the flights are ranged round an open well-hole, with a newel post at each angle.

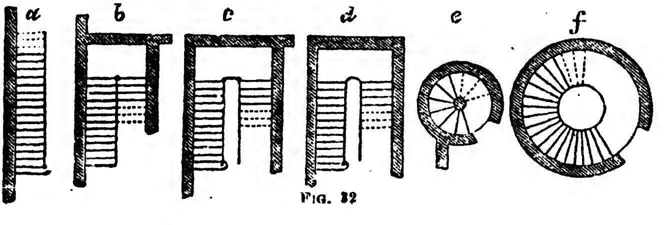

FIG. 32

4. *Geometrical—d*; similar to the last but with no newel posts: the handrail running uninterruptedly from bottom to top. The angles of the well-hole are generally rounded.

5. *Circular newel—e.*

6. *Circular geometrical—f*; when without a central newel.

Width—Stairs should be 3' 6" wide to allow two persons to pass easily.

***Tread and Rise.*—Tread should be from 9 ins. to 12 ins., rise from 6 ins. to 7½ ins. Some architects and builders increase the tread as the rise diminishes, but this is not satisfactory as there is no true mathematical relation between the tread and rise. The tread should be sufficiently large to accommodate average adult feet and the rise should not exceed 8 ins. for general use. Narrow treads and high rises are dangerous—particularly to elderly people and children—and should be avoided. If a very steep stairway with narrow treads is required it is better and much safer to make it in the form of a flat-runged ladder.**

***Safety treads* are increasingly used on public stairways. Their chief characteristic is a rough surface which will reduce slipping. This roughness may be obtained by using a cover of metal with a series of narrow grooves having sharp edges, but a still better method is to use a fine concrete containing a suitable proportion of small sharp particles of a very hard aggregate, such as carborundum; this grips the soles of the shoes sufficiently to prevent slipping, yet does not appreciably retard movement.**

The tread should be level throughout, strips fastened on to the head and projecting slightly above it are a cause of frequent accidents.

***Flights.*—It is dangerous to have a stair between two floors more than 9' apart in one continuous flight. It is desirable to limit height of one flight to about 7', and to avoid having two flights in one direction. *Winders* should be avoided if possible.**

Handrail.—Upper surface should be from 2' 7" to 2' 9" above the surface of the tread at the nosings, and on landings from 3' to 3' 3". Or, taking the height at landings as 3' subtract ½ the rise for height of rail from nosings of steps.

Materials.—In lofty dwellings it is desirable that stairs should be of stone or concrete, to be fireproof, at any rate in the lower storeys.

Stone Stairs.—Steps are supported by a wall at one or both sides. When at one side only they are called hanging steps, and should be built at least 9" into the wall. The bottom step is bedded on the floor, and the lower front edge of each other step rests on the upper back edge of the step below. The best form for the joint is shown in fig. 33, where the face *ab* is at right angles to the general inclination of the stair, and about 1" wide. Spandrel steps should have the sides which are built into the wall left square.

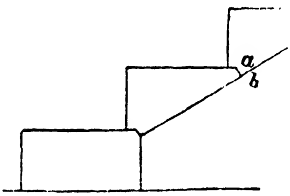

FIG. 33.

Repairing Stone Steps when Worn.—One plan is to fill up the hollows with Portland cement concrete made with fine sharp washed gravel about the size of a pea, 1 part gravel, 1 part cement. The worn part should be chiselled down, so as to give at least ¾" thickness of concrete in every part. The edge of concrete steps should always be rounded. Another method is to insert and cement slabs of artificial stone instead of concrete. **The surface of the whole tread must be flat when finished as any appreciable projection will probably cause accidents.**

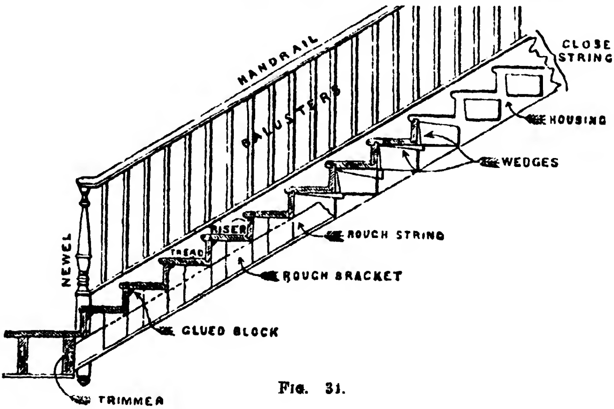

FIG. 34.

Wooden Stairs —Fig. 34.—Treads should be of hard wood, 1¼ in. thick, for steps 4 ins. long, increasing ⅛ in. for every additional 6 ins. of length.

The treads and risers are supported by a wall string and an outer string, the former 1¼ in. thick, the latter 2 ins. Treads and risers are housed into the wall string, and secured by wedges. The outer ends may be either housed into a close string, or may rest on and be mitred to the notches of an open string.

When stairs are more than 3 ft. wide, treads should be supported by rough strings or carriages fixed underneath and framed into the trimming joists of the landings. Scantlings of rough strings are calculated as bridging joists. Rough brackets are nailed to the side of the rough string to support the treads.

Joints between treads and risers are grooved and tongued, feathered or rebated. The last is the best joint.

BRICKWORK.

For *Regulations* concerning Brickwork, see Ministry of Health Byelaws, Series IV, Buildings (1938), Clauses 8–12 and 25–53 (H.M. Stationery Office, London, price 1*s*. 6*d*. net); see also p. 318.
For *Sizes of Bricks* see p. 365.

Brickwork is usually quoted in terms of a wall 1½ bricks or 14 ins. thick; such quotations are known as *reduced brickwork*. Thus, a wall of 320 sq. ft. area and 28 ins. thick would be quoted as 640 feet super of reduced brickwork. Such calculations only give roughly accurate results.

The thickness of walls is regulated by the size of the bricks, and walls are 4½ ins. or half-brick thick, 9 ins. or 1 brick thick, 14 ins. or 1½ bricks thick.

1 rod of brickwork = 272 superficial ft., 1½ bricks thick; = 11½ cubic yards = 296 cub. ft. = 235 ft. of bricks and 71 of mortar; = 4,500 bricks; = 15 tons average weight (see p. 317).

1 rod of brickwork requires about { 1 cubic yard of stone lime, 3½ cubic yards of sand; or 1½ yards of chalk lime, 3 yards of drift; or 1 cubic yard of cement, 3½ cubic yards of sand.

1 cubic yard of brickwork requires about { 6½ cubic feet of sand. 2½ " " lime.

1 builder's cart load of bricks = 500 bricks. 1,000 stock bricks, closely stacked = 55 ft. cube, 1,000 old bricks, cleaned and loosely stacked = 70 ft. cube. 1 ft. of reduced brickwork = 16 bricks. 1 ft. of superficial facing = 7 bricks. 1 ft. superficial of gauged arches = 10 bricks. 1 yard superficial in bricknogging, laid flat = 45 bricks and ¾ cubic foot of mortar. 1 yard superficial in bricknogging, laid on edge = 30 bricks and ½ cubic foot of mortar.

1 yard of paving = 36 stock bricks laid flat, = 52 bricks on edge. = 82 paving bricks on edge = 125 Dutch clinkers laid flat, = 140 Dutch clinkers on edge, = 136 Dutch clinkers laid herring-bone.

For crushing strength of bricks see p. 365, and for strength of brickwork see pp. 180, 365.

NUMBER OF PAVING BRICKS AND TILES.

(*Required per Square Yard.*)

The number of Paving Bricks or Flooring Tiles required per square yard (if all the joints are the same thickness) may be calculated from the formula *

$$N = \frac{1296}{L.W}$$

where N = number of bricks or tiles required per sq. yd.
L = length (in inches) of one brick or tile plus the thickness of one joint.
W = width (in inches) of one brick or tile plus the thickness of one joint.

When the tiles are square, L = W. It is often necessary to use some 'half tiles' to fit the desired space; this fact must be borne in mind when ordering.

ESTIMATING BRICKWORK.

A standard rod of brickwork is a wall 16½ ft. long, 16½ ft. wide and 1½ bricks (approx. 13½ in. thick.

The number of bricks in a rod of brickwork of any thickness depends on the size of the bricks and the thickness of the joints; it may be calculated from the formula †

---

* In this formula, no allowance is made for waste so that in practice a rather larger number of bricks or tiles should be ordered.

† No allowance is made for 'closers' or for waste, so that in practice a rather larger number of bricks should be ordered. An allowance of 3 per cent. for waste is usually ample but much depends on the thickness of the bricks, the conditions of transport and the manner in which they are handled.

$$N = \frac{39{,}204T}{H.L}$$

When N = Number of bricks.
L = Length (in inches) of one brick plus thickness of one joint.
H = Height (in inches) of one brick plus the thickness of one joint.
T = Thickness (in inches) of the wall divided by the width (in inches) of one brick.
In a standard rod, T = 3.

When standard bricks (British Standard Specification No. 657/1941) are used and all the joints are of equal thickness the number of bricks in a standard rod of brickwork is shown in the following table:

NUMBER OF BRICKS IN STANDARD ROD.

Height of brick (in.)	2	2	2	2	2⅝	2⅝	2⅝	2⅝	2⅞	2⅞	2⅞	2⅞
Thickness of joint (in.)	¼	⅜	½	⅝	¼	⅜	½	⅝	¼	⅜	½	⅝
Height of 4 courses (in.)	9	9½	10	10½	11½	12	12½	13	12½	13	13½	14
Number of bricks* (no waste)	5810	5439	5085	4780	4545	4300	4070	3860	4180	3965	3770	3585
Number of bricks (allowing 3 per cent. waste)[1]	5990	5600	5245	4930	4685	4430	4195	3980	4310	4090	3885	3695

[1] These figures are to the nearest five bricks.

Bricks absorb one-fifth of their weight of water, but the proportion varies greatly. Engineering bricks should be quite impervious to water.

A bricklayer's hod will hold 20 bricks, ⅝ cubic foot of mortar, or nearly ½ bushel.

In a day of 10 hours a bricklayer can lay about 1,500 to 1,600 bricks where the joints are left rough, about 1,000 when both faces are worked fair, or 500 when carefully pointed and faced with picked bricks.

For ordinary purposes, assume roughly that a bricklayer and labourer can, if they choose, turn out 2 cubic yards per diem, containing 800 bricks.

Bonds for Brickwork.

(Revised by E. A. W. Phillips, M.I.C.E., M C.I.)

ENGLISH THIN-WALL BOND (fig. 35) is the simplest for all ordinary work where the walls do not exceed three brick-lengths in thickness. The heading and stretching courses always alternate in this class of bond. No stretchers occur except those seen on faces of walls. No bricks in the same course should break joint with each other. All vertical joints in any course should be covered (by one-quarter brick laps at least) by the courses above and below, and this whether offsets occur or not, or other differences in the thicknesses of the walls.

FLEMISH BOND (fig. 36) shows headers and stretchers alternately in each course on the faces of walls. Is quite as strong as *English Thin-wall Bond*, since the quarter laps are in the same manner equally well maintained. *Flemish Bond* gives a better appearance for 9-inch walls, as a smoother face can be shown on both sides. In *double Flemish Bond*, both back and front of walls show Flemish Bond; in *single Flemish Bond*, one face shows Flemish, the other English bond, as above.

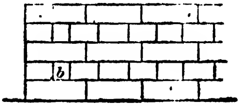

FIG. 35. English Bond.

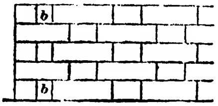

Fig. 36. Flemish Bond.

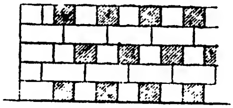

FIG. 37. English Thick-wall Bond.

ENGLISH THICK-WALL BOND (fig. 37). In this bond, every brick in a stretcher course should be a stretcher, and every brick in a header course should be a header. The bricks not only break joint, by half their lengths, with the bricks in the same description of course (i.e., stretcher or header) next above or below them, but also break joint, by half their lengths, in the same course. This is the strongest form of bond known, and should invariably be used in heavy walling, of 3½ bricks thickness and over. The quoin difficulty is best overcome by having a few specially moulded bricks, one brick-length in length, and ¾ of a brick-length in width, and of the usual thickness. The half-bricks on faces in fig. 37 are shaded.

* In this formula, no allowance is made for waste so that in practice a rather larger number of bricks or tiles should be ordered.

Garden-wall Bond is the *English Thick-wall Bond* adapted to thin one-brick walling, several courses of stretchers occurring to one course of headers. The same thing may be done with *chimneys*, where the walls are 9 ins. thick.

Diagonal Bond and **Herring Bone Bond** are only useful for paving. *English Thick-wall Bond* is stronger than either.

Header Bond consists entirely of headers, and is used for sharp curved or quick-sweep walls.

Stretcher Bond, entirely of stretchers, is used in ½-brick walls of all kinds.

Other bonds, Roman bond, and the Sussex bonds, are described in ' Indian Engineering. See also papers in the Minutes of Proceedings of Civil Engineers, vol. clxxi.

Closers, *b* (figs. 35, 36), are necessary in every alternate course to close the work on to any vertical line, or to start the bond from it; they run through the thickness of the wall.

Queen Closers, as *b*, are ½-headers formed by cutting a brick or a half-brick, called a *bat*, ongitudinally in half; ¾-stretchers, or ¾-*bats*, can be used as closers, but not so economically.

King Closers are bricks cut to a splay, so as to obtain as strong a bond as possible in closing on recessed openings, as for doors and windows.

Hoop-iron Bond, for walls, is generally formed of hoop iron, from 1 in. to 1½ in. wide and 18 B.W.G. ($\frac{1}{20}$ in.) to 16 B.W.G. ($\frac{1}{16}$ in.) thick; it should be clean bright and bedded in cement, for if allowed to rust it swells and injures the wall; it holds better if the edges are jagged. Useful in erecting works on bad foundations, but must not be relied on to give permanent strength unless laid as carefully as reinforcement.

LONDON BUILDING ACT (AMENDMENT) ACT, 1935.

(Abstract from the By-laws.)

For definitions of terms, see the ' London County Council By-laws for the Construction and Conversion of Buildings ' (obtainable from P. S. King & Son, Ltd., 14 Great Smith Street, Victoria Street, Westminster, S.W. 1).

Superimposed Loads.

The minimum superimposed load on each floor and on the roof shall be estimated as equivalent to the following dead loads :—

Class No.	Type of Building or Floor.	Slabs : lb. per sq. ft. of Floor Area.	Beams : lb. per sq. ft. of Floor Area.
1.	Rooms for residential purposes, corridors, stairs and landings in residences or flats	50	40
2.	Offices, floors above entrance floor .	80	50
3.	Offices, entrance floor and floors below, also garages for private cars of not more than 2½ tons net weight	80	80
4.	Corridors, stairs and landings other than Class I	100 or above.*	100 or above.*
5.	Workshops, factories and garages for cars other than those in Class 3	150 or above.*	120 or above.*
6.	Warehouses, book stores, stationery stores and the like.	200 or above.*	200 or above.*
7.	Any other purpose	*	*
	Roofs.	Slabs : lb. per sq. ft. of covered area.	Beams : lb. per sq. ft. of covered area.
8.	Flat roofs and roofs at an angle with the horizontal of not more than 20° .	50	30

On steeper roofs, a minimum superimposed load (including the wind load) of 15 lb. per sq. ft. of surface acting normal to the surface on the windward side and 10 lb. per sq. ft. of surface acting separately and not simultaneously outward on the leeward side. In estimating the vertical

* To be to the satisfaction of the L.C.C. surveyor.

superimposed roof load on all other parts of the construction a vertical superimposed load of 10 lb. per sq. ft. of covered area to be substituted.

In all cases of floors where the positions of partitions are not definitely located in the design, a uniformly distributed load to allow for them should be added to the dead floor load. For all floors of offices the minimum total allowance for internal partitions to be 20 lb. per sq. ft. of floor area.

Slabs and Beams.

Slabs and beams should be capable of carrying the following superimposed loads in any position on an otherwise unloaded floor :—

Class of Floor.	Minimum superimposed Load.	
	Slabs.	Beams.*
Floors of Class 1 (p. 318)	¼ ton uniformly distributed per foot width.	1 ton uniformly distributed.
All floors of Classes 2 to 6 (except garage floors of Class 5)	½ ton uniformly distributed per foot width.	2 tons uniformly distributed.
Garage floors of Class 5	1·5 × maximum possible combination of wheel loads, but each wheel load not less than 1 ton.	

Buildings of more than two storeys in height, in which loads and stresses are transmitted through each storey to the foundations, the superimposed loads of the roof and topmost storey shall be calculated in full in accordance with the table on p. 318, but for the lower storeys a reduction of the superimposed loads is permissible for all floors with a superimposed load of less than 100 lb. per sq. ft. namely :—

Next storey below topmost storey	10 per cent. reduction of its superimposed load
Next storey below	20 " " " "
Next storey below	30 " " " "
Next storey below	40 " " " "
Each succeeding storey below	50 " " " "

Where a superimposed load may move, proper provision to the satisfaction of the surveyor must be made.

Where floors are constructed for superimposed loads exceeding 100 lb. per sq. ft. a notice (in terms stated in the By-laws) must be shown in each storey having such a floor.

Wind Pressure.

All buildings must be able to resist a wind pressure in each horizontal direction of not less than 15 lb. per sq. ft. on the upper two-thirds of its surface up to the ridge of the roof and a further pressure in each horizontal direction of not less than 10 lb. per sq. ft. on all projections above the general roof level or ridge.

If the height of a building is less than twice the width of the base, the surveyor may not require the wind pressure to be calculated on the building as a whole.

Rules for the Walls of Buildings not Public and not of the Warehouse Class.

(*London Building Act (Amendment) Act*, 1935, *and By-laws* 39–62.)

According to this Act the external and party walls of dwelling-houses must be made throughout the different storeys of the thickness shown in the following Table, arranged according to the heights and lengths of the walls, and arranged for walls up to 120 feet in height, and supposed to be built of bricks not less than 8½ inches long or of stone or other blocks of hard and incombustible substance, the beds or courses being horizontal, the heights of the storeys being subject to the conditions given after the Table.

* Beams and ribs not more than 2½ ft. between centres shall be calculated for slab loads. Non-load bearing beams, such as those used solely as ties, are exempt.

TABLE I.

Height.	Length.	Thickness.
1. Up to 12 ft.	Unlimited.	8½ ins. throughout.
2. 12–25 ft.	Up to 30 ft.	8½ ins. throughout.
„	Over 30 ft.	13 ins. in lowest storey; 8½ ins. for remainder.
3. 25–30 ft.	Up to 20 ft.	8½ ins. throughout.
„	20–30 ft.	13 ins. for lowest storey; 8½ ins. for remainder.
„	Over 30 ft.	13 ins. for lowest two storeys; 8½ ins. for remainder.
4. 30–40 ft.	Up to 35 ft.	13½ ins. throughout except top storey which shall be 8½ ins
„	Over 35 ft.	17½ ins. for lowest storey, 8½ ins. in top storey and remainder 13½ ins.
5. 40–50 ft.	Up to 35 ft.	Ditto.
„	35–45 ft.	17½ ins. for lowest two storeys, remainder 13 ins.
„	Over 45 ft.	21½ ins. for lowest storey, 17½ ins. for the next storey and 13½ ins. for remainder.
6. 50–60 ft.	Up to 45 ft.	17½ ins. for lowest storey; 13½ ins. for remainder.
„	Over 45 ft.	21½ ins. for lowest storey; 17½ ins. for next two storeys, and 13 ins. for remainder.
7. 60–70 ft.	Up to 45 ft.	21½ ins. for lowest storey, 17½ ins. for next two storeys, and 13 ins. for remainder.
„	Over 45 ft.	Increased in thickness by 4½ ins. except in top two stories.*
8. 70–80 ft.	Up to 45 ft.	21½ ins. for lowest storey, 17½ ins. for next three storeys, and 13 ins. for remainder.
„	Over 45 ft.	Increased in thickness by 4½ ins. except in top two storeys.*
9. 80–90 ft.	Up to 45 ft.	26 ins. for lowest storey, 21½ ins. for next storey, 17½ ins. for next three storeys, and 13 ins. for remainder.
„	Over 45 ft.	Increased in thickness by 4½ ins. except in two top storeys.*
10. 90–100 ft.	Up to 45 ft.	26 ins. for lowest storey, 21 ins. for next two storeys, 17½ ins. for next three storeys and 13 ins. for remainder.
„	Over 45 ft.	Increased in thickness by 4½ ins. except in two top storeys.*
11. 100–120 ft.	Up to 45 ft.	30 ins. for lowest storey, 26 ins. for next two storeys, 21½ ins. for next two storeys, 17½ ins. for next three storeys, and 13 ins. for remainder.
„	Over 45 ft.	Increased in thickness by 4½ ins. except in top two storeys.*

NOTE.—If the thickness of the wall, calculated by the above Table, is less than one-sixteenth of the storey height, the thickness of the wall shall be increased to one-sixteenth of the storey height and the thickness of the wall below such storey height shall be increased to a like extent.

The Ministry of Health's Byelaws, Series IV, Buildings, 1938 (H.M. Stationery Office, London, price 1*s*. 6*d*. net) are compulsory in many localities.

Rules for the Walls of Buildings of the Warehouse Class.

(London Building Act (Amendment) Act, 1935, and By-laws 39–62.)

The external and party walls of buildings of the warehouse class must at the base be made of not less thickness than that shown in the following Table, arranged for walls up to 120 feet in height, and supposed to be built of bricks not less than 8½ inches, or of stone or other blocks of hard and incombustible substance, the beds or courses being horizontal.

In all walls exceeding 30 ft. in height the uppermost 16 ft. shall be less than 13 ins. thick, and the intermediate part between this 16 ft. and the base shall not be thinner than if the wall were to be built solid throughout the space between straight lines drawn on each side of the wall and joining the thickness at the base to the thickness at 16 ft. below the top or, where hereinafter specified, not less than 4½ ins. in excess of such thickness.

* Subject to By-law 53 respecting distribution in piers.

TABLE II.

Height.	Length.	Thickness.
1. Up to 25 ft.	Unlimited.	13 ins. at base.
2. 25–30 ft.	Up to 45 ft.	13 ins. at base.
"	Over 45 ft.	17½ ins. at base.
3. 30–40 ft.	Up to 35 ft.	13 ins. at base.
"	35–45 ft.	17½ ins. at base.
"	Over 45 ft.	21½ ins. at base.
4. 40–50 ft.	Up to 30 ft.	17½ ins. at base.
"	30–45 ft.	21½ ins. at base.
"	Over 45 ft.	26 ins. at base.
5. 50–60 ft.	Up to 45 ft.	21½ ins. at base.
"	Over 45 ft.	26 ins. at base.
6. 60–70 ft.	Up to 45 ft.	21½ ins. at base.
"	Over 45 ft.	Increased in thickness from base up to 16 ft. from top by 4½ ins.*
7. 70–80 ft.	Up to 45 ft.	21½ ins. at base.
"	Over 45 ft.	Increased in thickness from base up to 16 ft. from top by 4½ ins.*
8. 80–90 ft.	Up to 45 ft.	26 ins. at base.
"	Over 45 ft.	Increased in thickness from base to 16 ft. from top by 4½ ins.*
9. 90–100 ft.	Up to 45 ft.	26 ins. at base.
"	Over 45 ft.	Incteased in thickness up to 16 ft. from top by 4½ ins.*
10. 100–120 ft.	Up to 45 ft.	31 ins. at base.
"	Over 45 ft.	Increased from base up to 16 ft. from top by 4½ ins.*

NOTE.—If in any storey the thickness of an external or party wall as calculated from the above Table is less than one-fourteenth of the storey height, the thickness of the wall shall be increased to that figure and the thickness of the wall below such storey shall be increased to a like extent.

Rules for Permissible Stresses in Walls and Piers (where thicknesses are not determined as shown on pp. 320, 321).

(*London Building Act (Amendment) Act*, 1935, *and By-laws* 59–61.)

If in a storey, part of a wall is borne by a pier or a pier is borne by part of a wall, such pier together with the part of the wall of the storey directly above or below it shall be deemed to be a pier extending throughout such storey. Where a pier and a wall are in structural combination horizontally and the pier projects from the wall, if such projection from one face of the wall does not exceed one quarter of the wall thickness or if the sum of two projections from two faces does not exceed one-third the thickness of the wall such combination shall be deemed to be a wall. If such projections exceed the amounts mentioned above, the combination shall be deemed to be a pier, whose thickness or width shall be measured from the face of the projection on one side of the wall to the face of the projection on the other side.

The *slenderness ratio* of a wall or pier is the ratio of the effective height to the horizontal dimension lying in the direction of the lateral support.

The *effective height* of a wall or pier is :

Nature of Wall or Pier.	*Effective Height.*
(*a*) Wall without lateral support at the top.	1½ times the actual height.
(*b*) Wall with lateral support at the top.	¾ of the actual height.
(*c*) Pier without lateral support at the top.	Twice the actual height.
(*d*) Pier with lateral support at the top.	The actual height.

Any storey-height of a wall or pier not having a slenderness ratio exceeding 6, built of bricks or blocks, the total compressive stress due to the vertical load, horizontal pressure and any other forces shall not exceed the maximum pressure shown in Table III in respect of the bricks or blocks or the proportions of the mortar, whichever is the weaker. If the storey-height is built of concrete Table IV shows the maximum permissible compressive stress.

* See footnote to Table I, p. 320.

Where the slenderness ratio is 12, the total compressive stress shall not exceed 40 per cent. of those shown in Tables III or IV.

Where the slenderness ratio is between 6 and 12 the maximum permissible pressure shall be proportionate.

TABLE III.

MAXIMUM PERMISSIBLE PRESSURES ON WALLS OF BRICKS OR BLOCKS.

Class of Bricks or Blocks.	Compressive Strength of Bricks or Blocks. Lb. per sq. in.	Proportion of Mixture of Mortar (in Volumes). Cement	Lime.	Sand.	Maximum permissible Pressure on Wall. Tons per sq. ft.
Special	Over 10,000	1	—	2	$\frac{1}{500}$ of compressive strength of bricks + 10 but not exceeding 40
First	10,000	1	—	2½	30
Second	7,500	1	—	2½	23
Third	5,000	1	—	3	16
Fourth	4,000	1	—	3	13½
Fifth	3,000	1	—	4	11
Fifth	3,000	1	1	6	10
Sixth	1,500	1	—	4	8
Sixth	1,500	1	1	6	7
Sixth	1,500	1	2	9	6
Sixth	1,500	1	3	12	5½
Sixth	1,500	1	4	15	5
Sixth	1,500	1	5	18	4½
Sixth	1,500	—	1	3	4

TABLE IV.

MAXIMUM PERMISSIBLE PRESSURES ON WALLS OF PLAIN CONCRETE.

Concrete.	Cubic feet Aggregate per 112 lb. of Cement. Fine Aggregate	Coarse Aggregate.	Minimum Compressive Strength of Concrete 28 days after mixing.	Maximum permissible Pressure.
I.	1¼	2½	2,925 lb./sq. in.	40 tons/sq. ft.
II.	1⅝	3¾	2,500	35 „
III.	2½	5	2,250 „	30 „
IV.	7½		1,480 „	20 „
V.	10		1,110 „	15 „
VI.	12½		740 „	10 „
VII.	15		370 „	5 „

No solid wall of bricks, blocks or plain concrete shall have a slenderness ratio exceeding 12, but special provisions are made for cavity walls and some partition walls.

Where a wall or pier supports a beam or column and the stresses resulting from such local loading are distributed through adjacent material not so stressed, the compressive stress in the wall subject to local loading may exceed that shown in Tables III or IV by not more than 20 per cent.

Rules for the Use of Structural Steel.

(*London Building Act* (*Amendment*) *Act*, 1935, *and By-laws* 63-91.)*

The structural steel used shall comply with British Standard Specifications No. 4—1932, 4A—1934, or 6—1934, as the case may be.

Loading supported, collected or transmitted by structural steel shall be distributed upon the earth by concrete in conformity with the By-laws.

* For fuller details the Act and By-Laws should be studied. They are obtainable from P. S. King & Son, 14 Great Smith Street, Victoria Street, Westminster, S.W. 1.

The following rules only apply to structural steel which transmits the loads and stresses through each storey to the foundations:

(a) A steel column or beam in an external wall or in a recess in a party-wall shall be completely encased in brickwork, terra-cotta, concrete, stone or other incombustible material laid in Portland cement at least 4 ins. thick except on the underside and the edges of flanges, plates and angles where not less than 2 ins. will suffice.

(b) Other steel columns or beams shall be completely encased in similar material laid in Portland cement and to the satisfaction of the district surveyor, the casing being at least 2 ins. thick except on the upper surface of the upper flange and on projecting cleats, projecting rivet-heads and the like where a thickness of 1 in. may be permitted. This rule does not apply to buildings of one storey less than 25 ft. high.

(c) Except in buildings of one storey in which sufficient gussets and rivets are provided to transmit the whole load to the foundations, the foot of any steel column not of solid round section shall, after riveting, be properly machined over the whole area of the foot and shall have affixed thereto either—

(i) A base plate in effective contact with the whole area of the machined foot—the gusset plates, angles, cleats and stiffeners (if any) in combination with the bearing area of the foot and the base plate being sufficient to distribute the load properly.

(ii) A slab or bloom base-plate, in effective contact with the whole area of the machined column end. When the load under the slab is uniformly distributed the minimum thickness (in inches) of a rectangular slab shall be :—

$$\sqrt{\frac{3w}{4f}\,\frac{(B-b)}{D}} \text{ or } \sqrt{\frac{3w}{4f}\,\frac{(D-d)}{B}}$$

whichever is the greater

In this formula

w is the total axial load in tons.
B is the length (in inches) of the slab, measured at right angles to the web of the column.
b is the width (in inches) of the pillar, measured at right angles to the web of the column.
D is the length (in inches) of the slab measured parallel to the web of the column.
d is the width (in inches) of the pillar measured parallel to the web of the column.
f is the working stress in the steel taken as 9 tons per sq. in.

When the load under the slab is not uniformly distributed or where the slab is not rectangular the specified limits of stress shall not be exceeded.

(d) Except in buildings of one storey, both the ends of each length of steel column (other than a column of solid round section) shall, after riveting up complete with all gussets and end angle cleats, be properly machined over the whole area of the ends. All joints shall be close-butted and all caps and joint seating plates shall be in effective contact with the whole area of the column end.

(e) The bearing stress in any steel packing or beam between the ends of a superimposed column and a column beneath shall not exceed the permissible stress in the superimposed column and the width across such steel shall not be less than the corresponding width of the superimposed column.

(f) All joints in steel columns shall be as near as practicable to floor level. Where bending actions produce tensile stresses, the joints in columns shall be properly spliced to resist such bending. Column joints in which the resultant stress of all loads and bending moments is wholly compressive shall be sufficiently spliced to retain the members accurately in place and the length of each splice plate on each side of the joint shall be at least equal to the maximum breadth of the column flange or at least 12 ins. (whichever is the greater).

(g) Solid round structural steel columns shall have properly machined shouldered ends and shall be provided with caps and bases with bearing surfaces properly machined after being shrunk or screwed on. When the load under the cap is uniformly distributed the minimum thickness (in inches) of a rectangular cap or base shall be

$$\sqrt{\frac{3W}{4f}\,\frac{D}{B-d}}$$

where W is the axial load in tons.
B is the length of the shorter side of cap or base (in inches).
D is the length of the longer side of cap or base (in inches).
d is the diameter of the reduced end of the column (in inches).
f is the working stress in the steel, taken as 9 tons per sq. in.

No cap or base shall be less than $1\cdot5\ (d + 3)$ ins. in length B or in diameter.

Where the load is not uniformly distributed or the cap or base is not rectangular, the specified limits of stress shall not be exceeded.

(h) *Welding* may only be used if carried out under conditions prescribed by the Council in that case.

(i) Bolts and nuts shall conform to British Standard Specification No. 28—1932 (for black bolts) or 190—1924 (for turned bolts) except as regards the length of the threaded portion. Bolts

shall be provided with washers so that the thread is clear of the hole and the shanks shall project at least one full thread beyond the nuts and shall be secured so as to prevent the nuts from becoming loose. Washers shall be tapered, where necessary, to give the heads and nuts a true bearing.

(j) The diameter of a rivet shall be taken as that of the hole. The distance of a rivet hole or bolt-hole to the edge of the member shall not be less than the diameter of the rivet or bolt. Rivets shall not be closer (centre to centre) than three times their diameter. Tacking rivets (*i.e.* rivets connecting flange plates and not subject to calculated stress) shall have a pitch not exceeding 24 times the thickness of the thinnest outside plate or 12 ins., whichever is the lesser. For other rivets the straight line pitch in riveted members shall not exceed—

For parts in tension, 16 + the thickness of the thinnest outside plate with a maximum of 8 ins. For parts in compression, 16 + the thickness of the thinnest outside plate with a maximum of 6 ins.

Where two rows of staggered rivets occur in one flange of a single angle, the straight line pitch in the direction of stress shall not exceed 1½ times the distances stipulated above for parts in tension and compression respectively.

(k) Where two or more flange plates are employed, the edge-distance from the centre line of the nearest rivets connecting them to the web construction shall not be greater than 12 times the thickness of the thinnest outside plate, but tacking rivets shall also be used where such edge-distances exceeds 9 times the thickness. Where a single flange plate is used, the corresponding edge-distance shall not exceed 9 times the thickness of the plate.

(l) A flange plate or plate web of steel less than ⅜ in. thick shall not be used in a column.

(m) Subject to special provisions, the calculated working stresses upon structural steel shall not exceed:

(a) For parts in tension.	*Tons per square inch.*
On the net section for axial stresses or extreme fibre stress of all beams	8
On the net section of shop rivets for axial stress . .	5
On the net section of field rivets for axial stress, provided the rivets are of the usual type in accordance with British Standard Specification No. 275—1927, hot driven and that the parts when riveted are in close contact before riveting	4
On the net section of bolts for axial stress, the bolts being not less than ¾ in. diameter corresponding to British Standard Specification No. 28—1932 if black bolts, or No. 190—1924 if turned bolts, except as regards the length of the threaded portion and provided the parts to be bolted together are in contact before tightening the bolts	5

(b) For compression flanges of beams.	*Tons per square inch.*
On the gross section for extreme fibre stress of beams embedded in concrete or otherwise laterally secured . .	8
On the gross section for extreme fibre stress of uncased beams where the unsupported length L is less than 20 times the width b of the compressive flange . .	8
On the gross section for extreme fibre stress of uncased beams where L is greater than 20 times b . .	$11 - \frac{0{\cdot}15L}{b}$

For beams solidly encased, b may be taken as the width of the compression flange of the beam plus the lesser side concrete cover beyond the edge of the flange on one side only with a maximum of 4 ins.

The ratio L/b shall not exceed 50.

(c) For parts in shear.	*Tons per square inch.*
On the gross section of webs	5
On shop rivets and turned bolts of driving fit . .	6
On field rivets	5
On black bolts	4

The strength of rivets and bolts in double shear may be taken as twice that for single shear. The webs of beams shall be sufficiently stiff not to buckle.

(d) For parts in bearing.	*Tons per square inch.*
On packings, seatings and the like	12
On shop rivets and turned bolts of driving fit . .	12
On field rivets	10
On black bolts	8

(n) The span of any filler floor beam encased in concrete should not exceed 32 times the depth from the bottom flange of the beam to the top of the concrete. The span of any other beam shall not exceed 24 times its depth unless the deflections of the beam is less than $\frac{1}{325}$th of the span.

(o) The permissible ratio of effective column length to least radius of gyration in a steel column shall not exceed—

(a) For columns and struts forming part of the main structure	150
(b) For subsidiary members in compression . . .	200

The working loads per sq. in. in the shafts of columns and other compression members of structural steel shall not exceed those specified in the following Table except as provided in (o) and (p).

WORKING LOADS ON PILLARS.

Ratio of effective pillar length to least radius of gyration. $= \frac{l}{r}$	Working loads in tons per square inch of gross section. $= F_1$	Ratio of effective pillar length to least radius of gyration. $= \frac{l}{r}$	Working loads in tons per square inch of gross section. $= F_1$
20	7·2	130	2·6
30	6·9	140	2·3
40	6·6	150	2·0
50	6·3	160	1·8
60	5·9	170	1·6
70	5·4	180	1·5
80	4·9	190	1·3
90	4·3	200	1·2
100	3·8	—	—
110	3·3	—	—
120	2·9	—	—

Intermediate values may be obtained by interpolation.

(p) The effective column length shall be :

Type of Column.		Effective Column Length.
Columns of one storey	Properly restrained at both ends in direction and position.	0·75 × actual column length.
	Properly restrained at both ends in position but not in direction.	Actual column length.
	Properly restrained at one end in position and direction and imperfectly restrained in position and direction at the other end.	A value intermediate between the actual column length and twice that length.
Columns consisting of two storeys.	Properly restrained at both ends in position and direction.	0·75 × distance from floor level to floor level.
	Properly restrained at both ends in position and imperfectly restrained in direction at one or both ends.	A value intermediate between 0·75 and 1·00 × the distance from floor (or roof) level to floor level.
	Properly restrained at one end in position and direction and imperfectly restrained in both position and direction at the other end.	A value intermediate between the distance from floor level to floor level and twice that distance.

The above values are for typical cases only.

(q) In the case of eccentric loading on a steel column, the bending moment about each principle axis shall be calculated and the resulting bending stresses added to the axial load per sq. in. The working load may then be increased above that specified in (m) up to a limit F_2 where

$$F_2 = f_c + 7\cdot5\left(1 - \frac{f_c}{F_1}\right)\left(1 - 0\cdot002\frac{l}{r}\right)$$

where F_1 is the working load per sq. in. specified in (*m*). f_c is the total load on the column (in tons) divided by the gross cross-sectional area of the column (in sq. in.) and $\frac{l}{r}$ is the ratio of effective column length to least radius of gyration.

(*r*) The working loads and stresses specified for beams and columns and all their connections may be increased by 33⅓ per cent. where such increase is due solely to stresses induced by wind pressure. This does not apply to the stresses calculated in grillage beams of structural steel wholly embedded in concrete nor to those mentioned in (*l*).

(*s*) Where a beam is connected to a continuing column, the bending moment in the column due to the eccentricity of the reaction from the beam may be regarded as divided between the column lengths above and below the level of the beam, proportionately to their stiffness.

(*t*) In a continuing column all bending moments due to eccentricities of loading at any one floor level may be considered as entirely dissipated at the levels of the floor beams immediately above and below, provided that, at these latter levels, the column is effectively restrained in the direction of the eccentricity.

(*u*) Where structural steel is used and the loads and stresses are not transmitted through each storey to the foundations wholly by a skeleton framework of steel nor partly by such a skeleton and by a party wall the standards of stability and protection of such steel shall be to the satisfaction of the district surveyor, but not inferior to those required in these rules.

Foundations.

Within the area controlled by the London County Council foundations must conform to the London Building Act (Amendment) Act, 1935, and the By-laws associated therewith (obtainable from P. S. King & Son, Ltd., 4 Great Smith Street, Victoria Street, Westminster, S.W. 1).

Brick walls are made wider at the base, in order to spread the weight of the building over a larger area and produce an equality of settlement.

Figs. 38 to 44 show sections of footings (the wide courses at the base of a wall) of walls in English bond from one to three bricks in thickness. Trenches are excavated for beds of concrete usually from 2 feet to 7 feet in depth, and 12 inches wider than base of footings (6 inches on each

side). If the site on which a building is to be built be gravel, sand, or natural virgin soil, no concrete bedding need be used; otherwise the whole site should be covered with a layer of concrete, not less than 6 ins. thick, projecting at least 4 ins. on each side. See also pp. 435, 436.

MASONRY.

Lifting Stones.

There are various ways of laying hold of stones which are too heavy to be moved by hand. The following are those most frequently used :—

1. By a pair of nippers or iron claws or hooks, as in fig. 45, the ends of which catch in holes made, one in each side of the block, in the same vertical plane as, and at a convenient distance above, the centre of gravity of the block. 2. By a *Lewis*, or iron dovetail, as in fig. 46, made in three pieces, the two outer ones being first dropped into a corresponding dovetailed hole cut in the stone directly over its centre of gravity, then the centre-piece slipped in between them, the suspending-tackle put in its place, and finally a bolt passed through the whole and keyed up. 3. By two curved iron plugs, with a chain passing through eyes in their heads, placed in a dovetailed hole directly over the centre of gravity of the stone, as shown in fig. 47. 4. By an iron conical plug, with an eye at the top for a chain or hook to pass through, placed in a rather

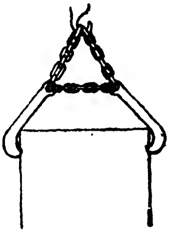

Fig. 45.

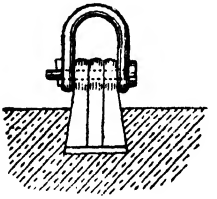

Fig. 46.

larger conical hole directly over the centre of gravity of the stone, with an iron wedge curved so as to fit the plug and the circumference of the hole, tightly driven in by its side, as shown in fig. 48. This plug was used for setting the heavy granite coping on the Thames Embankment

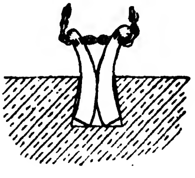

Fig. 47.

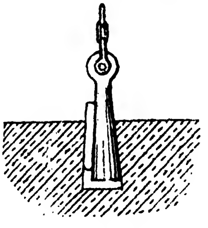

Fig. 48.

wall. 5. By a single iron plug, very slightly tapered, and driven into a cylindrical hole directly over the centre of gravity of the stone. By this simple means hard stones, such as granite, may be lifted with ease, a few side taps being sufficient to loosen the plug when required to be withdrawn.

Setting Stones.

All stones, except under peculiar circumstances, should be laid on their natural or quarry beds, or with their natural beds as far as possible perpendicular to the pressures they have to bear.

All dry and porous stones should be well wetted before being laid, so as not to absorb the moisture required for the proper setting of the mortar. Iron should never be placed in contact with stonework where, by rusting, in might disfigure it with stains, or split the stone, either by its increase in bulk during the process of oxidation, or by its expanding and contracting under the influence of heat and cold.

Descriptions of Masonry.

There are three descriptions of masonry in ordinary use, viz. :—

Rubble. Block-in-Course. Ashlar.

If the stone at disposal is thinly bedded, rough, or intractable, it should be used as *Rubble work*; if obtainable in blocks, and more or less easily wrought, it should be used as *Block-in-Course* or *Ashlar* according to circumstances.

The various systems are illustrated by figs. 49 to 58.

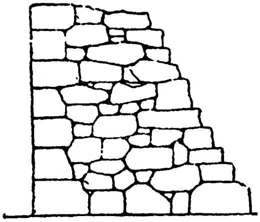

FIG. 49. Common, Rough, Uncoursed, or Random Rubble.

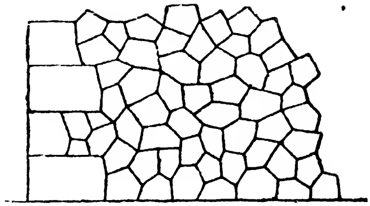

FIG. 50. Random Rubble, with hammer-dressed joints and no spalls on face.

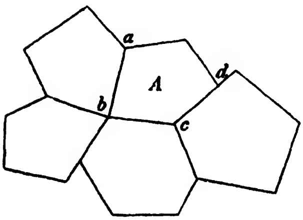

FIG. 51. Hammer-dressed Joints for Random Rubble.

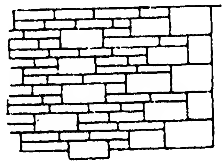

FIG. 52. Irregular-coursed, Random-coursed, Snecked, or Squared Rubble.

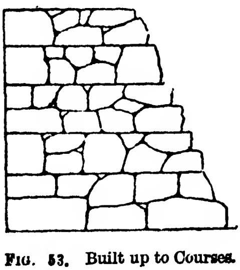

FIG. 53. Built up to Courses.

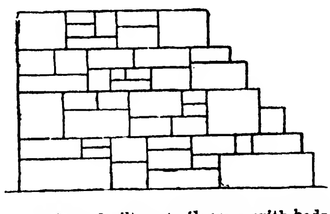

FIG. 54. Built up to Courses, with beds horizontal and joints vertical.

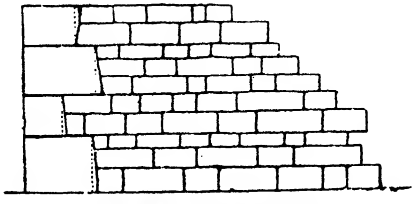

FIG. 55. Coursed Rubble.

RUBBLE MASONRY.

The best stones for rubble masonry are those that scabble freely, and such as lie in 4 or 5 in. beds. Basalts and stones of a crystalline structure are troublesome to use, as they fly under the hammer; but granite and sandstones work in well.

Rubble may be either *uncoursed*, *irregular*, or *random-coursed*, *worked up to courses*, or *coursed*, chiefly depending upon the character of the stone at disposal; some stones, such as Kentish rag, from their intractable nature, and the absence of any distinct lines of bedding, are specially adapted for *uncoursed* rubble, whilst others readily work into courses, and therefore should be used as *coursed* rubble.

In common, rough, uncoursed, or random rubble (fig. 49) the stones are laid at random, without being brought up to any level courses, the only tools required being a trowel, waller's hammer, and plumb or battering rules, as the case may require.

One bond stone should be used to at least every yard super of the face, and these should run about two-thirds to three-fourths through the wall, alternately from the opposite sides; this, in the case of dwelling-houses, diminishes the chances of damp being transmitted to the interior and is in all cases much preferable to a smaller number of *through* stones. In boundary and similar walls *through* stones may, of course, be used. In thick walls, such as piers, abutments, and retaining walls, the bond stones should tail into the work as far as possible; and the whole should be bonded together in the best way the sizes of the blocks will admit of.

It is necessary to see the bond stones actually built into the wall, for builders are apt to set large stones on edge, running only 3 or 4 ins. into the wall, instead of true bond stones—a trick which cannot well be detected after they have once been covered up. In random work (figs. 50 and 51) the stones cleave into irregular shapes, and are fitted closely together. Thus, in order to get A (fig. 51) into place the angles *abc*, *dcb*, are taken with the mason's bevel, and the joints are hammered and punched to fit truly. This is the most expensive kind of rubble work, and requires much more skill to build properly than any other class of rubble walling.

If the rubble stone is distinctly bedded, the beds varying much in depth, and often running very thin, the stones should be put together as in fig. in 52, what is called *irregular* or *random-coursed* rubble. The joints in this case are not necessarily vertical; but in a superior class of the same work all the joints are specified to be vertical and the beds horizontal, by which a more regular appearance is given to the work. The stones are all shaped and roughly squared as required, and hammer or axe faced, in the gross, ready for the waller to set in the wall. This class of masonry is very bold and effective for engineering purposes, when a good proportion of large stones are used, roughly hammer-dressed on face.

Both of the kinds of rubble masonry just described are very commonly worked up at intervals, with the line and level, to level courses, either regular or irregular in depth, the latter being preferable on account of its appearance and more suitable to the irregular sizes of the stones used. From 18 to 14 ins. are the ordinary depths of the courses, according to the nature of the stone. Figs. 53 and 54 show both common and irregular coursed rubble worked up to courses; the latter being also called *coursed header work* when the headers, occurring at intervals, run the full depth of the course. In fig. 55 a superior class of work is shown, the joints being all vertical, by which means a more regular appearance is obtained.

Rankine's 'Civil Engineering,' speaking of coursed rubble (such as fig. 55), says: '*One-fourth part* at least of the face in each course should consist of bond stones or headers, each header to be of the entire depth of the course, of a depth ranging from one and a half times to double that depth, and of a length extending into the building to from three to five times that depth, as in ashlar. These headers should be roughly squared with the hammer, and their beds hammer-dressed to approximate planes; and care should be taken not to place the headers of successive courses above each other, for that arrangement would cause a deficiency of bond in the intermediate parts of the course. Between the headers each course is to be built of smaller stones, of which there may be one, two, or more in the depth of the course. These are sometimes roughly squared, so as to have vertical side-joints; sometimes the stones are taken as they come, so that the side-joints are irregular; but no side-joint should form an angle with a bed-joint sharper than 60°. Care should be taken, not only that each stone shall rest on its natural bed, but that the sides parallel to that natural bed shall be the largest, so that the stone may be flat, and not be set on edge or on end. However small and irregular the stones may be, care should be taken to make the course break joint. Hollows between the larger stones should be carefully filled with smaller stones, completely embedded in mortar.'

The same authority gives the resistance of good coursed rubble masonry to crushing at about four-tenths of that of single blocks of the stone it is built with.

Coursed, or regular coursed rubble, as shown in fig. 55, is applicable where the beds, though thin, are pretty regular, so that a sufficient number of stones of a uniform depth can be got to allow of their being laid in regular courses of one stone only in depth. Larger stones, often of cut stone, equal in depth to two or three courses of the rubble work, are generally used at the quoins.

Whenever cut-stone is used in connection with rubble work, as at the quoins of a building, the ends adjoining or tailing into the rubble should never be cut square, but be left comparatively rough, so as to harmonise with the masonry in the body of the wall, and not appear as if cut off from it by straight lines.

Dry-walling is the simplest class of rubble work, and consists of stone roughly hammered, and bedded by pinning with spalls, without any mortar. It requires considerable skill to build properly, as its stability depends entirely on the firm bedding and bonding of the different stones. It is chiefly used for fencing land, for railway and canal embankments and cuttings, or at the backs of retaining-walls, to diminish the pressure of the earth on them, and to allow of water finding its way down to the drains below. Such walls—which are generally about 5 ft. high, increasing in thickness towards the bottom, and averaging about 18 ins. thick—are usually built to lines strained between trestles (fig. 56), in order to avoid plumbing the face.

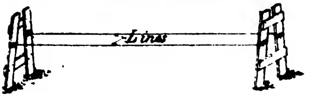

FIG. 56.

Dry-rubble walling is generally built in courses about 12 ins. high, and should have a waterproof top, or *coping*, to keep the water from getting into the body of the work and bursting it in frosty weather. The coping may be made of stones laid on edge in mortar, bituminous concrete, or, for want of anything better, clay puddle, or even sods.

When the stones come out in thin slabs the walls may be specified to be built of 'good sound, flat bedded stones of a fair average size (none less than 6 ins. broad across the narrowest part), set dry, and coped with stones, not less than 9 ins. deep, set on edge; each coping stone to extend across the full breadth of the wall, and to be properly set in good hydraulic mortar.' A high joint with a projecting ledge is very frequently used to mark the joints of rubble work: this is a bad system, and is sure to peel off under the influence of wet and frost.

A cubic yard of rubble masonry will, as a rule, require $\frac{1}{3}$ cubic yard of mortar and $1\frac{1}{4}$ cubic yard of stone.

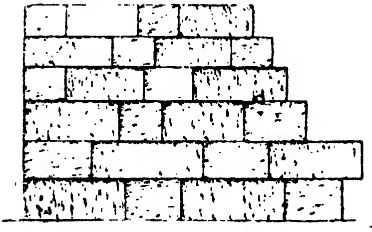

FIG. 57.—Block-in-Course.

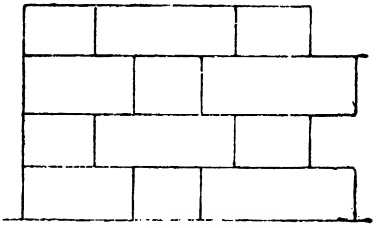

FIG. 58.—Ashlar.

BLOCK-IN-COURSE MASONRY.

Block-in-Course (fig. 57) is a term applied by engineers to a class of masonry much used in piers, abutments, wing walls, &c., when there is a suitable stone in the district and good solid work is required. The stones are all squared and brought to good fair joints, the faces being more or less worked, according to taste, but generally merely hammer-dressed; and the courses consist of single stones only in depth. It chiefly differs from ashlar in the smaller size of the stones and depth of the courses, the stones at command being—ordinarily rougher and more thinly bedded—chiefly *shoddies*, or stones under 12 ins. deep, whereas *ashlar* blocks range, as a rule, from 12 ins. to 14 ins. in depth.

The best stone for the purpose is a hard, self-bedded stone which will work easily into courses from 8 ins. to 10 ins. or 12 ins. in depth, the length of each stone being four or five times its depth. No attention is paid to uniformity in the depth of the courses.

ASHLAR MASONRY.

The term *ashlar* is applied to masonry built up of a thick-bedded stone which admits of being scabbled, or sawn into square blocks of given dimensions. It is also used to denote roughly squared blocks of stone over 12 ins. deep, as delivered from the quarry or stonecutter, or as prepared for setting. Ashlar work (fig. 58) is built in courses of uniform, or nearly uniform, depth—generally from 10 ins. to 14 ins.—ranging throughout with the quoins and dressings. It goes by different names according to the face put upon the stone, from quarry-pitched or rock ashlar up to wrought ashlar.

No stone should be laid in mortar without being first fitted into place and any irregularities in shape corrected. Large ashlars are first accurately fitted into place, and then set on a bed of mortar carefully spread out to receive them; after which the vertical joints have to be filled by stopping them up on the outsides with cement, and pouring in cement or mortar grout, which should be worked about with a piece of hoop iron, so as to ensure its completely filling the joints.

The beds and joints are worked to plane surfaces, so as to allow of close-fitting joints. These surfaces should not be too smooth, otherwise the mortar will not adhere so well to the stones, but in good work should be true enough to allow of joints not over $\frac{1}{8}$ in. thick; they are generally either left as they come from the saw (if sufficiently true), or taken out of winding by running chisel draughts round the margins, and dressing them down with the point, as in half-plain work, taking off any parts left projecting beyond the level of the chisel draughts with a chisel.

Stone Bridges and Arches.—See p. 466.

Piers.—See p. 472.

Stone Stairs.—See p. 315.

Safe Load on Stone Walls.—See p. 436. In many localities stone walls must comply with the Ministry of Health's Model Byelaws, Series IV, Buildings, 1938. See also the notes at the end of British Standard Specification No. 449 - 1937.

Strength of Stones.—See p. 180.

Artificial Stone.—See p. 358.

Concrete.—See p. 343.

Load-bearing Masonry.—See British Standard Specification No. 1145.

Proportions for Stones, Bond, &c.

In both block-in-course and ashlar masonry it is necessary to proportion the length, breadth, and thickness of the stones according to their hardness, in order to guard against their breaking across. Rankine says that in the weaker sandstones and granular limestones the length of a stone should not exceed three times its depth, nor the breadth one and a half to double its depth. In harder stones—such as require $2\frac{1}{2}$ or more tons to the inch to crush them—the length may be four or five times the depth, and the breadth three times the depth.

The best bond in masonry is that which shows on the face of the work alternate headers and stretchers in each course, as in Flemish bond in brickwork, each header coming over the centre of a stretcher in the course below. In such work one-third of the face consists of headers, if the length of the stretchers is twice the breadth of the headers; but as stones are rarely cut to exactly the same dimensions, it may be laid down that not less than one-fourth of the face of the wall should consist of headers, and that the stones should break joint from one to one and a half times the depth of a course.

The thickness of the joints will vary from $\frac{1}{8}$ to $\frac{1}{4}$ inch, according to the smoothness of, or amount of work bestowed upon, the beds, as it must be sufficient to transmit the pressures from stone to stone without permitting of actual contact at any point of their surfaces.

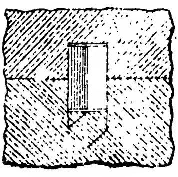

FIG. 59.

Dowelling.

For securing stones in places where the adhesion of the mortar or cement is not sufficient *dowelling* is the best method. Fig. 59 shows a method of doing this. It consists in making, exactly opposite each other, in the two stones two holes, either circular or square in section, and fitting into them a dowel or pin. These may preferably be of good hard slate, run with either brimstone or cement.

Measurement and Valuation of Masonry.

In districts where stone abounds, and forms the principal material for building purposes, ordinary walls are built of rubble stone, and measured by the cubic yard, or some other local standard, such as, in Ireland, by the running perch (21 feet), of a given height and thickness, or by the square perch of 21 feet super, at a standard thickness of 18 inches. In the West of England the square perch is employed, of 18 feet super, at a standard thickness of 2 feet, to which walls of any thickness are reduced; or the price per perch may vary with the thickness of the wall. In other parts masonry walling is measured by the rood of 36 square yards, or 24 cubic yards, the standard thickness being 2 feet; or by the rod of 272 feet super, as in brickwork, at a standard thickness of 18 inches or 2 feet.

In engineering, as distinct from architectural constructions, masonry is rarely valued otherwise than by the cubic yard for the roughest descriptions of work, and by the cubic foot for superior work.

The price in all cases varies with the quality and description of work, as 'coursed' or 'uncoursed' in 'walling' or 'foundations.'

The superficial content of the surface work is paid for separately by the square foot, yard, or rood of 36 square yards, including jointing or pointing, and such squaring to beds and joints as may be required, quoins, &c., of selected stones being often paid for at so much extra per foot run.

Superior work, such as squared masonry, whether in wallings or dressings, is usually valued by the foot cube as block stone, merely scabbled or sawn to the required dimensions and set. The work upon it is taken separately by the foot super.

When different descriptions of masonry occur in a wall, such as rubble faced with ashlar, instead of cubing out the rubble and ashlar work separately—in which case the latter is valued by the cubic foot prepared and set, including all beds and joints, the facework being taken by the foot superficial as tooled, pointed, &c.—the whole may be taken as rubble masonry, and so much extra allowed per foot superficial for the superior facing, including all extra labour, dressing, and pointing.

When walls are built of rubble masonry it is cheaper to use bricks for such parts as jambs and arches.

The block stone for use in a building is ordinarily sold by the cubic foot, or in large rough blocks by the ton, of from 13 to 17 cubic feet, 1 inch being allowed each way for irregularities and waste.

Permissible Pressures on Masonry.

The following are the pressures permitted in the Ministry of Health's Model Byelaws, Series IV, Buildings, 1938, for walls constructed of bricks or solid blocks and having a *slenderness ratio** not exceeding 6.

Column A shows the pressures allowed where the combined dead loading and superimposed loading can be assumed to be uniformly distributed over the area sustaining the load.

Column B shows the pressures allowed (subject to the average pressure not exceeding that in Column A) where the loading is a combination of the uniform pressure in Column A with increases in pressures due to eccentric loading and lateral forces.

Column C shows the pressures allowed at girder bearings, stanchion bases or other similar places where there are concentrated loads, taking into account the pressures in Columns A and B.

Effect of Weather on Stone.

Stones vary greatly in their resistance to weather according to the conditions to which they are exposed. Thus, some limestones will last for several centuries 'in the country,' but are rapidly destroyed by corrosion in London and other large towns where sulphurous and sulphuric acids are present in the atmosphere.

Stones which are not laid on their natural bed will corrode more rapidly than when properly laid.

Where atmospheric conditions are trying, as in most large towns, special care should be taken to use only stones which can withstand such conditions. The fact that they have lasted for many years in some other locality is not a sound guide. Some very ancient buildings have corroded more seriously during the last fifty years than in the preceding 1,400 years!

Preservatives for Stonework are numerous, but few are really effective. The best appear to be some form of *sodium silicate* or of *silicon ester.*

Cleaning Stonework should never be effected with strong alkaline or acid solutions. Hot water and brushes are the only safe cleaning agents and the brushes should not have very hard bristles.

SECTION X

MORTARS—CONCRETES—CEMENTS—GLUES—PLASTERS

(pp. 337–359.)

Revised and amplified by Alfred B. Searle
(Consulting Advisor on Cementitious Materials).

SECTION X

MORTARS—CONCRETES—CEMENTS—GLUES—PLASTERS

Revised and amplified by Alfred B. Searle
(Consulting Advisor on Cementitious Materials).

MORTARS.*

Mortars are pasty substances which gradually harden on exposure; they are used for uniting stones or bricks in the construction of masonry or brickwork.

The chief kinds of mortar are:

Lime mortar, composed of lime and sand.

Trass mortar, composed of lime, sand, and trass or brick-dust, or of lime and trass without sand.

Cement mortar, composed of Portland cement (or other siliceous cement) and sand.

Hydraulic mortar, composed of either hydraulic lime or cement, and sand, and characterised by its power of hardening under water.†

Clay mortar, consisting of a mixture of fireclay and crushed firebricks, and used chiefly in the construction of furnaces, kilns, and other structures which have to be heated to high temperatures.

Lime Mortar.*

The chief ingredients of ordinary lime mortar are lime and sand, but other materials, such as crushed bricks, ground stone or trass, and waste products such as ground slag, ashes, or coke, may, under suitable conditions, replace some of the sand. The tenacity of the mortar may be increased by the addition of hair or other fibrous material.

The best mortar for use in air † consists of a mixture of lime, sand, and brick-dust, but the latter is usually omitted on account of its cost.

Lime mortars made of fat or pure lime should not be used for roads, bridges, viaducts, waterworks, or any structure exposed to water, and some authorities maintain that even for churches, houses, and other buildings, it should not be used without the addition of trass or its equivalent, so as to prevent the flaking, crusts, and canker which are produced when too fat a lime is used.

Hydraulic lime mortar is composed of hydraulic lime and sand, the proportions varying from 3 to 6 measures for each measure of the lime (see *Lime Concrete*, p. 343). The chief use of this kind of mortar is for structures exposed to water, but unless the hydraulic lime is well selected, the structures may develop crusts and canker. Portland cement mortar is usually much superior to mortar made with hydraulic lime.

Trass Mortar.

Trass mortar is but little used in Great Britain, but has been used extensively abroad, and particularly in the East. The term 'trass mortar' is not confined to mortars containing true trass, but includes those containing similar materials, such as brick- or tile-dust, pozzolana, santorin earth, and other metamorphosed alumino-silicates, which combine with free lime to form an indefinite compound having cementitious properties. The use of trass or similar material overcomes the disadvantages which accompany the use of fat-lime. The best proportions for trass mortars are shown in the table on p. 341.

Trass was highly valued and greatly used by the Ancient Romans, but for several hundred years later its use was not understood and this valuable material fell into disuse. With the greatly extended use of Portland cement the importance of trass has again been realised, and during recent years the use of it has greatly increased in this country and abroad.

When wetted, Portland cement liberates free lime, combines with the latter and so is retained in the mortar. The resulting mortar or concrete is stronger than that in which no trass is used.

Trass is, in no sense, an adulterant but is, on the contrary, a simple means of increasing the strength of concrete and cement mortar.

Cement, mortars and concretes containing trass are more waterproof, more resistant to alkalis and to salt solutions than those in which no trass is used. The addition of trass is particularly important in concrete likely to be subjected to the action of sulphates in solution, e.g. concrete to be used for maritime structures.

Trass should not be added to aluminous cements, as to do so confers no benefit.

---

* In many localities the Ministry of Health Model Byelaws, Series IV, Buildings, 1938, Clauses 10–12 are compulsory (H.M. Stationery Office, London).

† Mortars for use under water are termed *hydraulic* mortars.

When trass was difficult to obtain the Ancient Romans used ground roofing tiles as a substitute and, more recently, burned clay has been used as a synthetic trass.

The natural material, when carefully selected and properly prepared, is superior to the artificial product and appears to contain a greater proportion of active colloidal material.

The following mixtures (by volume) are now customary:

TRASS-CEMENT CONCRETE.

	Cement.	Trass.	Sand.	Aggregate.
Mass concrete	1	½–¾	3	6–10
Rammed concrete	1	1–5	3–4	5–10
Reinforced concrete	1	½	–	6
Poured concrete	1	½	–	9
Solid foundations	1	¾	6	12
Road (R.C.) foundations	1	½	3	6
Pier foundations	1	1	–	12–14
R.C. piles	6	1	7	8

TRASS-LIME AND TRASS-LIME-CEMENT CONCRETE.

	Trass.	Lime.	Cement.	Sand.	Gravel.
Concrete poured under water	2	3	–	3	–
Quay walls	1	1	–	1	4–5
Reservoirs, etc.	1	⅔	–	4	8
Rammed concrete for foundations	1½	1	1	5	7
Walls and vaults	1	⅓	⅔	4	8
Concrete	2	1	1	3	5
Watertight vaults	1	¼	½	3	6

TRASS-CEMENT, TRASS-LIME AND TRASS-LIME-CEMENT MORTARS.

	Trass.	Lime.	Cement.	Sand.
Masonry work	2	–	3	2
Masonry work	1	–	1	4
Rendering	1	–	1	3
Watertight rendering	1	–	1	2
Construction work above ground level	1	2	–	4–5
Masonry and brickwork	1½	1	–	2–3
Foundations and cellars	1	1	–	3
Masonry	2½	1½	½	6
Rendering	1½	½	2½	2
Watertight rendering	2	1	1	4–8

Cement Mortar.*

Cement mortar consists of a mixture of sand and Portland cement, the usual proportions being 2 to 6 measures of sand to 1 of cement, according to the strength required. The best proportions for various purposes are shown in the table on p. 341. For structures exposed to the air there should be more than twice as much sand as cement, but for completely waterproof structures the proportion of cement should not be less than half the sand used.

Lime is sometimes added to cement mortar to increase its plasticity and to make it easier to use. The addition of not more than 20 per cent. of hydrated lime slightly increases the

* In localities where the Ministry of Health's Model Byelaws, Series IV, Buildings, 1938 (H.M. Stationery Office, London; price 1*s*. 6*d*. net), have been adopted, all cement used in mortar must conform to British Standard Specification No. 12—1931 or No. 146—1932 or be a high alumina cement having the tensile strength, soundness and setting time mentioned in British Standard Specification No. 12—1931 or any other cement not inferior to the cement first mentioned above.

strength of the concrete, but if the latter is exposed to water (inch rain), the free lime may be washed out, leaving a porous material which soon flakes and disintegrates when exposed to frost. These drawbacks can be avoided by adding trass instead of lime—a cement mortar composed of two measures of cement, one of trass and six measures of sand, being of wide application and easy to work.

All cement mortars are hydraulic—*i.e.* they harden readily under water.

Raw Materials for Mortars.

The chief materials for mortars are *lime* and *sand*, but *Portland Cement* (p. 355) is sometimes used to replace part or all of the lime.

The *lime* should be made by burning a calcareous limestone low in magnesia; magnesian limestone, or dolomite, is much less suitable. The burning should be effected in such a manner that the lime contains at least 85 per cent. of calcium oxide in the form of quicklime. Limes which have been imperfectly burned, and so contain 15 per cent. or more of unaltered calcium carbonate, are not suitable for mortar to be used on important work. A very pure lime (containing 95 per cent. of free calcium oxide) is not necessary for building and is usually too costly. The idea that a pure lime is, in itself, objectionable, is incorrect, provided a suitable sand is used. If a very pure lime is used with a very coarse sand, it may result in a weak mortar.

Lean (*i.e.* less pure) lime * and hydraulic lime, on the contrary, harden in a manner similar to cement. The addition of trass or brick-dust to slaked lime has a similar effect on the manner in which the mortar hardens.

Hydraulic limes differ from the 'fat' or quick limes in consisting of an indefinite compound of lime and clay, which may be regarded as a crude Portland cement (p. 355), containing a large excess of free lime. The hydraulic limes owe their power of setting and hardening under water to this lime-clay compound, and consequently form a stronger brickwork or masonry than is produced by common mortar. Some hydraulic limes consist of a mixture of quicklime, true hydraulic lime, and inert or unburned material; for important work they should be tested and the proportions of these ingredients ascertained, as in hydraulic lime the proportion of cementitious matter present is more important than the percentage of lime.

Lias lime is hydraulic lime obtained from clayey limestones occurring in the Lias formations.

Quicklime should be slaked or hydrated before use; hydraulic lime should be bought in the form of a powder. To save the trouble and time involved in slaking and the risk of 'blowing' and other defects due to imperfectly slaked lime, it is becoming increasingly the custom to use *hydrated lime*. This has been slaked under skilled supervision, so as to produce a fine powder which is free from all coarse material and quicklime; it is sold in bags of 1 cwt. and is ready for immediate use. All limes used for building purposes should comply with British Standard Specification No. 890—1940† and in many localities they must comply with the Ministry of Health's Byelaws, 1938‖.

The *sand* used for mortars should consist of sharp (angular) grains of various sizes. Rounded grains do not interlock sufficiently to produce a strong mortar.‡‖

Crystalline quartz sand is to be preferred to mica or felspar sand; the usual description 'good, clean, sharp sand' is much too wide. The grains of sand which are angular give the best results of tensile strength, those that are round give the highest compression strength. It is advisable to submit the sand to a microscopic examination to ascertain its suitability, as a considerable variation in the strength of mortar may occur, owing to the form and variety of the sand particles. From trials made with mortar composed of 1 of cement and 3 of sand a difference of strength varying from 171 lbs. to 313 lbs. per sq. in. was found, owing entirely to the difference in the sand; normal sand mixed in above proportions gave 256 lbs. per sq. in. in 28 days.

It is very important that the sand used for mortars and concrete should be free from clay and decomposed vegetable matter (*humus*). A simple test, devised by D. Abrams and O. Harder, consists in shaking the sand vigorously with a dilute solution of caustic soda, allowing the sand to settle and noting the colour of the overlying liquid. If it is dark-coloured, the sand is probably unsuitable for use; a very pale yellow colour may be neglected.

The grading of the sand, *i.e.* the proportions of grains of different sizes, deserves far more attention than has yet been paid to it. By the use of a suitably graded sand, it is easy to reduce the proportion of the more expensive lime or cement by about 33 per cent. of that required for a less suitable sand. For most purposes the sand should contain about 30 per cent. of air-spaces or voids between the grains. The proportion of voids may be estimated by filling a measure with sand, and then pouring in water until the water is level with the top of the sand. The ratio of the volume of water, added to the volume of the sand, is that of the volume of the voids to that of the sand.

The *water* used in the preparation of mortar should be free from decaying substances; hence, peaty water should not be used.†‖

---

* Limes which produce less than twice their volume of slaked lime in the form of an apparently dry powder are termed 'lean' or 'poor' limes.

† See p. 340.

‡ See *Sand and Gravel*, by A. B. Searle (Contractor's Record Ltd., London).

‖ In many localities the *sand* must comply with Clause 10 and the *water* with Clause 11 in the Ministry of Health's Byelaws, Series IV, Buildings, 1938 (H.M. Stationery Office, London).

BRITISH STANDARD SPECIFICATION FOR LIMES.*

(*Abstract of B.S. Specification No.* 890—1940.)

QUICKLIMES AND HYDRATED LIMES.

Classification—only two classes are recognised:

Class A.—Lime suitable for plastering finishing coat, coarse stuff and building mortar.

Class B.—Lime for coarse stuff and building mortar only.

Either class may be of the non-hydraulic or the semi-hydraulic type.
The purchaser should state:—

(a) Which class and type of lime is required.

(b) Whether a magnesian or calcium lime is required.

The vendor of lime containing more than 5 per cent. of magnesium oxide must always declare it as a magnesian lime.

QUICKLIMES.

Tests required—Class A. (Finishing.)

1. The *calcium and magnesium compounds* present, calculated as oxides, shall not be less than 70 per cent. of the ignited sample. The remainder shall consist essentially of silica and alumina soluble in a 5 per cent. solution of sodium carbonate.

2. The *loss on ignition* on lump quicklime not to exceed 5 per cent.; that on ground quicklime not to exceed 7 per cent.

3. The *carbon dioxide* not to exceed 7 per cent.

4. The *insoluble matter* (after treatment with sodium carbonate solution) not to exceed 3 per cent.

5. The *residue on slaking* left on a B.S. Sieve, No. 18, not to exceed 5 per cent.; the lime passing through that sieve not to leave a residue of more than 2 per cent. on a B.S. Sieve, No. 52.

6. The *volume yield of putty* (made in the prescribed manner) not to be less than 1·7 ml. per g. of quicklime for a calcium lime nor 1·4 ml. for a magnesian lime.

7. The *workability* shall be such that the putty when prepared and 'bumped' in a prescribed manner shall require not less than 13 bumps to cause a mass 11 cm. in diameter to spread to 19 cm. in diameter.

Tests required—Class B. (Coarse stuff and building mortar only.)

Nos. 1–4 same as for Class A.

5. The *residue on slaking* left on a B.S. Sieve, No. 18, not to exceed 5 per cent.

6. The *hydraulic strength* (of semi-hydraulic limes only) after 28 days damp storage to correspond to a modulus of rupture between 100 and 300 lb. per sq. in.

HYDRATED LIMES.

Condition.—The material must be in the form of a fine, dry powder.

Tests required—(identical for both Class A and Class B).

1. The *calcium and magnesium compounds* present, calculated as oxides, shall not be less than 70 per cent. of the ignited sample. The remainder shall consist essentially of soluble silica and alumina.

2. The *carbon dioxide* shall not exceed 5 per cent. by weight.

3. The *insoluble matter* (after treatment with sodium carbonate solution) shall not exceed 1 per cent.

4. The *workability* shall be such that the putty when prepared and 'bumped' in a prescribed manner shall require not less than 10 bumps to cause a mass 11 cm. in diameter to spread to 19 cm. in diameter.

5. *Fineness.*—The residue left on B.S. Sieve, No. 72, not to exceed 5 per cent. and the lime passing through this sieve shall not leave a residue of more than 10 per cent. on a B.S. Sieve, No. 170.

6. *Soundness.*—The expansion in a Le Chatelier mould not to exceed 10 mm. There shall be no signs of disintegration, pitting or popping.

7. The *Hydraulic strength* (of semi-hydraulic limes only) after 28 days' damp storage, to correspond to a modulus of rupture between 100 and 300 lb. per sq. in.

For details concerning modes of sampling and making prescribed tests, see B.S. Specification No. 890—1940.

* Published by the British Standards Institution, 28 Victoria Street, London, S.W. 1.

Proportions for Mortars.*

Mortars are usually made largely by guess-work, but to secure the best results—which are often the cheapest, as a large saving can be effected by preventing a waste of lime—it is necessary to determine the best proportion of sand for the particular lime used.

For many purposes, the most suitable proportions are from 2 to 5 measures of sand to 1 measure each of lime and brick-dust, or trass, but the latter is usually omitted, and large quantities of mortar consist of 1 measure of lime to 3 measures of sharp sand. When ashes † or coke dust are used, one measure of these materials usually replaces an equal amount of sand.

According to J. A. van der Kloes, who has investigated the matter very thoroughly, the best proportions for mortars for various purposes are as shown in the following table :—

Number.	Lean Lime.	Fat Lime.	Lime-Putty. Solid.	Lime-Putty. Fluid.	Trass.	Portland Cement.	Trass or Pozzolana Cement.	Sand.
A.—*Waterproof Mortars for Work which is continually under Water.*								
I.	1	—	—	—	1¼	—	—	1½
II.	—	1	—	—	1⅓	—	—	2
III. (*a*)	—	—	1	—	3	—	—	4
III. (*b*)	—	—	—	1	2¼	—	—	3
IV.	—	—	—	—	—	1	—	2
V.	—	—	—	—	1	1	—	2½
VI.	—	—	—	—	—	—	1	1–1½
B.—*Mortars for Quays, Sluice Walls, Damp-proof Courses, etc.*								
VII.	1	—	—	—	1¼	—	—	2–2½
VIII.	—	1	—	—	1⅓	—	—	2½–3
IX. (*a*)	—	—	1	—	3	—	—	5–6
IX. (*b*)	—	—	—	1	2¼	—	—	3¾–4½
X.	—	—	—	—	—	1	—	3
XI.	—	—	—	—	1	1	—	4
XII.	—	—	—	—	—	—	1	2
C.—*Mortars for Foundations and Buildings.*								
XIII.	1	—	—	—	1¼	—	—	3–4
XIV.	—	1	—	—	1⅓	—	—	4–5
XV. (*a*)	—	—	1	—	3	—	—	8–10
XV. (*b*)	—	—	—	1	2¼	—	—	6–7½
XVI.	—	—	—	—	—	1	—	3
XVII.	—	—	—	—	1	1	—	4–5
XVIII.	—	—	—	—	—	—	1	2½–3

For 1 cu. yd. of cement mortar, the following quantities of sand and Portland cement will be required :—

Proportions. Cement.	Proportions. Sand.	Sand. Cub. ft.	Cement. Lbs.
1	0	—	2,800
1	1	18·8	1,695
1	2	24·9	1,120
1	3	28·7	860
1	4	30·3	682
1	5	31·4	565
1	6	32·2	483

* See footnote on p. 338 and p. 343.

† The use of ashes in mortar is a frequent cause of scum or efflorescence in brickwork.

0·87 cu. ft. of neat cement mortar will result from mixing 0·36 cu. ft. of water with 1 cu. ft. of loose cement.

1 cu. ft. of loose Portland cement will make about—

4·1	**cu. ft. of concrete mixed**		**1 : 2 : 4**
5·0	**„**	**„**	**1 : 2½ : 5**
5·8	**„**	**„**	**1 : 3 : 6**
7·5	**„**	**„**	**1 : 4 : 8**

1 cu. ft. of loose Portland cement neat as cement mortar will cover about 10·4 sq. ft., 1 in. thick.
1 cu. ft. of loose Portland cement to 1 sand will cover about 17 sq. ft. 1 in. thick.
1 cu. ft. of loose Portland cement to 2 sand will cover about 25 sq. ft. 1 in. thick.
1 cu. ft. of loose Portland cement to 3 sand will cover about 34 sq. ft. 1 in. thick.
1 cu. ft. of loose Portland cement to 2 sand will lay about 146 bricks with ⅜-in. joint, and 247 bricks with ¼-in. joint.
1 cu. ft. of loose Portland cement to 3 sand will lay about 212 bricks with ⅜-in. joint, and 317 bricks with ¼-in. joint.
1 yd. super. of pointing brickwork in neat cement requires about 8 lbs. of cement.

The proportion of water required varies with the nature of the lime and sand used. (See the par. on *water*, on p. 339.)

Mixing Mortars.

Small quantities of mortar may be mixed by repeatedly turning over the materials with a shovel, and afterwards with a trowel, so as to mix them very thoroughly. Machine-made mortar is often more reliable than that mixed by hand. The most suitable machine for mixing mortar consists of an edge-runner or pan mill of moderately light construction, in which the materials are treated for 20 to 30 minutes. No pieces larger than ¼ in. diameter should be introduced into a mortar mill, and if any materials more than $\frac{1}{16}$ in. diameter are present, the mixing must be prolonged until they have all been reduced to $\frac{1}{32}$ in. or less in diameter.

Ready-made mortar is obtainable in some localities and has several advantages.

Choice of Mortar.

Mortar made with ordinary lime should not be exposed to water.

Mortar made with hydraulic lime should not be exposed to running water, unless the mortar also contains trass.

Cement-mortar is best where great strength is required a short time after completing the structure, but where a longer period of hardening is permissible, lime-trass mortar is cheaper and equally durable.

For the interior of kilns, furnaces, and flues, clay mortar or a refractory cement should be used.

See footnote on p. 338 and p. 343

Coloured Mortars.

Tints Given to Portland Cement Mortar containing Two Parts of River Sand to One Part of Cement.

Pigment.	Weight of Dry Pigment to 100 Pounds of Cement.			
	½ Lb.	1 Lb.	2 Lbs.	4 Lbs.
Lamp black	Light slate	Light gray	Blue gray	Dark blue slate
Prussian blue	Light green slate	Light blue slate	Blue slate	Bright blue slate
Ultramarine blue	—	Light blue slate	Blue slate	Bright blue slate
Yellow ochre	Light green	—	—	Light buff
Burnt umber	Light pinkish slate	Pinkish slate	Dull lavender pink	Chocolate
Venetian red	Slate, pink tinge	Bright pinkish slate	Light dull pink	Dull pink
Chattanooga iron ore	Light pinkish slate	Dull pink	Light terra cotta	Light brick red
Red iron ore	Pinkish slate	Dull pink	Terra cotta	Light brick red

(*L. G. Sabin.*

The pigments should conform to British Standard Specification No. 1014—1942.
Coloured cements can now be purchased. They are superior to amateur mixtures. See p. 348.

Specifications of Mortars.*

The Department of Scientific and Industrial Research has issued in *Building Research Board Report No.* 9—1927 (p. 340), the following tentative specifications for lime:

Quicklime for mortar—quicklime, Class A or B.

Hydrated lime for mortar—hydrated lime, Class A or B. Hydrated hydraulic lime is *not* suitable.

Hydraulic lime for mortar—hydraulic lime, C2 or C3.

See British Standard Specification for Building Limes (No. 890—1940) and pp. 339–340.

Mortar for structural work (*i.e.* exclusive of plaster, stucco, and parging) to consist of a plastic mixture of lime, putty, or hydrated lime, sand, and water, with or without pozzolanic material. The *lime* for work above ground-level should be Class C1, or preferably C2 or C3 (see table), and for below ground or water level, C2, C3, or a lime-cement mixture. Lime and hydrated lime of Class A should not be used without a pozzolanic material in such proportion that the lime, when mixed with three parts by weight of sand and the proposed proportion of pozzolanic material, shall have a minimum tensile strength of 50 lbs. per sq. in. The pozzolanic material may replace an equal weight of sand up to one-third of the weight of sand stated above. Mixtures containing less sand must have higher tensile strengths (see the *Report*). The *sand* shall not pass more than 10 per cent. of its weight through a Standard I.M.M. No. 80 sieve, and the proportions of particles of different sizes shall be well distributed. In lieu of sand, hard rock, slag, clean bricks, clean clinker, coal-cinder of approved origin or hard-burned clay, may be used if crushed so that all the material passes through a Standard I.M.M. No. 5 sieve. The *water* must be free from unusual proportions of dissolved salts and gases and must not be brackish.

In structures below ground or water level and subject to load, not more than one volume of sand shall be used to one volume of hydraulic lime. In structures above ground-level, subject to load, two volumes of sand may be used to one volume of hydraulic lime. In structures above ground not subject to load and in work of less importance, three volumes of sand to one volume of hydraulic lime may be used. Pozzolanic material may replace part of the lime by agreement with the architect.

CONCRETES.*

Concretes are very coarse mortars, containing stones, gravel or ballast, sand, and a binding agent such as lime or cement. They are known by various names, according to the binding agent employed.

Lime concrete usually consists of a mixture of 1 part lime, 4 parts gravel, and 2 parts sand.

The best way of making lime concrete is by mixing together unslaked or hot, fresh-ground lime with sand and ballast, in the required proportions, on a stone, brick, or wooden floor, turning it over twice to dry, and then, as it is shovelled to a third heap, adding from the rose of a watering-can sufficient water only to slake the lime and make the ingredients cling together in a pasty mass, turning it over well as the water is added. Generally speaking, it will take about ½ gallon to each cubic foot of ballast, but much will depend on the nature of the concrete and the dryness of the ballast employed.

Although frequently employed, fat or quick lime should not be used for lime concrete exposed to the weather, only hydraulic lime being suitable.

Beton is a French term, originally applied to lime concrete, but now used for any kind of concrete.

Cement concrete (more commonly known as *concrete* or *mass concrete*) is a mixture of stones, gravel or ballast, sand, and cement. Coke, clinker, and other materials are sometimes used to replace part of the stones, etc.

Breeze concrete consists of a mixture of 3 measures of small pieces of coke (preferably gas-works coke breeze), 1 of sand, and 1 of Portland cement. It is cheap, and nails can readily be driven into it. Its great disadvantage is that, in the event of a conflagration, it may take fire and increase the resulting damage instead of diminishing it.

Concrete made of ashes or clinker is sometimes, but erroneously, termed 'breeze concrete.'

Slag concrete is a mixture of crushed slag and Portland cement. It has been reported as having a greater compressive strength, less weight per cubic yard, and greater resistance to impact than concrete made with natural stone, but various failures which have occurred when slag concrete has been used have made many engineers unwilling to employ it. According to Dr. J. E. Stead, these failures were chiefly due to (1) using too little cement and (2) the use of fine slag contaminated with ashes and other deleterious substances. Blast-furnace slag for use in concrete should comply with British Standard Specification No. 877—1939.

Reinforced concrete or *ferro-concrete* consists of a concrete structure, the strength of which is increased by the immersion of steel rods or wires in the concrete (see Section XII, p. 381).

* Apart from the Byelaws mentioned in the footnote on p. 337 as a general guide, there is no official specification which applies to all mortars and concretes used in the British Isles, but in localities where the Ministry of Health's Byelaws, Series IV, Buildings, 1938, have been adopted the mortar must conform to them.

Foamed concrete is being increasingly used for sound-proof partitions and other light walls. Several processes are available for introducing air or hydrogen or carbon dioxide into the concrete paste and this imparts a spongy structure resembling pumice.

Refractory concrete is made of aluminous cement and crushed firebricks.

Raw Materials for Concrete.*

All concretes consist essentially of a coarse aggregate, a fine aggregate, and a binding material or cement.

The *coarse aggregate* should consist of suitable stone, gravel or ballast, coke breeze,† clinker, or other hard material of ample resistance to crushing, low porosity (absorbing less than 6 per cent. of its weight of water), and not liable to rapid disintegration by frost. The aggregate should be clean, and if necessary it should be washed before use. Except for the largest and roughest work, all the pieces of coarse aggregate should pass through a 2-in. ring.

The British Standard Specifications for aggregates for concrete are Nos. 877, 882, 1047 and 1165.

Gravel is probably used to a greater extent for concrete than any other one material. As it is a natural substance of very variable composition, even in the same deposit, care should be taken to ascertain its suitability before use. Some gravels contain too large a proportion of soft sandstone to be satisfactory and should not be used.

The best gravel is that with the lowest proportion of voids, *i.e.* that which contains stones of many different sizes in suitable proportion. The preliminary washing and screening of the gravel is usually done by the supplier, but the user should test the proportions of pieces of various sizes, the hardness of the softer pieces, and the percentage of voids, so as to ensure a suitable gravel being used.

The *fine aggregate* should consist of sharp, quartzose sand, similar to that used for mortar (p. 339). If trass is added, the concrete will be more resistant to water. Wet sand requires more cement than dry sand. The sand should be free from clay, and if necessary should be washed before use.

For some purposes, part of the fine aggregate may consist of *Trass* (p. 338) or other *pozzuolana* which combines chemically with any lime set free on wetting the cement and so forms an additional bond.

The *cement* may consist of hydraulic lime, Portland cement, or one of the cruder cements, such as *natural cement*, *Roman cement*, *Grappier cement*, *slag cement* (*iron Portland cement*), or various mixtures of Portland cement with sand, blast furnace slag (*Montan cement*), iron ore, etc. Of these, Portland cement is the strongest and most reliable. It should conform to the Standard Specification (p. 355).*

The *water* used for concrete should be the same as that for mortar (p. 339).

The *pigments* for concrete should conform to British Standard Specification No. 1014—1942.

Proportions for Concrete.*

It is being increasingly realised that the best concrete is that in which the coarse and fine aggregates are most completely immersed in a paste made of cement and water, no excessive amount of such paste being present. A concrete made on this basis is often much cheaper than those compounded on a 'voids' basis. For the newer method no definite proportions can be prescribed in advance; the best ones must be found by trial, as different batches of coarse and fine aggregate differ greatly.

To secure uniformity of consistency a *slump test* is generally used. In this, a conical tube 12 ins. high, with a lower diameter of 8 ins. and an upper one of 4 ins., is placed upright and filled with the concrete to be tested. The filling is effected in three stages, the layer formed in each stage being lightly tamped with a metal rod 21 ins. long and ⅝ in. in diameter. Immediately afterwards the tube is lifted off and the slump or settlement is measured.

According to Duff Abrams, a concrete with a slump of 1 in. or less will contain a little more water than is necessary for the maximum strength but will be too stiff for most constructional work. If 10 per cent. more water is present, the slump will be increased to 3–4 ins., 25 per cent. more water will increase the slump to 6–7 ins.

Instead of using the amount of subsidence or slump as a direct measure, some engineers prefer the term *consistency*. The following table shows the relation between the two :—

Slump in inches.	Consistency.	Slump in inches.	Consistency.
0–½	0·90	3–4	1·10
½–1	1·00	5–6	1·15
1–2	1·05	6–7	1·25
2–3	1·08	8–10	1·30

* In many localities only materials and proportions complying with the Ministry of Health's Byelaws, Series IV, Buildings, 1938, may be used. See also British Standard Specification No. 882—1940.

† On the danger of coke breeze, cinders, and other coal residues see p. 349.

Some engineers still prefer to base the proportions of the various materials on the voids of interstices between each; others make experimental mixtures with various proportions and determine the crushing strength of the concrete after 28 days.

As the determination of the voids is often troublesome, many engineers adopt definite proportions, such as 1 of Portland cement to 2 of sand to 4 of coarse material, or 1 : 2½ : 5, or even 1 : 4 : 8. In large masses of concrete and in foundations, large stones (commonly called 'plums') can often be placed in the mass some little distance apart so as to allow them to be surrounded by the concrete; these economise considerably, without greatly reducing the strength of the mass.

For concrete to be used under water, a mixture corresponding to a cement-trass mortar is preferable (see the table on p. 338).

The following table shows the relative weights required to produce the proportions mentioned in the first column: from it the cost of materials per cu. yd. of concrete for various mixturer can be ascertained.

MATERIALS FOR 1 CU. YD. OF CONCRETE.

Based on loose cement weighing 90 lbs. per cu. ft., with an average specific gravity of 3·12 and a cu. ft. of loose, moist, coarse sand weighing 89 lbs. when dried. (*Only approximate.*)

Proportions.	Kind of Coarse Material.	Lbs. Portland Cement in 1 cu. yd.	Sand cu. yds. in 1 cu. yd.	Coarse Material, cu. yds. in 1 cu. yd.
1 : 1½ : 3	Shingle (40 per cent. voids) .	666	·41	·82
Do.	Broken stone (45 per cent. voids)	697	·43	·86
1 : 1¾ : 3½	Shingle	610	·42	·84
Do.	Broken stone	640	·44	·88
1 : 2 : 4	Shingle	520	·43	·86
Do.	Broken stone	548	·45	·90
1 : 2½ : 5	Shingle	430	·44	·88
Do.	Broken stone	450	·46	·92
1 : 3 : 6	Shingle	364	·45	·90
Do.	Broken stone	383	·47	·94
1 : 4 : 8	Shingle	280	·46	·92
Do.	Broken stone	294	·48	·97

This table does not apply to concrete made with a single aggregate, such as Thames ballast, to which no sand is added, but where proper scientifically proportioned concrete is employed, as should always be the case, the values given in the table correspond with experience.

In measuring out the materials, the fact must not be overlooked that about 34 cu. ft. of stone, sand, and cement will be required for each cu. yd. of concrete, as the sand and cement occupy the interstices between the pieces of coarse aggregate.

Gravel passing the same screens as stone always has less voids than the stone.

Fine sand concrete has a smaller weight per cubic foot than coarse sand concrete.

Fine sand plus large aggregate (without cement) gives a *smaller* volume than coarse. Fine sand plus large aggregate (with cement) gives a *larger* volume than coarse.

Fine sand concrete is easier worked than coarse sand concrete for equal amounts of sand.

The finer the aggregate the more deleterious material and air it carries with it into the concrete.

The finer the sand the less should be used.

Mixing Concrete.

Concrete may be mixed by hand, as described on p. 343, but large quantities are preferably mixed by machinery. Various types of mixing machines have proved satisfactory, but the ones most largely used consist of a cylinder, fitted with baffle plates internally and mounted on trunnions so as to be revolved rapidly.

Combined Table of Working Capacities and Leading Dimensions of Concrete Mixers.

No. of Mixer.	00	0	1	2	3	4	5
Nominal batch capacity (cu. yds.)	0·08	¼	½	¾	1	1½	2
Hopper batch (cu. ft.)	3	6·75	13·5	20	30	56	80
Approximate output per batch of broken stone (cu. ft.)	2	5	11	16	24	38	54
Approximate output per batch of ballast or gravel (cu. ft.)	2·25	5·5	12	18	27	42	60
Approximate output per 10-hour day of broken stone (cu. yds.)	22	55	118	180	270	415	592
Approximate output per 10-hour day of ballast or gravel (cu. yds.)	25	60	133	200	300	470	660
Capacity output which has been obtained per 10-hour day (cu. yds.)	50	120	266	400	600	940	1,320
R.P.M. (driving shaft)	174	132	118	122	94	99	90
R.P.M. (drum)	24	18	16	15	14½	14	12
Mean speed of elevator (ft. per min.)	50	50	45	47	50	50	50
Size of pulleys (ins.)	15×2½	18×4½	21×6½	24×7½	32×9½	42×10½	60×12½
Diameter of driving shaft (ins.)	1½	1¾	2¼	2¼	2½	3	3½
Capacity of water tank (galls.)	4	10	20	30	35	35	70
Diameter of drum	2′ 9″	3′ 6″	4′ 6″	5′ 0″	5′ 6″	6′ 6″	7′ 6″
Width of drum	2′ 0″	2′ 6″	3′ 0″	3′ 6″	4′ 6″	5′ 0″	5′ 9″
Approximate B.H.P. absorbed (varies according to material)	2	5	7	12	15	20	40

Note.—In the production of concrete it is impossible to guarantee definitely the exact amount of mixed material which will be produced from a given quantity of aggregate, owing to the varied nature and size of the stone used, but the above figures, based on actual results, may be taken as approximately correct.

The mixing should be as rapid as possible, consistent with thoroughness, as the concrete should be placed in position before it has begun to set.

Remixed concrete should never be used.

For descriptions of mechanical mixers and further information on mixing concrete, see 'Cement, Concrete, and Bricks,' by A. B. Searle (Constable).

Placing Concrete.

In ordinary foundations, the concrete should be deposited in horizontal layers, not more than a foot thick, and care should be taken to cover any joints in one layer by the succeeding one, as the joint between two days work is always a weak part; moreover, the last-laid layer should be well wetted, to ensure a proper connection with the next.

The chief mistake made in placing mass concrete is in failing to secure sufficient adhesion to the previously placed material. In reinforced concrete there is often a danger of incomplete filling, particularly around the more complex portions of the reinforcement; this may be minimised by the use of a wetter mixture or by efficient damping or vibration. If the latter is effected mechanically, care must be taken not to continue it so long that the setting of the concrete is disturbed.

Fine concrete or cement mortar may be sprayed on to the surface to be covered by means of a Cement Gun or Sprayer, operated by compressed air. This method is particularly effective for 'plastering' with cement mortar, or in the construction of walls about 2 ins. thick on a basis of expanded metal or wire netting.

As the right placing of concrete is of great importance, it may be desirable to consult one or more text-books on the subject.

Various articles formerly made by carving stone are now made of concrete at a much lower cost (see 'Artificial Stone,' p. 358).

Volume of Concrete

The volume of a mass of concrete is much less than that of the separate ingredients, owing to the voids or interstices between the particles of coarse aggregate being occupied, in the concrete, by the sand and cement. Roughly,

Mixture.	Volume of coarse aggregate.	Volume of concrete.
1 : 2 : 4	1 cu. yd.	1·07 cu. yd.
1 : 2½: 5	1 cu. yd.	1·02 cu. yd.
1 : 2 : 8	1 cu. yd.	1 cu. yd.

1 cu. ft. of loose Portland cement will make about :—

4 cu. ft. of 1 : 2 : 4 concrete.	6 cu. ft. of 1 : 3 : 6 concrete.
5 cu. ft. of 1 : 2½: 5 ,,	7½ cu. ft. of 1 : 4 : 8 ,,

Weight of Concrete.

The weight of 1 cu. ft. of concrete varies with the proportion and nature of the aggregate used.

The average weight of 1 : 2 : 4 concrete, using sand as fine aggregate and one of the following coarse aggregates, is : coke breeze, 100 lbs. per cu. ft. ; clinker, 110 lbs. per cu. ft. ; sandstone, 120 lbs. per cu. ft. ; bricks, 125 lbs. per cu. ft. ; limestone, 135 lbs. per cu. ft. ; shingle, 145 lbs. per cu. ft. ; granite, 145–150 lbs. per cu. ft.

Strength of Concrete.*

The proportion of water used in mixing concrete is much more important than is commonly realised, as it has a great influence on the strength of the concrete. According to D. A. Abrams,

$$\text{Compressive strength of concrete in lbs. per sq. in.} = \frac{14{,}000}{7^x},$$

where x is the ratio (by volume) of water : cement. If this is the case, a comparatively small excess of water must have a very harmful effect. The American practice of using a very wet mixture is not to be recommended where great strength is required.

Too little water, as well as a large excess of water, are adverse to the production of strong concrete.

Concrete containing too much cement may be weaker than that containing less cement.

Badly mixed concrete is weak in some parts and strong in others.

The addition of 10 per cent. calcium chloride to the mixing water increases the strength of mass concrete, but cannot be used for reinforced concrete as it corrodes the reinforcement.

The compressive strength of most concretes, as commercially made, can be increased 25 to 100 per cent. or more by employing rigid inspection, which will ensure proper methods of fabrication of the materials.

For equal working consistency and equal cement, gravel concrete is as strong as stone concrete.

30–40 per cent. higher strengths are obtained with 3·16 in. cubes than with 6 in. cubes.

Small cubes are more uncertain and inconsistent in the strength values than larger cubes.

The requirements of the London County Council and the Specification drawn up by a Joint Committee of the Royal Institute of British Architects, District Surveyors' Association, Institute of Builders, Institution of Municipal and County Engineers, War Office, Admiralty, London County Council, and the Concrete Institute, call for a crushing strength of 1,800 lbs. per sq. in. at 28 days and 2,400 lbs. per sq. in. at 90 days, for a 1 : 2 : 4 mixture.

The figures 1,400 at 28 days and 2,000 at 90 days more nearly represent the results obtained under ordinary working conditions, with an aggregate like Thames ballast.

The strength of concrete continues to increase long after it has been made, and is by no means at its maximum after 90 days.

According to the U.S. Bureau of Standards, if S_{28} be the strength of concrete at 28 days, and S_7 the strength at 7 days, then :

$$S_{28} = S_7 + 30\sqrt{S_7}.$$

Weather conditions have a marked effect on concrete work. Heat hastens the hardening process; cold delays it. The effect of cold becomes noticeable when temperatures fall below 50° F., and becomes more marked with lower temperatures. As a rule, concrete does not show any serious effects from having once been frozen if, after it thaws out, it is not again frozen until early hardening is complete. It is better, however, to protect the concrete from freezing for

* See footnote on p. 343.

from forty-eight hours to four or five days, depending upon the degree of the cold, rather than to expose it to the possibility of freezing. Warmth and moisture are necessary to the proper hardening of concrete.

It is especially important to keep concrete thoroughly saturated with water for at least a week, as if it is allowed to dry too soon, it never develops its full strength.

Colouring Concrete and Effect of Addition of Pigments.

Coloured concrete may be obtained by adding the substances described on p. 342, or by using a coloured Portland cement.

Trials have been made by the British Portland Cement Association and others to test the effect on the strength of concrete produced by the addition of pigments. Red oxide of iron produced no effect; green chromium oxide, ultramarine blue, yellow ochre, and manganese dioxide slightly reduced the strength. Carbon black reduced the strength very noticeably.

Effect of Sea-water on Concrete.

The effect of sea-water on concrete depends on the permeability of the latter, dense, waterproof concrete being largely resistant to sea-water, whilst porous concrete corrodes readily. For exposure to sea-water, the concrete should contain a considerable proportion of trass, or equivalent, a suitable mixture consisting of 1 measure of trass, 1 of Portland cement, and 2½ to 3 measures of aggregate. The aggregate should consist of coarse and moderately fine particles, in such proportions as to produce a concrete of maximum impermeability.

Condensation on Concrete.

Interior plastering will prevent condensation on any sort of concrete. A good method is to cover the interior of the concrete walls with ordinary plasterer's lime and sand mortar (about 3 of sand to 1 of lime), lightly keyed in the usual manner to receive the final setting coat. This coat must be left until strong pressure from the thumb makes no impression. It may be necessary to leave it for several days, according to the weather. The finishing coat of lime, putty, sand and plaster of Paris may then be applied with safety. Immediately before this latter coat sets, it should be finished with a soft hair brush, which produces a granular surface, a further method of absorbing moisture.

The best and most easily obtainable finishing coat is the following:

3 parts of lime putty or chalk lime; 6 parts of washed sand; 1 part of plaster of Paris. It gives a good finish, sets well, and works quickly.

Instead of making dense concrete for walls, it is much cheaper and more hygienic to use a very porous concrete, and to render it with a cement waterproofed exterior coating, for the fiercest driving rain cannot penetrate a ¾-in. pudloed cement rendering. Porous concrete, like all porous materials, has also the quality of retaining the heat engendered in the room, thus giving a warmer dwelling. Therefore porous concrete has the dual advantage of assisting the absorption of condensation and of conserving heat.

Preventing Scaling and Cracking of Concrete.

The best method of preventing *scaling* is to keep the concrete thoroughly wet for a week or more after it has been placed, the surface being protected with wet cloths, sawdust, or other porous material. The surface may also be covered with about 2 in. of calcium chloride.

Cracking may be prevented in the same manner, except in those cases where insufficient allowance has been made for stresses due to load or to expansion.

Permeability of Concrete.

The permeability of concrete depends on the number and size of the pores or interstices between the grains. If all the particles were spherical and of the same size, permeability would be at a maximum. It can be reduced by the use of very small particles of sand or of lean clay, but these tend to reduce the strength of the concrete. The addition of lime-soaps (sold under registered names) or of trass also reduces permeability and so does spraying the surface with an impermeable medium (such as a lacquer) or with a substance which combines with some constituent in the concrete (such as silicon ester, some silicofluorides and soluble silicates). (See p. 349.)

Rust Prevention in Reinforced Concrete.

Various methods have been proposed for preventing the reinforcement from rusting. Under ordinary circumstances, no special precautions are necessary, and if the corrosion is due to electric currents no application of chemicals can be satisfactory.

The use of galvanised reinforcement has been stated to prevent rusting, and also to secure greater adhesion between the metal and the concrete.

Steel cannot rust when embedded in a strongly alkaline substance. In the setting of Portland cement concrete a relatively large quantity of caustic lime (lime hydrate) is produced, and the concrete becomes saturated with it. This is strongly alkaline, and by decreasing the number of hydrogen ions present makes any corrosion of the steel impossible.

Coal Residues in Concrete.

A Joint Committee appointed by certain institutes and associations to investigate the subject of the use of coal residues in concrete, has issued a report * giving a summary of the objections and dangers attendant on the use of such, especially in contact with steel.

The objections to this material arise mainly under two headings: (1) The corrosive effect on the steel; (2) expansion.

The report gives in Part 1 the existing laws in Great Britain. Part 2 gives the results of an exhaustive examination as to corrosion, and Part 3 as to expansion. Part 4 contains personal commentaries arising on the two foregoing, together with practical experience of various authorities and individuals on the subject.

There is no regulation whatever as to material used in other concrete in contact with steel.

Treatment of Dusty Concrete Floors.

Various hardening solutions are sold for preventing concrete floors from being dusty, and to give a better wearing surface. The composition of most of these solutions is a trade secret.

Two excellent hardening solutions are the following :—

(1) Mix 1 part silicate of soda to 4 or 5 parts water. Brush or sprinkle the floor well with this solution, and allow to dry. Then, after 4 hours and within 24 hours, wash clean with clean water. Repeat the treatment three times.

(2) The following solution has been recommended by *Concrete* :—

To 10 gallons of cold water add 1 fluid ounce of sulphuric acid. Heat the liquid to boiling point and stir in 25 lbs. of sulphate of alumina. Let the solution cool and strain. Sweep and thoroughly wash the concrete surface. After drying, lay on the hardener in four applications of varying strength, ranging from 30 per cent. solution and 70 per cent. water, up to 100 per cent. solution. The above quantity suffices for the complete treatment of an area of from 50 square yards to 100 square yards, depending upon the porosity of the surface treated.

To Waterproof Concrete.

Concrete may be made waterproof by taking care to use such proportions of the various ingredients as will produce a dense and impermeable material.

As this is not always practicable, it is often preferable to add a waterproofing agent prior to mixing the various ingredients. The chief of these additions are :

(1) *Oil* or a solution of paraffin wax in benzoline or other cheap volatile solvent.

(2) *Insoluble soap* such as a lime-soap, 'Pudlo' being one of the best known. It is not advisable to attempt to prepare a soap *in situ*.

(3) *Water-glass* (silicate of soda) applied in the form of a wash or spray, several applications being necessary at suitable intervals.

(4) *Special mixtures* sold under various trade names, such as Pudlo Waterex, Prufito Prufit, etc.

See also p. 359.

CONCRETE BLOCKS, TILES, AND OTHER ARTICLES.

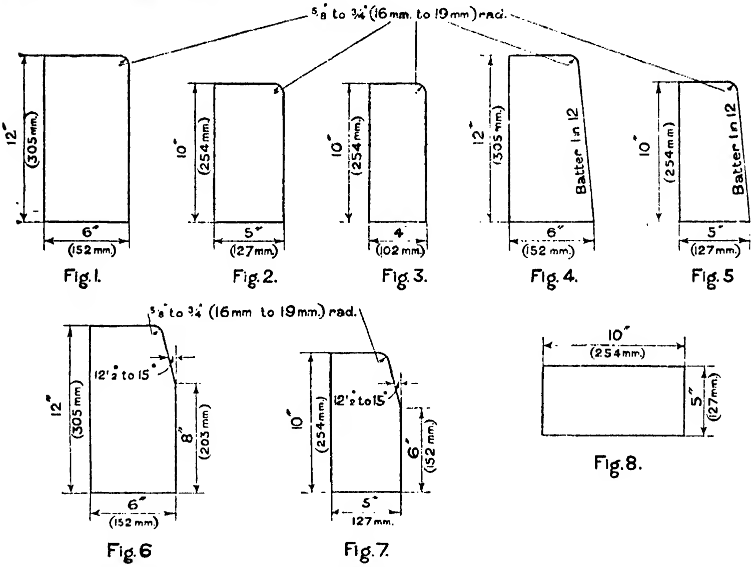
In addition to masses of concrete moulded *in situ*, large quantities of blocks, tiles, garden vases, fencing posts, troughs, and other articles made of concrete or of cement-sand mortar (p. 338) are in regular use, and afford clear proof of the manifold uses of this material.*

See British Standard Specifications Nos. 192 and 834; also see pp. 352, 353, and below.

BRITISH STANDARD SPECIFICATION FOR CONCRETE KERBS, CHANNELS AND QUADRANTS.†

(No. 340—1936.) (*Abstract.*)

The kerbs, channels and quadrants shall be composed of one part by volume of cement ‡ and not more than four parts by volume of aggregate, thoroughly mixed in a dry state Clean water shall then be added and the materials again thoroughly mixed. All the mixing shall be in an efficient mechanical mixer.



FIGS. 1–8.

The *Cement* shall conform to British Standard Specification No. 12 (see p. 355) for Portland cement, or No. 146 for Portland blast-furnace cement or of rapid-hardening cement which complies with the foregoing specifications and, in the case of neat cement and cement and sand, attains the specified breaking strengths in not less than two days and eight days respectively.

*** For further details see *Concrete and Constructional Engineering*, *Everyday Uses of Portland Cement*, and various text-books on concrete.**

† By permission of the British Standards Institution.

‡ The volume is based on an assumed density of 90 lb. per cu. ft. If rapid hardening cement is used, it must be assumed to have a density of only 80 lb. per cu. ft., so that 1·12 volumes will be required to each 4 volumes of aggregate.

The *Aggregate* shall be of best quality, thoroughly clean, and of a material approved by the purchaser. The whole shall pass through a sieve having meshes not more than ¾-in. square.

The *Moulds* shall be accurate in size and form. The inner surfaces shall be clean and true.

Moulding shall be begun immediately after mixing and shall be followed by consolidating by pressure, vibration, or other effective method. Hydraulically-pressed articles shall be subjected to an even pressure over the entire surface of not less than 1,000 lb. per sq. in.

The escape of fine particles shall be prevented as far as practicable. The material shall not be disturbed after the initial set has begun.

No material subjected to frost shall be used until it has been fully thawed.

Dimensions.—Straight kerbs shall be 3 ft. long and to sections shown in figs. 1–7.*

Radius kerbs shall be made to the sections shown in figs. 1–7, and to radii of 6 ft., 8 ft., and 10 ft. respectively, these radii being measured half-way down the outer face of the kerb.

Straight channels shall be 3 ft. long and to the section shown in fig. 8.

Radius channels shall be made to the section shown in fig. 8, and to three radii, 6 ft., 8 ft., and 10 ft. respectively, these radii being those of the inner faces of the channels.

Quadrants shall be 10 in. deep, 18 in. radius, and with faces to match the sections shown in figs. 2, 5, and 7.*

Angles.—All angles (except those resulting from the battered face in figs. 4–7) shall be true right-angles

All *edges* shall be clean and, with the exception of the radiused edge, sharp. The wearing surfaces shall be true, out of winding, and free from excrescences and depressions. All fractures shall present a clean, homogeneous appearance.

Maturity.—No kerbs, channels, or quadrants manufactured less than three months prior to delivery shall be supplied under this Specification unless the whole of the cement used is rapid-hardening cement, in which case they may be delivered fourteen days after manufacture.

Tests are restricted to (i) accuracy of size ; (ii) transverse strength ; (iii) absorption ; and (iv) volume-weight.

Transverse Strength.—The article shall be supported on two steel bearers, each ½ in. wide on the supporting surfaces, placed parallel to each other and 30 in. apart. A kerb shall be placed with the greatest width of wearing face uppermost. A channel with the wearing face uppermost and with the longer sides at right angles to the supports. The load shall be applied to a space 2 in. wide in the centre of the article, extending across its whole width and parallel to the bearers. The load shall be applied steadily and uniformly at a rate not exceeding 112 lb. per foot of width in 10 seconds.

Where necessary the kerb shall be restrained from moving on the bearers, and on battered kerbs a taper strip shall be applied between the kerb and the weight, so that the weight may be truly applied.

Absorption Test.—From each sample kerb or channel a test piece approximately cubicle in form, weighing between 4 and 6 lb. and having not less than three cut faces, shall be taken. The test pieces shall be dried for 72 hours in a suitably ventilated drying oven, the temperature of which, as measured by a thermometer suspended centrally, is between 185° and 204° F. On removal from the oven they shall be weighed and immediately submerged in water, the temperature of which is between 58° and 64° F. for a period of ten minutes, at the end of which time they shall be taken out, immediately wiped with a dry cloth for a period of half a minute and again weighed. They shall then be submerged in water again for a total period of twenty-four hours, at the end of which time they shall be taken out, wiped with a dry cloth and weighed.

Volume-Weight.—A sample which has been dried at 100° C. shall not weigh less than 140 lb. per cu. ft.

* The ⅜–½-in. radii shall in each case be formed along the edge joining the two wearing faces.

BRITISH STANDARD SPECIFICATION FOR CONCRETE FLAGS.*

(No. 368—1936.) (*Abstract.*)

The flags shall be composed of one part by volume of cement † and not more than three parts by volume of aggregate.

The *cement* shall be as for kerbs, channels, etc. (see p. 350).

Flags made with rapid-hardening cement shall have the letter R impressed on the back. This impression shall be 2 in. high and $\frac{1}{4}$ in. deep.

The *aggregate* shall be as for kerbs, etc. (see p. 351), but the whole shall pass through a sieve having meshes not more than $\frac{3}{8}$ in. square.

The conditions for moulds, moulding and freedom from frost and defects are the same as for kerbs, etc. (see p. 351).

Dimensions.—The flags shall be of the following sizes :—

3 ft. × 2 ft. × 2 in.	2 ft. × 2 ft. × 2 in.
3 ft. × 2 ft. × $2\frac{1}{2}$ in.	2 ft. × 2 ft. × $2\frac{1}{2}$ in.
2 ft. 6 in. × 2 ft. × 2 in.	1 ft. 6 in. × 2 ft. × 2 in.
2 ft. 6 in. × 2 ft. × $2\frac{1}{2}$ in.	1 ft. 6 in. × 2 ft. × $2\frac{1}{2}$ in.

Tests.—(i) The aggregate shall be tested for size and the flags for (ii) transverse strength; (iii) rate of wear; (iv) absorption; and (v) volume-weight.

Transverse Strength.—The flag shall be supported on horizontal hard, unyielding bearers, each $\frac{1}{2}$ in. wide on the supporting surface, placed parallel to each other and 18 in. apart. The wearing surface of the flag shall be uppermost and the longer sides at right angles to the supports. The load shall be applied to a space 2 in. wide in the centre of the flag, extending the whole width and parallel to the bearers, and shall be applied at a uniform rate not exceeding 112 lb. per ft. of width per ten seconds.

Flags 2-in. thick shall support a load of at least 1,120 lb. for each foot of width for at least one minute. For flags $2\frac{1}{2}$ in. thick this figure shall be increased to 1,736 lb.

Rate of Wear.—The samples shall be 2 ft. × 1 ft. They shall be dried at not more than 37° C. and then tested by an apparatus which consists of two end-plates mounted on a shaft so as to form, with four samples, a rectangular drum with the samples as sides.

A charge of 1,000 balls of hard steel or chilled cast iron, each with a diameter of $\frac{3}{8}$–$\frac{7}{16}$ in., is placed in the drum, which is then revolved for 24 hours at a regular speed of 60 r.p.m. in one direction, and a further 24 hours in the opposite direction.

The wear on the faces of the samples shall be uniform, and when the faces have been dried as before and the faces brushed free of dust, the loss in weight shall not exceed 3 lb.

Absorption.—Samples about 18 in. square, having two moulded and two cut edges shall, after being dried at 37° C., be weighed, immersed in water for 48 hours, wiped and re-weighed, and shall not show an increase in weight of more than $1\frac{1}{2}$ per cent.

Volume-Weight.—A sample, prepared as for the absorption test, shall weigh not less than 140 lb. per cu. ft.

BRITISH STANDARD SPECIFICATIONS FOR CONCRETE BLOCKS.*

(Nos. 492 and 834.)

The sizes, composition, mode of curing and tests are all specified.

CONCRETE PIPES AND TUBES.

Concrete pipes are of two kinds :—

(i) *Plain pipes* made by simple moulding without reinforcement and only suitable for situations in which great strength is not required.

(ii) *Reinforced pipes* which are designed to resist any pressure likely to be applied to them in the ordinary course of use.

For *plain pipes* see British Standard Specification No. 556—1934 ‡ with a revised absorption test (described in OE(PW)3124 ‡ issued in March 1937), also No. 1194.

* By permission of the British Standards Institution.
† See footnote ‡ on p. 350.
‡ Issued by the British Standards Institution.

Its chief provisions are:—

A *tube* is defined as a hollow cylinder of uniform diameter throughout its length or with an ogee or rebate at each end.

A *pipe* is defined as a hollow cylinder with a socket at one end.

The cement, aggregate, composition, some of the dimensions and conditions of maturing are specified.

The tests are: a hydraulic test to show impermeability to water under pressure, an absorption test, and a crushing test.

For *reinforced pipes* see p. 405. There is no Standard Specification for reinforced concrete pipes.

BRITISH STANDARD SPECIFICATIONS FOR PIPES OF ASBESTOS CEMENT ETC.

Rainwater Pipes, Gutters and Fittings,* No. 569—1934.

Flue-Pipes and Fittings for Stoves,* No. 835—1939.

Soil, Waste and Ventilating Pipes,* No. 582—1934.

Pipes for Gas-Fired Appliances,* No. 567—1934.

Pressure Pipes,* No. 486—1933.

BRITISH STANDARD SPECIFICATION FOR ASBESTOS SHEETS.

British Standard Specification No. 690—1940 relates to asbestos sheets—both flat and corrugated.

BRITISH STANDARD SPECIFICATION FOR CONCRETE ROOFING TILES.*

For Plain Tiles—No. 473—1944.

For Interlocking Tiles—No. 550—1934.

In both these Specifications, the nature of the cements, aggregate, and pigment to be used, also shape and size of the tiles are specified. The only tests are for the modulus of rupture and the permeability.

Adhesive Cements.

Cements are materials used for uniting other materials or articles so that they adhere permanently. There are many kinds of cements, but the more important ones may be grouped as follows:—

Mastic cements, in which the chief ingredient is a gum (such as resin, shellac, wax, or rubber), boiled oil, or bituminous material to which is added a 'filler,' such as sand, rock dust, or other inert powder. If boiled oil is used red lead must usually be added as well as the filler. Mastic cements are used for uniting leather, paper, wood and other materials to each other or to metal, stone or slate. They are also used to fill joints in building- and road-construction as they are waterproof.

Rubber cements are chiefly made by dissolving shredded rubber in carbon disulphide or other solvent. They are chiefly used for uniting leather or rubber.

Fish-glues or *liquid glues* are made by treating fish bones with acetic acid. *Seccotine* is of this nature.

Casein cements consist of casein (milk curd) and an alkali; they are resistant to moderate heat, water, and oil vapours, but not to acid fumes. For use, the cement is mixed with water; if mixed with a weak solution of gelatine glue the strength will be about 10 per cent. greater. Average breaking stress, about 1,000 lbs. per sq. in.

Bituminous cements are those in which the chief ingredient is asphalt, tar, pitch or bitumen (see also *Mastic cements*). They are used for uniting glass for photographic and microscopical uses, also for coating wood, concrete, brick work, steel, stone, slate, stoneware, etc., and for *caulking*.

Water-glass or *silicate cements* consist chiefly of an inert material mixed (such as asbestos, sand, glass-powder or silica flour) with water-glass (syrupy silicate of soda) or solid silicate of soda.

* Published by the British Standards Institution, London.

Calcareous cements, such as hydraulic lime, Roman cement, the various natural cements and Portland cement. *Hydraulic limes* are described on p. 339. *Roman cement* is a brown, quick-setting cement, made by calcining and grinding the septaria or calcareous claystones found in London clay. It is one of the natural cements.

Natural cements (so-called) are made by heating natural mixtures of clay and limestone to redness, so as to effect a combination between the lime and clay similar to that in Portland cement. Such natural cements are comparable to a mixture of Portland cement with either an excess of lime or clay, as the case may be. Their composition is irregular and uncertain, so that they are inferior to Portland cement for all work of importance.

Portland cement is described on pp. 355–357.

Ciment Fondu or *Electric Cement* is composed of lime and alumina, heated to incipient fusion in an electric furnace and afterwards ground to powder. This high alumina cement attains a great strength very much more quickly than Portland cement, and is said to be unaffected by sea-water. It should comply with the requirements of British Standard Specification No. 91b — 1940.

Rapid hardening cements are a special variety of Portland cement or of ciment fondu which attains almost its maximum strength in three days, and is, therefore, invaluable in road work and in some building construction (see p. 357).

Gypsum cements include plaster of Paris, Keene's cement, Parian cement (see *Plasters*, p. 357).

Oxychloride cements, of which the best known is *Sorel cement*, are composed of dense magnesia and syrupy magnesium chloride, or zinc oxide and zinc phosphate. They depend very largely on the use of suitably calcined oxides and on the chloride or phosphate being of suitable density, so that it is wise to follow the manufacturers' instructions.

Magnesium oxychloride cements may be diluted with fillers such as china clay, or may be coloured with mineral pigments such as ultramarine, ochre, etc. They are largely used for forming *floors*; these should not be repeatedly subjected to the action of water as this tends to soften them and causes them to wear badly (see p. 305).

Pastes made of flour or starch are largely used for fastening papers to each other or to walls, and ceilings. (See p. 359.)

Celluloid cements are made by dissolving celluloid or similar materials in a suitable solvent, such as amyl acetate. They are excellent adhesives for general use and will satisfactorily unite pottery, paper and wood, china, silk or cotton fabrics, leather, etc. They are waterproof.

Celluloid cements for various purposes are on the market; they are sometimes known as *dopes*.

Refractory and *fire-resisting cements* are those which are specially resistant to heat and are used in repairing furnaces, etc. (see p. 373)

Glues.

Commercial glue is made by boiling animal flesh, bones, etc., in water, removing fat and other mpurities and concentrating by evaporating the greater part of the water. It is usually sold in thin cakes or flakes, or in the powdered form, and should be kept in a dry place.

See British Standard Specifications Nos. 745—1937, and 647—1938.

Ground glue should be soaked in cold water at least three hours, flake glue, eight hours and cake glue, twelve hours. It should then be placed in a glue-kettle and heated until soft and tacky; its temperature should not exceed 150° F.

After being heated, the glue may be diluted with hot water to the required consistency. Glue should never be heated sufficiently to make it boil. It is also bad practice to prepare large quantities of glue at a time, because it loses its strength rapidly after being under heat for about four hours.

Glue that has cooled should never be reheated or it will lose about 50 per cent. of its strength.

Core glues are largely used in foundries. They consist of sand mixed with an adhesive, such as dextrine, resin soap or powdered glue to unite the sand grains into a firm mass.

Waterproof glues are best if bought ready-made, as most of the published recipes are unreliable. Casein cements, celluloid cements, and mastic cements are all waterproof.

Marine glue is a mixture of rubber, shellac, and naphtha. It has now been largely replaced by mastic cements.

For *fish glues* and *liquid glues*, see p. 353.

Portland Cement.

Portland cement is usually made from a mixture of chalk, or limestone, and clay ground together to an extreme degree of fineness, and subsequently dried, calcined, and ground to the fineness of flour. Pats or briquettes made from it should, when broken, exhibit a bluish-grey colour in the fracture.

Portland cement * may be obtained quick or slow setting. If there are no special reasons which make quick setting desirable, it is advisable to employ a cement which requires at least two hours to pass from the pasty state into the hard, solid one, as quick-setting cements require exceptional care and skill in gauging; otherwise they begin to set and to spoil before they have been placed in their proper position in the structure.

Most manufacturers add a little gypsum when grinding the cement clinker, and thereby adjust the rate of setting of the cement to suit the user's requirements. If required, the time taken for setting may be increased by exposing the cement to moist air before use, but this is not altogether satisfactory, and it is better to purchase a cement which sets at the desired rate.

Temperature has a very great effect upon the setting time of cement. A sample tested in a temperature of 61° Fahr. and gauged with water at the same temperature took six hours to set hard. The same sample gauged in a temperature of 90° Fahr. and gauged with water of equal temperature set hard in one hour fifty minutes. This is a point which is often lost sight of.

Testing Portland Cement.

The tests suggested by the British Standard Specification (*below*) are usually regarded as sufficient, but others are used for special purposes. The following notes indicate the purpose of the various tests:

Chemical Composition.—This test is for the detection of adulterants, or to determine whether certain constituents are present in amounts exceeding that believed to be safe.

Fineness.—The fineness of the cement is a measure of its cementing value; a fine cement will be much stronger when mixed into a mortar, or it can be mixed with a larger proportion of sand than a coarse one, and yet attain the same strength.

Crushing or Compression Strength.—The most generally comprehensive test of a Portland cement or of a mixture of it with sand would be a determination of the crushing strength of a cube of 4 in. side. Unfortunately, this requires a very costly machine, so that it is usual to substitute a tensile test which can be made much more cheaply.

Tensile Strength is determined in order to gain some idea of the cohesion between the particles. This property is not required in cement and concrete, but as it is roughly proportional to the crushing strength and the tensile strength is easier to determine, it is usually substituted for a crushing test.

Time of Setting.—This is determined in order to ascertain whether a cement sets at a rate suitable for a given piece of work. If a cement sets before it has been properly placed in position the work will be defective; hence where there is any doubt, a slow-setting cement should be used. There is no necessary relationship between the time of setting and that of hardening or attaining the maximum strength; a slow-setting cement may harden more rapidly than a quick-setting one, and *vice versâ*. *Rapid Hardening* cements and the aluminous cements, such as *Ciment Fondu*, set slowly but harden very rapidly.

Soundness.—The object of this test is to hasten the rate at which cement or concrete attains its maximum strength and to subject it to conditions more severe than are likely to occur in regular use. By thus exaggerating the conditions some idea is gained of the lasting properties of the material much more rapidly than would otherwise be the case. The soundness test is in some respects, the most important of all, for if a sample passes all other tests satisfactorily yet fails in the soundness test, it is worthless as a constructional material. To pass the soundness test a cement or concrete must retain a *constant volume* under the conditions of the test; failure is revealed by the test-piece cracking, swelling, or disintegrating in any other way.

The actual testing of cement and concrete requires considerable skill. The methods described in the British Standard Specification for Portland Cement (see below) are satisfactory, but require considerable practice before accurate results can be obtained.

British Standard Specification for Portland Cement.†

Ordinary and Rapid Hardening—No. 12—1940. (*Abstract.*)

The cement shall be manufactured by intimately mixing together calcareous and argillaceous or other silica and alumina bearing materials, burning them at a clinkering temperature and grinding the resulting clinker, so as to produce a cement capable of complying with the specification.

* The composition of Portland cements is highly complex. Some further indications of it are given in 'Cement, Concrete, and Bricks,' by A. B. Searle (Constable & Co. Ltd., London.).

† By permission of the British Standards Institution.

No addition of any material shall be made after burning other than calcium sulphate, or water, or both. For a specification which permits added slag, see No. 146—1932 (*below*).

The sample or samples shall be tested for :—(*a*) fineness ; (*b*) chemical composition ; (*c*) tensile strength (cement and sand) ; (*d*) setting time, and (*e*) soundness.

Fineness.—The residue on a sieve of B.S. Mesh No. 170 not to exceed 10 per cent. With a Rapid Hardening cement the residue not to exceed 5 per cent.

Chemical Composition.—

(*a*) The percentage of lime, after deduction of that necessary to combine with the sulphuric anhydride present, not to be more than 2·8 times the percentage of silica + 1·2 times the percentage of alumina + 0·65 times the percentage of iron oxide nor less than two-thirds of that amount.

(*b*) The Loss on Ignition not to exceed 3 per cent. in temperate climates, or 4 per cent. in hot climates.

(*c*) Insoluble Residue not to exceed 1 per cent.

(*d*) Magnesia not to exceed 4 per cent.

(*e*) Total Sulphur (calculated as sulphuric anhydride) not to exceed 2·75 per cent.

Tensile Strength (cement and sand).—3 : 1 sand-cement mortar not less than 300 lb. per sq. in. at 3 days. Strength at 7 days to be greater and not less than 375 lb. per sq. in.

Tensile strength of *Rapid Hardening* cement-sand mortar not to be less than 300 lb. per sq. in. at 1 day. Strength at 3 days to show an increase and not be less than 450 lb. per sq. in.

Compressive Strength (alternative to Tensile Strength) on 2·78 in. cubes made of cement 185 g., sand 555 g., water 74 g. at 3 days not less than 1,600 lb. per sq. in. At 7 days to show an increase and not be less than 2,500 lb. per sq. in. *Rapid Hardening* cement-sand mortar at 1 day not to be less than 1,600 lb. per sq. in. At 3 days to show an increase and not be less than 3,500 lb. per sq. in.

Setting Time.—The normal initial setting time should not be less than 30 minutes and the final setting time not more than 10 hours.

A quick setting cement shall have an initial setting time of not less than 5 minutes, and a final setting time of not more than 30 minutes.

Soundness.—The cement shall be tested for soundness by the Le Chatelier method, in the manner specified, and shall not expand more than 10 mm.

Effect of Climate.—Cement intended to be used in hot climates may be tested at any temperature up to 95° F. (instead of 58–64° F. required in temperate climates) and shall then conform to the Standard Specification. The requirements as to the setting time and strength may be altered if agreed between vendor and purchaser.

British Standard Specification for Portland Blast-Furnace Cement.*

(*No.* 146—*Revised* 1941.) (*Abstract.*)

This cement shall consist of a mixture of Portland cement clinker and granulated blast-furnace slag in such proportions as the manufacturer may prefer, but in no case shall the proportion of slag exceed 65 per cent.

The Portland cement clinker and the granulated blast-furnace slag shall be thoroughly and intimately mixed, and shall produce a cement capable of complying with the specification.

The cement shall comply with the following conditions of fineness :—100 grammes (or, say, 4 ozs.) of cement shall be continuously sifted for a period of 15 minutes on a B.S. Mesh 170 sieve and the residue, by weight, shall not exceed 10 per cent.

The cement shall comply with the following conditions as to its chemical composition. The percentage of insoluble residue shall not exceed 1 per cent. ; that of magnesia shall not exceed 5 per cent. Sulphur present as, and calculated as, sulphuric anhydride shall not exceed 2 per cent., and sulphur present as sulphide shall not exceed 1·2 per cent. sulphur, these being equivalent to a maximum total of 5·00 per cent. of sulphuric anhydride. The total loss on ignition shall not exceed 3 per cent. The composition of the Portland cement clinker portion of the mixture shall comply with the requirements of the current British Standard Specification for Portland Cement.

Tensile Strength at 3 days not to be less than 300 lb. per sq. in. The tensile strength at 7 days shall show an increase on the breaking strength at 3 days and shall be at least 375 lb. per sq. in.

The methods of making the tests are the same as for Portland cement (see p. 355).

* By permission of the British Standards Institution.

Rapid Hardening Cements.

Concrete made with some Portland cements and also concrete made with aluminous cement (*Ciment Fondu*) (see p. 354) are as strong after 24 hours as ordinary Portland cement concrete which is 90 days old.

Concrete made with 'Ferrocrete' (a rapid hardening Portland cement) has in 4 days the same strength as concrete made with ordinary cement has in 28 days; there is also a continuous increase in strength. Most rapid hardening cements and aluminous cements set slowly, but harden rapidly (see p. 354).

The British Standard Specification for Rapid Hardening Cements is No. 12—1940; that for Aluminous Cements is No. 915—1940.

Waterproof Cements.

Strictly speaking, no calcareous cement is wholly waterproof, but concrete can be made sufficiently so for most purposes by using suitable aggregates and the correct proportion of water, cement and aggregate. Where additional certainty is needed one of the materials described on p. 349 (waterproofing concrete) should be used.

PLASTERS.

Plasters are pasty materials applied to walls, ceilings, etc., to give a hard, smooth finish. They resemble lime mortars in many respects but serve a different purpose. Common plaster is made of lime and sand, with or without ½ lb. of hair to each cu. ft. of plaster. It is made harder and has smoother finish if 20 per cent. of plaster of Paris is added.

According to a tentative specification issued by the Department of Scientific and Industrial Research (*Building Research, Special Report, No.* 9, 1927) the lime to be used for plaster, fine and coarse stuff, should be *Quicklime, Class A*, or *High Magnesium Quicklime, Class A*, and, for coarse stuff only, *Quicklime, Class B* (see p. 340).

The British Standard Specification for gypsum and anhydrite plasters is No. 1191.

For *floors*, a hard-burned plaster of Paris is used, or a mixture of ordinary plaster with a slight excess of lime is laid, and then treated with zinc sulphate (white), iron sulphate (red), boiled oil (mahogany), or copal varnish.

Stucco for external use consists of 1 part of hydraulic lime to 3 parts of sand, but for more durable work a cement mortar (p. 338) is often used.

Rough cast is sometimes made of the same materials as stucco, or of cement mortar (p. 338).

Plaster of Paris is made by calcining gypsum and grinding the product. The resulting powder, when mixed with water, forms a smooth paste which rapidly sets to a white, solid mass.

Hard Plasters.

Keene's, Martin's, and Parian cements are hard-setting forms of plaster of Paris. Keene's cement is made by soaking calcined gypsum in a solution of alum or borax and cream of tartar. For Martin's cement, a solution of potassium carbonate is used, and Parian cement is an intimate mixture of gypsum and borax which has been calcined and then ground to powder. Both thes and other hard cements can be purchased and are more satisfactory than home-made preparations.

Plastering.

Coarse stuff is mortar composed of 1 part lime (carefully-slaked fat or pure lime is generally used) and 1 or 2 of sharp fresh-water sand, with 1 lb. hair to 3 cu. ft of mortar.

Hydrated lime is usually superior to lime which has been slaked by hand and can be used at once, whereas ordinary slaked lime must be kept in the form of a putty until slaking is complete.

Fine Stuff is made of pure lime slaked with a little water, after which water is added to bring it to the consistency of cream; it is then left to settle, the superfluous water poured off, and the water evaporated until it is of proper thickness. In ceilings a small portion of white hair is mixed with it.

Bricklayers' and plasterers' putty is fine stuff brought to the proper consistency.

Gauged stuff is ¾ fine stuff mixed with ¼ plaster of Paris.

Common stucco is 1 lime to 3 or 4 clean-washed sand.

Bastard stuff is ⅔ fine stuff and ⅓ clean sand, with a little hair.

Lath-and-Plaster, or *One-Coat Work.*—A coat of coarse stuff, ½ inch to ⅝ inch thick. laid on the laths and smoothed off with the trowel.

Lath, Plaster, and Set, or *Two-coat Work.*—The first, or 'pricking-up' coat of coarse stuff is scored with a birch broom or undercut with a lath, and a thin finishing coat of fine stuff or gauged stuff added.

Lath, Plaster, Float, and Set, **or *Three-coat Work.*—When the pricking-up coat is dry, the surface is scored, and divided into 8-foot squares by *screeds* of coarse stuff, 8 inches wide, carefully levelled. These are then filled in with coarse stuff, floated carefully level. The finishing coat is then put on as before.**

Materials.	1 in. Thick.	¾ in. Thick.	½ in. Thick.
1 bushel of cement, or 1·28 cubic feet, will cover .	1 1/7 sq. yds.	1½ sq. yds.	2¼ sq. yds
1 cement and 1 sand ,, .	2¼ ,,	3 ,,	4½ ,,
1 cement and 2 sand ,, .	3⅓ ,,	4½ ,,	6¾ ,,

1 cubic yard of lime, 2 yards of sand, and 3 bushels of hair will cover 75 yards superficial, render and set, on brick, or 70 yards on lath.

Reconstructed or Artificial Stone.*

ARTIFICIAL BUILDING STONE, NO. 1.—Mix 100 parts of hydraulic lime which has fallen to a powder with water to form a paste. To this add 250 parts of gravel and 50 of coal ashes or lixiviated wood ashes. The mass is then thoroughly mixed, and a sufficient quantity of water added to make the volume of the mass equal to 500 parts. It is then poured into moulds made of pine-boards, where it is allowed to remain until set.

No. 2.—125 parts of hydraulic lime which has fallen to a powder are mixed with a sufficient quantity of water to form a paste. To this are added 250 parts of ground oyster shells and 150 parts of ground peat ashes, and a sufficient quantity of water to make the bulk of the mass equal to 500 parts. It is then poured into moulds as in No. 1, and dried.

ARTIFICIAL STONE FROM QUARTZ SAND AND PLUMBIC OXIDE.—Ground quartz sand is mixed with 2 to 10 per cent. of finely-ground plumbic oxide. The harder the stones are to be, the more plumbic oxide must be used. The mixture is moistened with water-glass, again thoroughly mixed, and then pressed firmly into moulds. The resulting stone is dried and then burned.

VICTORIA STONE.—The refuse of granite quarries is broken up into pieces of suitable size, and 4 parts of the fragments thus obtained are mixed with 1 part of Portland cement, and sufficient water added to bring the whole to the consistency of dough. The mass is run into moulds, in which it is allowed to remain for several days, or until it has set solid. The blocks are then immersed in a solution of silicate of soda.

RANSOME'S ARTIFICIAL STONE.—Clean and dry sand and other suitable siliceous and earthy ingredients are thoroughly incorporated in a mixing mill with silicate of soda. The resulting pasty mass is then pressed into moulds of any required pattern or size, and when set sufficiently immersed in a solution of chloride of calcium. In the case of large pieces the saturation with chloride of calcium is facilitated by the use of an air-pump. The resulting reaction is the formation, by double decomposition of the ingredients of an insoluble calcium silicate out of sodium chloride. The first-named forms a solid and indurate binding material for the stone, and the sodium chloride is removed by a subsequent thorough washing with water. This last operation is important, since, if the sodium chloride is not completely removed from the stone, it will make its appearance subsequently in the form of a white efflorescence on the surface.

TO IMITATE VARIEGATED MARBLE.—Mix hydraulic lime and ground marble and incorporate with the mixture a solution of alum and suitable colouring substances. Differently coloured masses are then mixed together and cut into slabs.

ARTIFICIAL MARBLE.—The following mixtures have been recommended for making artificial marble. Grind and thoroughly mix comminuted stone, 280 parts; limestone or chalk, 140 parts; burned calamine, 5 parts; calcined felspar, 3 parts; fluorspar, 2 parts; calcium phosphate, 2 parts; water-glass, 40 parts.

On the addition of the water-glass the ingredients are quickly mixed, and thereupon pressed into moulds. The finished pieces are dried at a temperature gradually rising to 125° F.

RECONSTRUCTED STONE.—Many artificial or reconstructed stones sold under proprietary names are really carefully prepared concrete which has been moulded to the desired shapes. See p. 350 and British Standard Specification No. 834—1939.

*** The manufacture of artificial stones, *lime-sand* bricks and blocks, is dealt with at length in 'Bricks and Artificial Stones of Non-Plastic Materials,' by A. B. Searle (J. & A. Churchill, London).**

To Remedy Dampness in Walls.

Before attempting to cure dampness, serious efforts should be made to ascertain the cause which is often remote from the damp spot. For instance, a leaky channel or valley in the roof may introduce water into the wall, but the water may not be revealed until it reaches a more porous part of the structure or one from which it cannot drain freely. Too low a flashing behind a parapet wall is a common cause of dampness. When the source has been definitely found it is usually easy to prevent further trouble. The serious cases are those in which the source is not discovered.

Other methods of reducing or preventing dampness in walls include:

1. Cut out a course of bricks foot by foot, insert an asphalt damp-course (British Standard Specification No. 743—1937), and re-brick.

2. Remove plastering and re-point wall outside after wall has become dry. If it is inconvenient to renew plaster, the latter (although wet) may be varnished over with a solution of shellac in naphtha (4 ozs. shellac, 1 quart naphtha); this almost immediately hardens, and paper may be pasted over it.

3. A good coating of hot coal-tar laid on the exterior of a brick wall will prevent the entrance of rain, but should only be applied where its appearance is not objectionable. Spraying the wall with a silicon ester (silicone) will often prevent the further infiltration of rain and is less disfiguring than tar.

4. Cover the surface of the wall with a mixture of 1 part of Portland cement with 2 parts of fine sand, and water enough to bring the ingredients to the consistency of thick cream. Apply two coats of the mixture, and when it is quite dry finish with a coat of paint.

5. Re-plaster the wall with sand and cement impregnated with one of the special water-proofing agents, such as 'Pudlo,' 'Bareau,' 'Waterex,' or 'Silicon Ester.'

6. Spray or paint the wall with: (*a*) a solution of water-glass (sodium silicate), followed by a solution of calcium chloride, which forms an insoluble silicate; (*b*) a solution of various fluo-silicates with a subsequent application of calcium chloride to form an insoluble calcium fluosilicate in the pores of the wall; or (*c*) one of various substances, dissolved in acetone, alcohol, or other volatile solvent, which remain in the pores when the solvent has evaporated; (*d*) silicon ester.

Each of these methods is suitable for certain walls, but some walls appear to resist every kind of treatment yet applied to them.

British Standard Specification No. 743—1941 relates to *Damp-Proof Courses.*

Effects of Moisture Changes on Building Materials.

A Bulletin (No. 3) on this subject has been issued by the Building Research branch of the Department of Scientific and Industrial Research. Price 1*s*. net.; postage extra. H.M. Stationery Office, London, York House, Kingsway, W.C. 2.

FLOUR PASTE. (See p. 354.)

The most satisfactory method of making flour paste is to mix flour with a little cold water, stirring until it forms a smooth cream. This is then poured slowly into boiling water, with constant stirring. The total weight of water is usually five times that of the flour (4 oz. of flour to each pint of water). The mixture is boiled for a short time, with constant stirring, and is then allowed to cool.

For some purposes an adhesive paste with twice as much water is satisfactory.

Before the mixture is quite cold a little formalin or carbolic acid may be added and thoroughly stirred in: it acts as a preservative.

CLAYS AND EARTHS.

For engineering purposes, clays and earths may be regarded as (1) substances which must be excavated and transported from their present situation; (2) the raw materials from which earthwork, puddle, etc., are made; and (3) the raw materials used in the production of bricks, drain pipes and many other articles employed by engineers. The term 'clay' in the broadest possible sense is applied to a material which is tenacious and plastic when wet. Such clays may contain only a small proportion of true clay, together with a large proportion of inert material such as sand. For many engineering purposes a perfectly pure clay would be useless, as it might be of so fine a texture and so highly plastic that it would shrink excessively on drying, and it would be extremely difficult to make into bricks or other desired articles. When made, these articles would be deficient in certain important properties, such as resistance to crushing, impermeability to water, etc.

The term 'earth' is usually applied to a friable material partaking of the general properties of soil, though not necessarily of any agricultural value. It usually consists chiefly of inert material, the particles of which are united by a very variable proportion of clay, humus, or other adhesive. Hence the 'earths' are often regarded as 'clays' of low plasticity, but both these terms are used very loosely by many engineers and no really satisfactory definition of them has yet been formulated.

In selecting a 'clay' or 'earth' for any given purpose, the engineer must, therefore, decide what properties are essential to his requirements and must endeavour to find a natural material possessing these properties, or to prepare a mixture of two or more materials which suit his purpose.

The chemical and physical properties of 'clays' depend chiefly on the composition and plasticity of the material, it being obvious that a 'clay' containing 50 per cent. of quartz-grains must behave very differently from one which consists wholly of 'true clay.' The *plasticity* of clays varies with the nature of the clay and the amount of water present. Dry clays are friable and devoid of plasticity; on mixing clay with an equal weight of water a liquid slurry or slip is formed which is not really plastic, but becomes so when a suitable proportion of the water has been removed by evaporation or otherwise. No generally accepted explanation of the cause of plasticity has been published; this property may be due to the presence of colloidal particles which may be derived from the clay itself or from impurities which have become associated with it. The purest clays—e.g. 'china clay'—are very feebly plastic; the highly plastic ball clays which are supposed to have been derived from them are rich in carbonaceous matter, to which their plasticity is sometimes attributed. The clays commonly used for bricks, pipes, terra-cotta, etc., are never pure; they are naturally occurring complex mixtures possessing the requisite properties to make them useful for specific purposes.

It is a great mistake to suppose that any plastic 'clay' can be made into bricks, or that any 'system' of manufacture is equally suitable for all 'clays.' On the contrary, the manufacture of clay products is in reality so complex (notwithstanding its apparent simplicity) and the ordinary manufacturer depends on the simultaneous occurrence of so many fortuitous circumstances that it is not surprising that many firms fail to manufacture clay goods of uniform quality.*

BRICKS.

Many kinds of bricks are in use. The most important are: *Common Bricks*, used for ordinary building purposes; *Facing Bricks*, used for external work where appearance is important; *Paviours*, used for yards, footpaths, and other locations where a hard-wearing and impervious brick is required (for *Road Bricks*, see p. 562); *Blue Bricks*, which are similar in many respects to 'paviours' and are employed where exceptional strength and impermeability are important; *Stock Bricks*, which are practically the same as 'common bricks,' but have usually been burned in a clamp instead of in a kiln; they have proved exceptionally resistant to the climatic conditions of London, but are seldom, if ever, used in other large industrial centres (in some localities the term 'stock bricks' relates to 'facing bricks').

Bricks are also known according to the manner of their production. Thus, *Malms* contain a large proportion of chalk, either naturally or artificially mixed with the clay; *Wire-cut Bricks* are made by cutting up a column of clay issuing from a machine, by means of wires; *Pressed Bricks* have been made in presses; *Semi-plastic* or *Stiff Plastic Bricks* have been made from a paste which is stiffer and less plastic than that used for hand-moulded or wire-cut bricks; *Semi-dry Bricks* are made by compressing the powdered clay in powerful presses instead of first converting it into a paste.† *Place Bricks*, *Grizzles*, and *Chuffs* are inferior bricks which are soft through insufficient burning; *Crozzles* are excessively hard, misshapen bricks which have been partially melted and overheated. *Rubbers* and *Cutters* are soft, sandy bricks.

Glazed Bricks are used where a smooth and impervious surface is required (see 'Glazed Tiles').

Sand-lime Bricks.—Sand-lime bricks are made of high silica content mixed with about 8 per cent. of lime. After pressing they are placed in autoclaves, or 'hardening chambers,' fed by steam under pressure where an irreversible chemical change occurs and calcium is formed; the absence of 'burning' results in a brick of perfect shape and square corners. The efficiency of the manufacturing process enables them to be sold at a price comparable with the cheapest clay bricks (see p. 366). Sand-lime bricks have been made in this country for nearly fifty years but their serious entry into the market became noticeable only in the last fifteen years, during which time they have made marked commercial progress. Their strength is equal to that of good quality clay bricks and their porosity is no higher. Unjustifiable doubts have often existed on the latter point through their tendency to show change of colour on immersion.

Cement-concrete Bricks.‡—These bricks have attracted attention, but are not so suitable as larger blocks of concrete for general purposes, as the cost of production is relatively high. See also p. 367.

Engineering Bricks is the term usually applied to bricks of an exceptionally dense and vitreous character of which the best known are the *Staffordshire* blue bricks. These owe their unusual strength and impermeability to the fact that they have been burned under such conditions that the particles composing them are united very firmly by means of a film of clinker surrounding each. For purposes where a somewhat weaker brick has ample strength, well-made *pressed* or *stiff plastic* bricks are usually satisfactory and much less costly, but they are more porous and therefore less suitable for supporting heavy masses of material on a boggy or damp subsoil. Bricks for *boilers* should be accurate in size and shape so as to enable the thinnest possible joints to be used. In order to prevent undue leakage they should be glazed or painted with tar or other impervious material.

For *fireboxes*, *furnaces*, etc., firebricks and blocks are employed.

Colliery Bricks are usually of very poor quality, due to their being made from unsuitable material, or from good clay which has been spoiled by mixing it with rubbish.

Panel Bricks have a hollow portion (known as a *frog* or *panel*) which reduces the weight and may serve as a key for the mortar. According to the Ministry of Health Model Byelaws, Series IV, Buildings (1938), the volume of solid material shall not be less than one-half of the total volume and the aggregate width of the solid material (measured horizontally at right angles to the face) shall not be less than one-third of the width of the brick.

Cavity Bricks usually have a larger hollow portion than panel bricks; the same regulation as to the volume of the cavity applies to them as to panel bricks.

Hollow Bricks and Blocks.—See p. 369.

Crushing Strength of Bricks.

Opinions differ greatly as to the respective values of different kinds of bricks, and as the crushing strength of bricks taken from the same works at different times varies 25 per cent. and even more, it is clear that no comparison of crushing strength tests can be of much value in deciding between various kinds of bricks. The chief use of the tests is in fixing a minimum crushing strength which shall ensure the safety of the structure, but as the strength of even the commonest bricks is much greater than that of average brickwork (the mortar being usually weak), it is difficult to stipulate any satisfactory minimum strength for bricks.

The following figures are the averages of a large number of bricks, but it must be clearly understood that bricks from any given works may be either much stronger or much weaker than the ones mentioned.

Description.	Crushing Commences.	Ultimate Crushing.
	Tons per square foot.	Tons per square foot.
Common stocks	40–60	80–120
London best stocks	80–140	100–180
Gault white, wire-cut	40–120	135–200
Aylesford, red pressed	70	140
Manchester, common red	75	120
" wire-cut	85	260
Accrington, plastic *	690	1005
Leicester, wire-cut	115–250	230–340
Rugby, common red	160	190
Fletton	125–200	170–250
Notts.	60–300	120–400
Ruabon.	360	—
Staffordshire blue bricks	250–450	400–750
Terra-cotta blocks	—	100–260
Glazed bricks	70–165	165–175
Stourbridge fire bricks	90–160	110–210
Sand-lime bricks	150–200	180–230

The crushing strength of brickwork is shown on p. 180.

See also Building Research Special Report No. 22 (1934) (H.M. Stationery Office, London), and London County Council Byelaws, 1938.

Sizes of Bricks.

In many countries there is no official standard; the following are average sizes:—

Standard Sizes of Bricks in Different Countries.†

Country.	Length, inches.	Breadth, inches.	Thickness, inches.
Great Britain	9	$4\frac{3}{8}$	$2\frac{5}{8}$ ‡
Germany	10	$4\frac{3}{4}$	$2\frac{1}{2}$
Austria	$11\frac{3}{8}$	$5\frac{5}{8}$	$2\frac{5}{8}$
France	$8\frac{5}{8}$	$4\frac{3}{8}$	$2\frac{1}{4}$
Italy	9	$5\frac{7}{8}$	$2\frac{3}{8}$
Holland and Belgium	$9\frac{3}{8}$	$4\frac{1}{4}$	$2\frac{3}{8}$
Switzerland	10	$4\frac{3}{4}$	$2\frac{3}{8}$
Russia (varies greatly).	$11\frac{1}{4}$	$5\frac{1}{4}$	$2\frac{3}{4}$
United States	8	4	$2\frac{1}{4}$

Standard Specification for Bricks.

The sizes of bricks vary in different parts of Great Britain, but there are many advantages in adopting the British Standard Specification No. 657—1936 and 1941, summarised on p. 366.

Unfortunately, many users still order bricks of non-standard sizes and so fail to secure the advantages they might obtain, viz. readier and more accurate designing of clear openings in brickwork, more accurate assessment of the number of bricks required, reduction in the cost of bricks and cost of laying which arise when different sizes are used for facings and backing, and quicker delivery from stock.

* These figures supplied by The Accrington Brick and Co., 1926.

† See also p. 316.

‡ In Scotland, $2\frac{7}{8}$ in. or 3 in.

BRITISH STANDARD SPECIFICATION FOR BRICKS MADE OF CLAY,* No. 657—1941.
(*Abstract.*)

The dimensions of the bricks shall be as shown in the following table :—

Length.		Width.		Depth.					
				Type I.		Type II.		Type III.	
In.	Total in.	In.	Total in.	In.	Total in.	In.	Total in.	In.	Total in.
8¾	± ⅛	4 3/16	± 1/16	2	± 1/16	2⅝	± 1/16	2⅞	± 1/16

Method of Measurement.—The bricks laid dry shall measure as follows :—

(*a*) Eight bricks laid dry, end-to-end, in contact, in a straight line.
Maximum length, 71 in.
Minimum length, 69 in.

(*b*) Eight bricks laid dry, side-by-side, in contact, in a straight line.
Maximum length, 34 in.
Minimum length, 33 in.

(*c*) Eight bricks laid on edge, bedding surface to bedding surface, in contact, in a straight line.

	Type I.	Type II.	Type III.
Maximum length	16½ in.	21½ in.	23½ in.
Minimum length	15½ in.	20½ in	22½ in.

Snap Headers shall be 4 3/16 ± 1/16 in. in length, with width and depth as in the table.

Closers shall have the length and depth shown in the table, and the width shall be 2 ± 1/16 in.

All backing bricks should have the same dimensions as the facing bricks.

Joints should be ¼ in. thick, and an extra 1/16th, making 5/16th, for the bed joints to cover irregularities in the bricks. This gives a standard length of 9¼ ins. centre to centre of joints.

TESTS OF BRICKS.

All dry bricks should *ring clearly* when two, held in the hands, are struck sharply together. If a dull sound is emitted the bricks are either saturated with water or they have not been sufficiently well burned.

The *porosity* of bricks is usually tested by soaking them in water, wiping dry and noting the increase in weight. Whilst many good building bricks will absorb one-fifth of their weight of water, this is no criterion of the value from an engineering standpoint ; on the contrary, engineers usually prefer bricks with low porosity on account of their greater strength.

Rattler Test.—In the United States, and to a much smaller extent in this country, engineering bricks are tested for toughness and resistance to abrasion by placing a weighed quantity of them in a cylinder with steel balls and rotating the cylinder a thousand times in about half-an-hour.† The contents of the cylinder are then removed, all pieces of brick larger than 1 in. diameter are picked out and reweighed. The loss in weight is regarded as a measure of the inferiority of the bricks. The rattler test is particularly applicable to bricks used for road making and for lining furnaces.

For standard methods of testing bricks, see British Standard No. 1257.

SPECIFICATION FOR SAND-LIME BRICKS.‡

(No. 187—1942.) (*Abstract.*)

(Sand-lime bricks are described on p. 364.)

Four classes of sand-lime bricks are recognised: —
Bricks for special purposes.
Building Bricks, Class A (i).
Building Bricks, Class A (ii)..
Building Bricks, Class B (for internal use only).

The length of the bricks shall be 8¾ in. ± ⅛., and the width shall be 4 3/16 ± 1/16 in. unless otherwise agreed.

* The term 'clay' is used in a general sense to exclude sand-lime bricks and glazed bricks.

† The weight of the balls, the number of revolutions, and the size of the rejected pieces, differ with various engineers.

‡ By permission of the British Standards Institution.

The thickness shall be agreed between the manufacturer and the purchaser and shall not differ from the agreed figure by more than ± $\frac{1}{16}$ in.

Samples.—Fifteen bricks per 100,000 (or other agreed number from stock) shall be taken; twelve to be used for the Crushing Test or Transverse Test and three for the Chemical Tests.

Fifteen other bricks to be sealed and reserved in case of dispute.

Strength Test may be either Crushing Test or Transverse Test, as agreed.

Crushing Test.—On twelve whole bricks tested flat in wet state after soaking in cold water for 24 hours:—

Bricks for special purposes . . . 2,500 lb. per sq. in.
Building bricks, Class A . . . . 1,750 lb. per sq. in.
Building bricks, Class B . . . . 1,000 lb. per sq. in.

Transverse Test.—On twelve whole bricks in wet state, laid flat with frog uppermost on rounded supports of ½ in. radius and 7 in. apart, the load being applied at mid-span through a similar bar of ½ in. radius. Modulus of rupture to be not less than:—

Bricks for special purposes . . . 500 lb. per sq. in.
Building bricks, Class A . . . 350 lb. per sq. in.
Building bricks, Class B . . . . 200 lb. per sq. in.

Uniformity.—The average crushing strength (or the average modulus of rupture) of the seven bricks giving the lowest results expressed as a percentage of the average crushing strength of the twelve bricks should not be less than:—

Bricks for special purposes . . . 90 per cent.
Building bricks, Class A . . . . 80 per cent.
Building bricks, Class B.

Composition.—The bricks shall consist essentially of an intimate uniform mixture of siliceous sand and slaked lime, combined by the action of high-pressure steam and, after being crushed and screened through a British Standard test-sieve No. 52, shall correspond on testing in approved manner to:—

	Total Silica not less than per cent.	Total Free Lime not more than per cent.	Total Calcium Oxide present as Silicate not less than per cent.
Bricks for special purposes .	75	1·0	3·5
Building bricks, Class A . . .	75	1·5	3·0
Building bricks, Class B . . .	75	2·0	3·0

For further details of the tests, see Specification No. 187—1942.

Concrete Bricks.

Bricks made of 6 parts of sand and 1 part of Portland cement are cheap to produce when the sand is on the building site. Ordinarily they cost more than clay bricks. They are made in plain moulds, and must be kept wet for a fortnight. Concrete bricks are as durable as sandstone: they are suitably made in isolated places where sand is available and carriage is costly. See British Standard Specification No. 657—1941.

TILES.

A 'Code of Practice for Roofing with Plain Tiles,' published by the Building Industries National Council, 110 Bickenhall Mansions, W.1. (Price 9*d.*) should be read.

Roofing Tiles are made of materials similar to those used for bricks, but of a somewhat finer texture. No official specifications have been published, but it is recognised that roofing tiles should be light, tough, and ring clearly when struck, be impervious to water in the sense that even under a continuous supply of water no dripping will occur from the underside of the tile when placed at the same angle as when in use on a roof. It is desirable that tiles should be moderately porous, so as to avoid undue condensation of their underfaces. (See p. 299.)

BRITISH STANDARD SPECIFICATION FOR CLAY OR MARL PLAIN ROOFING TILES.*

(No. 402—1930.) (*Abstract.*) (See also No. 1424—1948.)

British Standard Plain Roofing Tiles may be either hand-made or machine-made, as specified. They shall be made from well-weathered and ground clay or marl.

Particles of lime, visible to the naked eye, either on a surface or a fracture, shall be a cause for rejection, unless the lime has been water-slaked by *docking* the tiles as they come from the kiln.

* By permission of the British Standards Institution.

The tiles shall be true in shape, free from fire-cracks, dense, tough, show a clean fracture when broken, and well-burned throughout.

Nibs.—Hand-made tiles shall have not less than two nibs, each not less than $\frac{3}{4}$ in. wide and a depth of $\frac{3}{8}$–$\frac{1}{2}$ in.

Machine-made tiles shall have not less than two nibs not less than $\frac{3}{4}$ in. wide or a continuous nib $\frac{3}{8}$–$\frac{1}{2}$ in. deep.

Note.—Nibless tiles may be used by agreement.

Nail-holes.—Two nail-holes shall be provided, the centre of each being 1–1$\frac{1}{4}$ in from the side of the tile and $\frac{5}{8}$ in. from the under side of the nib. The holes shall not exceed $\frac{1}{4}$ in. in diameter.

Size.—The standard size is 10$\frac{1}{2}$ in. × 6$\frac{1}{2}$ in., with a tolerance of ± $\frac{1}{8}$ in. on the width and ± $\frac{1}{4}$ in. on the length.

Tiles 11 in. × 7 in. may be used if this size is definitely stated.

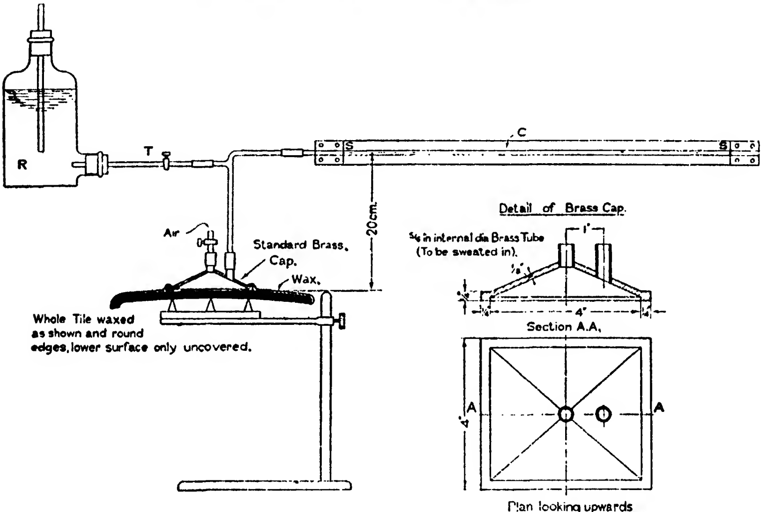

FIG. 1.

Thickness.—Hand-made tiles shall not be less than $\frac{1}{2}$-in. thick. Machine made tiles shall not be less than $\frac{3}{8}$ in. thick.

Camber.—Hand-made tiles shall have a camber of $\frac{3}{16}$–$\frac{7}{16}$ in.

Machine-made tiles shall have a camber of $\frac{1}{8}$–$\frac{1}{4}$ in.

Transverse Test.—The average breaking load applied along the centre line of a tile at right angles to its length shall not be less than :—

	10$\frac{1}{2}$ × 6$\frac{1}{2}$ in. tile.	11 × 7 in. tile.
Hand-made tiles . . .	175 lb.	189 lb.
Machine-made tiles . . .	125 lb.	189 lb.

The tiles shall be soaked in water for 24 hours prior to testing and shall be tested wet. They shall be supported on wooden bars 1 in. wide, rounded on the bearing edges to $\frac{1}{8}$ in. radius, and placed at 7$\frac{1}{2}$ in. centres. The load shall be applied through a similar wooden bar, placed parallel to the supports. The average of six tiles should be taken. If the test fails a further six tiles may be tested.

The test shall be made before delivering.

Freezing Test.—Four tiles shall be soaked by gradual immersion in water, 4 hours being required for immersion, followed by a further 20 hours. The tiles shall then be wrapped in wet cloths and immersed in a freezing mixture of ice and salt (4 :1 by volume) for 24 hours at a temperature below − 10° C. They shall then be thawed for 24 hours at 16° C. and be again immersed in the freezing mixture, the process being repeated ten times.

The tiles shall not show any sign of lamination, pitting, or cracking.

The test shall be made before delivery.

Permeability Test.—Three tiles shall be dried at 90–100° C., then waxed on to a special metal cap with Faraday wax (fig. 1). The upper surface and sides shall be coated with Faraday wax as far as the four sides of the cap. Tubing is used to connect the interior of the metal cover to a head of water and to a capillary tube. The rate of flow of water is deduced from the rate at which the water travels along the capillary tube when the tap, T, is closed.

The rate of flow through the specimen with the tap, T, open shall not in 24 hours exceed that indicated by a rate of flow of 4 in. per min. along a capillary tube of 1 mm. bore under a head of 20 cm. The test shall be made before delivery.

Concrete Roofing Tiles should comply with British Standard Specification No. 473—1932 or No. 550—1934.

Glazed Tiles are used partly for decorative purposes, but chiefly for sanitary reasons. The glaze should be sufficiently hard to resist all reasonable abrasion and it should not craze (forming hair-like cracks) after prolonged use. For chemical laboratories and other special purposes a felspathic glaze burned at about 1300° C. must be used in order that it may be sufficiently resistant to corrosive fluids, etc. (see 'Stoneware,' p. 370).

Paving Tiles, like paving bricks, should be very hard and resistant to abrasion. To prevent animals slipping on them, the surface may be channelled with small grooves forming a diamond pattern.

Paving tiles are usually made of the same material and in the same manner as paving or engineering bricks.

BLOCKS AND TERRA-COTTA

The chief requirements of *blocks* made of clay and allied materials are accuracy in shape and size, and ample strength to carry the superimposed loads. For external work, appearance is also important.

Terra-cotta is largely used in conjunction with structural steel work, the latter taking the bulk of the stresses and the terra-cotta forming a sort of filler and cover of great resistance to climatic conditions and of pleasing appearance. There is no necessity to impose any conditions as to its strength, as in a properly designed structure it would not be exposed to any severe stresses.

Solid Terra-cotta weighs 117–148 lbs. per cu. ft.

Blocks for boilers are made of special shapes. They must be sufficiently heat-resisting not to be affected by the conditions to which they are subject when in use. They must be very accurate in shape and size or there will be a serious leakage into the side flues.

HOLLOW BLOCKS.

For many years in France and in some of the Colonies, but more recently in this country, the advantages which hollow blocks possess over building bricks have been realised. Such blocks are only one-third of the weight of the same number of bricks; they can be laid about four times as rapidly, and they are of ample strength for all purposes for which ordinary bricks are used. In addition, they automatically form a cavity wall, with all its advantages of warmth

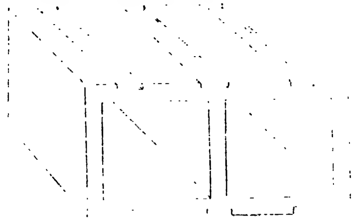

FIG. 2.

and soundproofness. Their great strength is really due to the fact that the bricks in a solid mass of brickwork have about ten times the crushing strength of the brickwork as a whole. Consequently a large proportion of the solid interior is quite useless and only adds to the cost of material, carriage, and labour; these costs are saved when hollow blocks are used.

Hollow building blocks are made in various shapes and sizes, according to the purposes for which they are to be used, and numerous patents have been granted in connection with them.

The *clays* used for making hollow blocks are the same as those employed in the manufacture of terra-cotta and roofing tiles. Such clays must vitrify sufficiently to form a strong, weather-resisting mass when fired. They must retain their shape perfectly at any temperature to which they may be exposed in the kiln, and whenever possible they should have a pleasing colour so as to avoid the necessity of 'rough casting.' Suitable clays and shales are found in various parts of the country, particularly in the Midlands. The lower grades of fireclays found in the various coalfields are also suitable, provided their buff colour is not regarded as objectionable.

The *process* of manufacture consists in preparing a clay paste of suitable consistency and extruding it through a die or mouthpiece, the interior of which is fitted with a number of cores, corresponding to the hollow portions of the blocks, fig. 2. The extruded column of clay is then cut by wires into suitable lengths, and the resulting blocks are dried and burned like bricks or architectural terra-cotta.

No standard specifications for hollow blocks have as yet been issued, but it is obvious that if the crushing strength of such blocks when they are laid in the same position as that in which they will be used, is greater than the normal strength of brickwork, such blocks will have ample strength. In most cases the blocks themselves have more than twice the strength of normal brickwork.

Where hollow blocks of exceptional lightness or great insulating power are needed, the clay is mixed with diatomite (kieselguhr) or sawdust.

Hollow Concrete Blocks 8½ in. thick weigh 4·25 lb. per sq. ft. for each inch of overall thickness of block, as laid. Similar blocks 2½ in. thick weigh 6·25 lb. per sq. ft. for each inch of overall thickness of block, as laid.

Hollow Blocks of Diatomaceous Earth weigh 2·50–2·65 lbs. per sq. ft. for each inch of thickness of block, as laid.

STONEWARE, SANITARY WARE, AND DRAIN PIPES.

Stoneware, as used by engineers, is chiefly employed in chemical works in the construction of appliances for dealing with corrosive fluids both at low and high temperatures.

The conditions under which it is used are exceptionally severe and yet are so varied that no widely acceptable specifications have been found possible. For chemical and industrial purposes, stoneware should consist of an impervious body of great crushing strength and with a minimum sensitiveness to sudden changes in temperature. The ideal is closely approached by the porcelain crucibles used in chemical laboratories, but this is too costly and too fragile for most commercial purposes and various coarser substitutes are therefore employed. To a very large extent the manufacturers of stoneware appliances may be relied upon to supply a satisfactory product if they are fully informed as to the conditions to which it will be subjected. Where troubles arise, they are often due to an engineer requiring a piece of stoneware of a design or shape which is incompatible with the nature of the material used.

Sanitary Ware is not subjected to the same conditions as stoneware, and may therefore consist of a porous body covered with a hard felspathic glaze, though an impervious body is preferable where expense is no object. It is highly important that the glaze should be of a suitable character, earthenware and lead glazes seldom being sufficiently durable. In designing sanitary ware it is desirable to work in close co-operation with the manufacturer, as in this way much delay in production and a considerable saving in cost may be effected, and the ware is likely to be more satisfactory. As far as possible, joints and sharp arrises or corners should be avoided.

Drain Pipes are frequently made of a porous body which is covered with a salt-glaze, but for the best work a vitreous or impervious body should be used. If the glaze is defective or damaged an impervious body will maintain the efficiency of the pipes, but a porous body may permit seepage of a disagreeable or even harmful character.

British Standard Specifications No. 65—1937 and 539—1937, deal with salt-glazed drain pipes, bends, junctions and fittings, and No. 540—1937 deals with salt-glazed glass (vitreous) enamelled fireclay pipes, *i.e.* pipes and fittings which have been glazed internally with a preparation of ground glass or other suitable materials and externally with salt-glaze. The required dimensions and permissible variations are stated and the hydraulic test and absorption test are described. All pipes marked 'Tested' must have been tested hydraulically and have shown no leakage when subject to a hydraulic pressure of 20 lb. per sq. in. for one minute.

The Specifications are illustrated and are of such a nature that they cannot be briefly summarised so that direct reference to them is essential.

According to the Ministry of Health's Model Byelaws, Series IV, Buildings, 1938, all drain-pipes must conform to British Standard Specification No. 65—1937, or No. 540—1937, or No. 437, or No. 556, or No. 1191, according as they are made of burned clay, cast iron or concrete.

ELECTRICAL WARE.

Electrical Ware is chiefly used in the form of conduits, insulators, and fittings. The conduits are usually made of coarse stoneware and are similar in many respects to salt-glazed drain pipes (*supra*).

Other electrical ware is made of fine stoneware or porcelain. Insulators must have a fine and uniform texture and their fractured surface should be free from holes and fissures; they must be able to resist the passage of electric currents of the desired voltage without appreciable leakage, and should be tested at a considerably higher voltage to ensure this.

REFRACTORY MATERIALS.*

The term '*Refractory*' is applied to various heat-resisting materials, such as firebricks, crucibles, and furnace linings. There is no official definition of this term, but it is becoming increasingly customary to regard 1580° C. (2876° F.) as a minimum temperature, materials which

* See also *Refractory Materials, their Manufacture and Uses* (3rd edn.), by A. B. Searle (Griffin & Co., Ltd., London).

suffer deformation when heated rather slowly to this temperature being excluded from what are generally regarded as refractory materials.

As the rate of heating has an important influence on the temperature at which deformation occurs, it is necessary, for comparative purposes, to specify the conditions of heating.

MELTING POINTS OF REFRACTORY MATERIALS.

	°C.		°C.
Alumina (pure)	2010*	Ganister	1700 to 1800
Bauxite	1820*	Kaolin	1835 to 1740*
Bauxite brick	1565 to 1785*	Magnesia brick	2165
Bauxite clay	1795*	Silica—Pure	1750*
Chromite	2180*	Pure (fine grains)	1650
Chromite brick	2050*	Pure with 14·5 per cent. alumina	1680
Fireclay brick—Highest grade	1843	Pure with 63·0 per cent. alumina	1790
General grade	1680 (average)	Brick	1700 to 1750
General grade	1649 (average of 41 samples)*		

The term 'melting point' is misleading when applied to refractory materials, as these are seldom, if ever, melted, and the term is generally used to indicate the temperature at which a small pyramid or 'cone' of the material bends over until its apex is on a level with its base, or, alternatively, at which the angular edges of the pyramid begin to lose their angularity.

FIREBRICKS.

Fireclay bricks are made of clays derived chiefly from the coal measures. These clays are crushed to powder, mixed with water and made into bricks either by hand-moulding or machines of the stiff-plastic or semi-dry type; the bricks are then dried and are afterwards burned in kilns. The temperature attained in burning should be at least as high as that to which the bricks will be subjected when in use, as otherwise shrinkage and other defects may occur. It is seldom that bricks burned at such high temperatures are obtained unless they are definitely specified; and for some purposes, such as lining steel-melting furnaces, users must be content with bricks fired at a lower temperature than that at which they will be employed. The highest temperature ordinarily attained in burning fireclay bricks is about 1350° C.; in silica bricks 1500° C.

Firebricks are also made of silica (in which case they are known as *Ganister* or *Silica Bricks*), alumina (*Bauxite* or *Semi-bauxite Bricks*), magnesia (*Magnesia* or *Magnesite Bricks*), chrome iron ore (*Chromite Bricks*), sillimanite (*Sillimanite Bricks*), zirconia (*Zirconia Bricks*).

Firebricks made of clay or silica are acid in character and are readily attacked by the limestone used as a flux in steel furnaces.

The materials of which *acid* bricks are made may be classified into three groups:

(*a*) Aluminous clays.
(*b*) Siliceous clays.
(*c*) Silica rock (sometimes erroneously termed 'silica clays').

The *Aluminous clays* include the Stourbridge, Yorkshire, Scotch, Welsh, and other Coal Measure fireclays, which contain, on an average, about 65 per cent. of silica. The *Siliceous clays* include those which contain 80–92 per cent. of silica, such as Ewell clay. *Silica rock* contains more than 92 per cent. of silica, such as Dinas rock and ganister. The composition of some of these materials is shown in the following table †:

	Stourbridge Clay.	Ewell Clay.	Dinas Clay.	Black Ganister.‡
Silica	64·62	87.57	97.60	98·5
Alumina	21·65	3·60	0·50	0·3
Ferric oxide	1·48	4·80	1·50	1·3
Lime	1·88	0·74	0·20	0·2
Magnesia	0·62	0·41	—	—
Potash	—	0·69	0·09	trace
Soda	—	0·10	0·08	trace
Moisture	9·62	—	—	—
Combined water	—	2·09	—	—

* Kanolt. The temperatures are those at which the materials were first seen to flow easily.

† Analyses of these and other heat-resisting materials will be found in *Refractory Materials*, by A. B. Searle (Griffin & Co., Ltd., London).

‡ The Dinas material is not a true clay, but a silica rock composed of almost pure quartz, ganister is similar, but consists of much smaller particles.

Ordinary fireclays contain 58 to 75 per cent. of silica, 25 to 36 per cent. of alumina, and ½ to 2 per cent. of iron oxide. Good silica bricks contain upwards of 95 per cent. of silica, little or no alumina, and under 2 per cent. of lime. Ganister bricks contain about 90 per cent. of silica, 5 per cent. of alumina, and less than 2 per cent. of iron oxide. Magnesia bricks consist almost wholly of magnesia, unless about 5 per cent. of clay or iron oxide has been used to bind the particles together.

Basic Bricks are made of magnesia, whilst *Neutral Bricks* are made of bauxite, sillimanite, zirconia, chromite, or carbon; the two latter are chiefly used as an intermediate course between acid and basic bricks in furnace linings. The materials used for silica and neutral firebricks usually need a 'binder' such as fireclay or lime, but the clays are self-binding. Firebricks made of sillimanite appear to be specially suitable for use at very high temperatures. As natural sillimanite ($Al_2O_3.SiO_2$) is a rare mineral which has to be imported from Northern India, an artificial material made by heating fireclay and bauxite in a blast-furnace is frequently used instead; the artificial product is not true sillimanite, but more closely resembles millite ($3Al_2O_3.2SiO_2$). Those made of zirconia have proved disappointing—chiefly on account of the impurities in the zirconia used.

The impurities in fireclays, i.e. those constituents other than the silica and alumina, have a most harmful effect on the refractoriness of the material owing to their low fusing point. These constituents should, if possible, never be allowed to exceed more than 4 to 5 per cent. Much must, of course, depend upon the type of clay, and it is possible to point to certain substances containing so much as 4 per cent. of iron alone, and yet they are highly refractory. Green clay when fired is subject to considerable shrinkage, and it is for this reason that chamotte, or 'grog,' is added in varying proportions before the article is placed in the kiln. This 'grog' is usually prepared from a clay which originated in the same seam as the clay with which it is mixed. It should be prepared specially for the purpose, and should not consist of the crushings from defective and broken articles which have passed through the kiln. The quantity of 'grog' added varies, of course, with the material required and the kind of clay made use of. For firebricks and smaller articles it is usually added in a proportion of 15 to 20 per cent. For larger articles, such as retorts, the amount is increased to 30 to 40 per cent.

The deformation or softening points of firebricks vary considerably. The following are fairly typical:—

Fireclay bricks, 1610°–1770° C.; Silica bricks, 1670°–1790° C.; Magnesia bricks, 1730°–2000° C.

Highly porous fireclay bricks—see p. 377.

Specification for Fireclay Bricks.

(Institution of Gas Engineers, 1934.)

(1) *Refractoriness.*—Two grades of material are covered by the specification:—

Grade No. 1.—The material which shows no sign of fusion when heated to a temperature of not less than Seger Cone 29 (about 1650° C.).

Grade No. 2.—Material which shows no sign of fusion when heated to a temperature of not less than Seger Cone 26 (about 1580° C.).

Note.—Firebricks with a refractoriness of Cone 32 are deemed to be 'Special Refractory Materials,' for which no Specification has been prepared.

(2) *Surfaces and Texture.*—The material shall be evenly burnt throughout and the texture regular, containing no holes or flaws. All surfaces shall be reasonably true.

(3) *Contraction or Expansion.*—Two test pieces, when heated to and maintained for two hours at a temperature of 1410° C. shall not show more than the following linear contraction or expansion:—

No. 1 grade, 0·75 per cent.; No. 2 grade, 1·15 per cent.*

The test pieces shall be 2½–3 inches long and 1½–2 inches square, the ends being ground flat, and the contraction being measured by means of vernier calipers reading to 0·1 mm., a suitable mark being made on the test piece, so that the calipers may be placed in the same position before and after firing.

(4) *Variations from Specified Dimensions.*—In the case of ordinary bricks, 9 ins. by 4½ ins. by 3 ins. or 2½ ins. thick, there shall not be more than ± 1½ per cent. variation in length, nor more than + 1½ per cent. or − 2½ per cent. variation in width and ± 2 per cent, variation in thickness. In the case of special bricks, blocks or tiles, there shall not be more than ± 2 per cent. variation from any of the specified dimensions.

(5) *Crushing Strength.*—The cold material shall be capable of withstanding a crushing strain of not less than 1,800 lbs. per sq. in. when applied to whole bricks placed with their long side vertical between the jaws of the machine, giving a vertical thrust. Not less than three bricks must be used.

* A tolerance of 0·1 per cent. is allowed.

SPECIFICATION FOR SILICA BRICKS

(Institution of Gas Engineers, 1934.)

The material covered by this specification is divided into two classes:—

(*i*) That containing 92 per cent. and upwards of silica, and hereinafter called 'silica' material.

(*ii*) That containing from 78 to 92 per cent. of silica, and hereinafter called 'siliceous' material.

(1) *Refractoriness.*—Test pieces of the material shall show no sign of fusion when heated to the following temperatures:—
'Silica' material not less than Seger Cone 31 (about 1690° C.).
'Siliceous' material not less than Seger Cone 29 (about 1650° C.).
The test shall be carried out in an oxidising atmosphere, the temperature of the furnace being increased at the rate of about 50° C. per five minutes.

(2) *Surface and Texture.*—The material should be evenly burned throughout, and the texture regular, with no holes or flaws. All surfaces shall be reasonably true.

(3) *Contraction and Expansion.*—Two test pieces when heated in a gas muffle or electric furnace to a temperature of 1450° C., and maintained at that temperature for two hours, shall not show on cooling more than 0·5 per cent. linear contraction or expansion, with a tolerance of 0·1 per cent.

Siliceous material shall pass the same test, but at 1410° C.

The test pieces shall be the same size and shape as in Clause 3 in the specification for Fireclay Bricks (above).

(4) *Variations.*—In the case of all bricks, blocks and tiles there shall not be more than $\pm 1\frac{1}{4}$ per cent. variation in length, width or thickness except for dimensions of 3 ins. or less, when the permissible variation shall be $\pm \frac{1}{16}$ in.

Marking.—All bricks or blocks shall be distinctly marked to indicate the grade to which they belong.

Inspection and Testing.—The arrangements for inspection and for making tests are specified.

SPECIFICATIONS FOR REFRACTORY MORTAR OR CEMENT.

(Institution of Gas Engineers, 1911, but withdrawn in 1934.)

Cementing clay or fireclay mortar shall be machine-ground, and, at the discretion of the manufacturer, may contain a suitable percentage of fine grog; but in all cases the cement-clay shall be quite suitable for the purpose of binding together the bricks, blocks or tiles for which it is supplied, and shall be capable of withstanding the same test for refractoriness.

FIREBRICKS USED IN GASWORKS.

The firebricks used in gasworks should conform to the specifications of the Institution of Gas Engineers (p. 372). They are usually, but by no means invariably, made of the materials mentioned on p. 371.

BRICKS OR BLOCKS FOR FURNACE LININGS.*

The bricks or blocks used for lining furnaces should be selected according to the conditions to which they will be subjected. It is almost impossible to obtain a material which is wholly efficient in every respect, and some compromise is essential. Thus, great resistance to abrasion can only be obtained by increasing the amount of vitreous material and thereby lowering the refractoriness of the bricks. Answers to the following questions will usually provide most of the information required:—

(*a*) What is the highest temperature to which the brick will be exposed (excessive or only moderate), and will it be constant or fluctuating? (*b*) Will the material come into contact with any flame, and will the latter be of an 'oxidising' or 'reducing' character? (*c*) Is mechanical strength required? (*d*) Is heat to be conducted or retained? (*e*) Is the brick expected to withstand sudden and repeated changes in temperature? (*f*) Will the brick come into contact with fluid slags or glass, or with flue-dust, cement or other fluxes? (*g*) Must the brick resist blows, shocks and other unavoidable strains? (*h*) What is the nature of the fuel used and is it fed by hand or mechanically? (*i*) Is the electrical conductivity important?

To meet (*a*), refractoriness is of much importance, but, in most cases, other factors deserve even greater attention. For (*b*) and (*c*) the texture of the surface of the brick must be right or the brick will not be durable, no matter how great its refractoriness. If mechanical strength

* For a much fuller description of the properties required in bricks and blocks used for various furnaces, kilns, etc., see *Refractory Materials*, by A. B. Searle (Griffin & Co., Ltd., London. 5th Edn.).

is needed, the brick cannot be as refractory as otherwise, for great strength is dependent on the presence of a large amount of bond, which is necessarily less refractory than the particles to be bound together. For (*d*), it will be found that the conduction of heat depends chiefly on the density of the material if made of clay or silica and on its chemical composition if made of graphite, plumbago or other carbonaceous material. Graphite, fused alumina and zirconia are good heat conductors, whilst clay, silica and magnesia are good heat retainers. For (*e*) a lean, coarse and porous material should be used, whilst for (*f*) a fat, close material is required, i.e. exactly opposite to that for (*e*), and for (*g*) a hard-burned material which has not been heated more than once is preferable; broken bricks and other refractory articles should not be used as grog in this case, and the mass should not be either too lean or too fine-grained.

Consideration of the above points will show that there is some difficulty in deciding upon the correct description of the material for use in the ordinary type of industrial furnace. Where bricks of high refractoriness are required to withstand the temperature employed, heat must be retained and radiation reduced to a minimum, though most of these requirements are satisfied by using an open-grained, porous material. Still greater difficulty arises in dealing with furnaces in which fluxes are brought into contact with the firebricks, and in these the material must be close-grained, even if this is accompanied by the loss of some heat resistance.

Where great resistance to fluxes (flue-dust, lime and other bases) is required, the refractoriness of the brick is of secondary importance to the closeness of texture. Under such conditions, a porous, highly refractory brick will be far less durable than a dense brick of much lower fusing point. The fluxes act less rapidly on a comparatively smooth, dense surface than on a more porous one, so that the 'life' of the former brick will be longer than the latter, notwithstanding the fact that its actual heat resistance may be lower. For this reason, many fireclays which are of No. 2 quality as regards heat resistance are preferable for use in some furnaces and for flue work generally.

In some heating appliances, the draught and the atmosphere to which the refractory material is exposed have a far greater influence on the durability of the latter than is generally supposed. Unless properly managed, such furnaces may cause firebricks to be destroyed in a few weeks, whereas under proper conditions of draught they would last almost as many years. This is a matter which can only be properly investigated by a specialist in refractory materials.

RAMMED FURNACE LININGS.

Furnaces are sometimes lined with a stiff paste which is rammed into position. The composition of such rammed linings varies with the purpose for which the furnace is used; a well-known material consists of ganister to which a little lime has been added and the mixture then made into a very stiff paste with water.

Various kinds of sand, with or without sufficient clay or other binding agent to make the mass adhesive, are largely used for lining and repairing furnaces. (See also 'Refractory Cements,' p. 376.)

GAS RETORTS.

The chief forms of gas retorts are briefly described in Section XXXIII. They are usually made of a mixture of fireclay and 'grog,' the latter consisting of fireclay which has previously been burned and reduced to a very coarse powder. The grog should not consist of particles of uniform size, but should be graded so as to produce a material capable of withstanding sudden changes in temperature. The proportions of grog and clay must be adapted to the nature of the clay and the size and shape of the retort. The retorts require to be dried very slowly and carefully, and to be burned at a sufficiently high temperature to prevent them shrinking unduly when in use.

A useful test code for horizontal retorts and intermittent vertical chambers is contained in British Standard Specification No. 819—1938.

The following paragraphs contain the salient features of the Specification for Gas Retorts issued by the Institution of Gas Engineers:

Specification for Moulded Gas Retorts.*

(Institution of Gas Engineers, 1934.)

Refractoriness.—Test pieces of the material shall show no signs of fusion when heated to a temperature not less than Seger Cone 28 (about 1630° C.), the heat being increased at a rate of about 50° C. per five minutes in an oxidising atmosphere.

The material is to be chipped to the form and size of a Seger Cone, 1½ ins. high, with a triangular base of ½ in. sides, and tested against standard Seger Cones.

Surface and Texture.—All surfaces shall be reasonably true and free from flaws or winding, and after burning no 'washing' shall be done without the consent of the purchaser. The material shall be evenly burned throughout and of regular texture.

---

* Segmental retorts come within the specifications for silica, siliceous or fireclay bricks (p. 372).

Contraction or Expansion.—Test pieces, when heated to a temperature of 1410° C. and maintained at that temperature for two hours, shall not show, when cold, more than 0·75 per cent. linear contraction or expansion.* The test piece shall be 2½–3 ins. by 1½–2 ins. square, the ends being ground flat, and the contraction being measured by means of vernier calipers, reading to 0·1 mm., a suitable mark being made on the test piece, so that the calipers may be placed in the same position before and after firing.

Variation from Dimensions.—Moulded retorts shall be longitudinally straight, true to template in cross-section, of even bore throughout, uniform in thickness, and not warped or twisted. The permissible variation from the straight shall not exceed ⅜ in. in 7 ft. of length or more than ± ¼ in. in any cross-sectional dimension.

Inspection and Testing.—Arrangements for sampling, inspection and testing are specified.

CRUCIBLES.

Crucibles are made of (*i*) fireclay to which a suitable proportion of sand has been added, (*ii*) graphite or plumbago with a sufficient amount of clay or other binder, and (*iii*) various other materials of a special character such as magnesia, zirconia, etc. Crucibles must be sufficiently refractory to withstand the heat to which they are subjected, and whilst at the highest temperature at which they are used they must be sufficiently strong to be lifted out of the furnace, with their contents. Equally important is the resistance offered to the action of their contents, and as no crucible is equally suitable for all purposes careful selection is necessary.

A common test for the ability of a crucible to withstand corrosion is to half fill it with copper and to add a little borax. As the copper melts, part of it will be oxidised, the borax will absorb the oxide and will rapidly corrode the crucible, unless the latter is of excellent quality.

Another useful test consists in melting red lead and copper oxide in the crucible to be tested. Most crucibles will be perforated by the fused mixture after a few minutes' heating, but a satisfactory crucible will stand prolonged heating.

Silica is more readily corroded than clay or grog, but graphite is not affected at all. Hence, for highly corrosive contents, grog or graphite crucibles and not siliceous ones should be used.

Resistance to sudden changes in temperature is an essential property of a good crucible. How necessary is this resistance may be realised from the fact that a crucible may be withdrawn from a furnace at 1800°C., with its contents of 80 lbs. of steel at 1500°C. The steel is at once poured out and replaced by air at a temperature of only 20°C. Yet, notwithstanding the severity of such conditions, crucibles are regularly used for this purpose. On the other hand, many clay crucibles which have been used once and allowed to become cold cannot be used again, as they crack when reheated.

Further information will be found in *Refractory Materials*, by A. B. Searle (Griffin & Co., Ltd., London).

HEAT-INSULATING MATERIALS.†

Attention is being increasingly paid to the saving of fuel by retaining heat in structures from which it ordinarily escapes very rapidly. Thus the loss of steam and of heat in hot gases passing through pipes, cylinders, etc., may be greatly reduced by coating the pipes or cylinders with a highly porous material, such as kieselguhr, light magnesia, felt, cork, or various fibrous materials such as wood-wool, slag-wool and spun glass. The choice of a material must depend partly on the temperatures to which it will be raised when in use; for instance, felt and fibrous vegetable materials should not be raised to more than 220° F., but kieselguhr can be used at a bright red heat.

The prevention of the transference of heat through partitions and furnace-walls is best effected by constructing them of highly porous materials because air is a very poor conductor of heat though its insulating power is much lower at temperatures above 2200° F. With most materials, the larger the number of separate pores per cubic foot, the better will be the insulating power. Where the temperature is relatively low (*e.g.* below 500° F.) the insulating medium may consist of thin slabs or 'containers,' with porous or fibrous material between and blankets made of glass silk and particularly efficient. Highly porous slabs or bricks may also be used.

For higher temperatures it is necessary to use highly porous bricks or blocks made chiefly of kieselguhr or of a highly plastic fireclay or ball clay mixed with a very large proportion of sawdust; the latter burns away during manufacture, leaving a very highly porous mass of great resistance to heat. Such 'insulating bricks' are sold by several firms and are being increasingly used in the construction of kilns and furnaces, in which they effect a notable saving in fuel.

The most effective insulation of kilns and furnaces is in the form of a 'wall' of insulating bricks between the firebrick lining and the exterior. Such bricks should not be placed where their temperature will exceed 2000° F., or they will not long remain effective. They are most efficient at temperatures below 1800° F. They must be protected from damp, which would fill the pores, and so are not suitable for exterior work which is exposed to the weather.

* A tolerance of 0·1 per cent. is allowed.

† See British Standard Specification No. 874—1939 for definitions.

FIRE-RESISTING OR REFRACTORY CEMENTS.

These cements—usually sold under a fancy name—are used for patching furnaces, and other appliances subjected to heat. The precise nature of most of these cements is regarded as a trade secret, but many of them are composed of fireclay, ground firebricks, and Portland cement or water-glass. These materials, when properly selected and mixed in the proper proportions, form a paste which adheres readily to cold brickwork, and when the latter is heated the nature of the cement is changed and a strong heat-resisting material is produced.

The commonest cements for use with various bricks consist of a slip made from the same material as that of the bricks. Thus, a mixture of fireclay and brick-dust (grog) is used with fireclay bricks, whilst a mixture of sand and sodium silicate is often used for bonding silica bricks.

Ground ganister or a mixture of silica rock and fireclay is largely used for lining furnaces.

Special cements are used in certain cases; fused alumina and carborundum cements are sometimes used in retorts and muffles, a small proportion of clay being used as a bonding agent. Powdered zirconia, ground so as to pass through a 200-mesh sieve, is very effective at exceptionally high temperatures, whilst other special mixtures may also be employed where a mixture of unusual composition is needed.

Other refractory cements include:

(*a*) A mixture of fireclay and plumbago made into a paste with water; it may also be used to coat glass to protect it from flame.

(*b*) Equal parts of flour and lime and half a part of fireclay are made into a paste with water; white of egg is sometimes added. This is a fire-resistant cement and not highly refractory. It is sometimes used for patching retorts.

For patching *crucibles and melting pots*:

(*c*) Sift brickdust and mix with equal quantity of red lead; rub together with boiled linseed-oil, which has been mixed with sand to a stiffness of cement.

(*d*) Put freshly slaked lime with concentrated solution of borax, apply with a stiff brush and allow to dry. Upon heating, a fused glaze is obtained.

(*e*) Litharge, 6 parts; fresh burnt lime, 4 parts; china clay, 2 parts; and mix with cold nseed-oil. This is only fire-resisting.

(*f*) Alumina, 1 part; sand, 4 parts; slaked lime, 1 part; borax, ½ part; water to make a stiff paste.

FIRE-RESISTING MATERIALS AND FIRE-PROOFING.

Some substances may be raised to almost any temperature without being melted; they are known as *refractory materials*, and include firebricks of all kinds, crucibles, ladles, retorts, and other appliances as well as the substances from which these are made. Refractory materials and articles differ greatly in their resistance to heat, but all can safely be heated to a temperature of 1500° C., and many of them to 1800° C., or even higher. At about 2000° C. all refractory articles tend to collapse (see p. 371).

Many substances are not sufficiently refractory to stand such intense heating for long periods, but they can endure short periods of intense heat without much damage. Such substances are termed *fire-resistant* and sometimes *fireproof*, though the latter term implies a greater resistance than the former.

The most fire-resistant materials are bricks, tiles, and other articles made of burned clay, stones of various kinds and, to a lesser degree, iron, steel, plaster, and concrete.

Girders, stanchions, and other structures of iron or steel are highly resistant to fire, but they expand so much when heated that they tend to bring about the disruption of structures in which they are used. They must, therefore, be protected by covering them with some material of low thermal conductivity such as blocks or bricks of fireclay, or even with plaster or concrete (see figs. 7–10, p. 306).

Concrete is only moderately resistant to fire. If the aggregate consists of burned clay, trap rock, or blast-furnace clay, the concrete will be more resistant to fire than one with a limestone or silica aggregate. The fire resistance of concrete structures can be increased by surrounding or facing them with expanded metal, or equivalent netting and embedding this in concrete.

Natural Stone varies greatly in its resistance to fire. Some sandstones and limestones crumble readily when heated and then cooled suddenly, as with water.

Artificial stone resembles concrete in its resistance to fire.

Sheet iron is fairly resistant to fire, if free to expand, but under normal conditions it tends to 'buckle,' and may then be useless.

Asbestos, in various forms, has a high fire-resistance, though it is not regarded as a refractory material.

Wood, **when uncovered, is easily set alight, but if coated with a fireproof paint, or with waterglass, followed by a solution of calcium chloride and dried, its resistance is considerably increased. A solution of alum or one of sodium tungstate has a similar effect.**

Painted surfaces **may have their fire resistance increased by the use of suitable paints, but no coating of equivalent thickness to paint can render wood wholly inert to fire. Even the famous ' American Government Whitewash ' will only retard the effect of fire for a short time.**

Definitions of Fire-Resistance of Materials and Structures, and methods of Testing, see British Standard Specification No. 476—1932.

Fire-resisting doors **are classified as shown in Section XXXIV, Part IV.**

Fire-resisting buildings**—see Section XXXIV, Part IV.**

Fire-resisting cements **are described on p. 376.**

Highly Porous Fireclay Bricks.

Highly porous fireclay bricks are used :

(i) as Insulating Bricks (p. 375).

(ii) as permeable bricks through which the products of combustion pass to an annulus or ring-flue and thence to the main flue and chimney. By this means the waste gases act as a heat-insulating medium and much heat is saved. Such bricks are usually known as *hot face insulating bricks*.

SECTION XII

REINFORCED CONCRETE CONSTRUCTION

(pp. 381-418.)

(Revised by J. D. W. Ball, A.M.I.C.E.)

SECTION XII

REINFORCED CONCRETE CONSTRUCTION.

(Revised by J. D. W. Ball, A.M.I.C.E.)

LONDON COUNTY COUNCIL.

By-laws for the construction and conversion of buildings, made by the London County Council in pursuance of the London Building Act (Amendment) Act, 1935.

(Extracts reproduced by permission of the London County Council.)

. . . .

PART I—LOADING.

2. Every part of a building shall be so constructed as to be capable of safely sustaining and transmitting all the dead and superimposed loading thereon without exceeding the appropriate limitations of permissible stresses provided in these by-laws.

3. For the purpose of calculating dead loading the weights of materials shall be taken to be as set forth in the British Standard Specification (Schedule of Unit Weights of Building Materials) No. 648—1935 unless otherwise agreed with the district surveyor.

4. (a)—*Schedule of loading*—The minimum superimposed load on each floor and on the roof shall be estimated as equivalent to the following dead loads :—

Class No.	Type of Building or Floor.	Slabs : lb. per sq. ft. of Floor Area.	Beams : lb. per sq. ft. of Floor Area.
1	Rooms used for residential purposes ; and corridors, stairs and landings within the curtilage of a flat or residence.	50	40
2	Offices, floors above entrance floors . . .	80	50
3	Offices, entrance floor and floors below entrance floor ; retail shops ; and garages for private cars of not more than two and one quarter tons net weight.	80	80
4	Corridors, stairs and landings not provided for in class 1.	Loading to be provided for to be ascertained to the satisfaction of the district surveyor, but not less than :— 100	100
5	Workshops and factories ; and garages for motor vehicles other than private cars of not more than two and one-quarter tons net weight.	Loading to be provided for to be ascertained to the satisfaction of the district surveyor, but not less than :— 150	120
6	Warehouses, book stores, stationery stores and the like.	Loading to be provided for to be ascertained to the satisfaction of the district surveyor, but not less than :— 200	200
7	Any purpose not herein specified . . .	Loading to be provided for to be ascertained to the satisfaction of the district surveyor.	

Beams and ribs not spaced further apart than two feet six inches between centres shall be designed for slab loads.

Class No.	Roofs.	Slabs: lb. per sq. ft. of Covered Area.	Beams: lb. per sq. ft. of Covered Area.
8	Flat-roofs and roofs inclined at an angle with the horizontal of not more than twenty degrees.	50	30

Subject to the provision of paragraph (*d*) of this by-law, all columns, piers, walls, foundations, and other supports to beams shall be calculated for the superimposed loads tabulated above in this paragraph for beams.

On roofs inclined at an angle with the horizontal of more than twenty degrees a minimum superimposed load (deemed to include the wind load) of fifteen pounds per square foot of surface shall be assumed acting normal to the surface inwards on the windward side, and ten pounds per square foot of surface acting separately and not simultaneously outwards on the leeward side. This requirement shall apply only in the design of the roof construction, and a vertical superimposed load of ten pounds per square foot of covered area shall be substituted for it in estimating the vertical superimposed roof load upon all other parts of the construction.

(*b*) In all cases of floors where the positions of partitions are not definitely located in the design, a uniformly distributed load sufficient to allow for them shall be added to the dead floor load. For all floors of rooms used for offices the minimum total allowance for internal partitions shall be at the rate of twenty pounds per square foot of floor area.

(*c*) Slabs and beams shall be capable of carrying in accordance with these by-laws the following superimposed loads in any position on an otherwise unloaded floor:–

Class of Floor.	Minimum Superimposed Load.	
	Slabs.	Beams.
Floors tabulated under class 1.	¼ ton uniformly distributed per foot width	1 ton uniformly distributed.
All floors tabulated under classes 2 to 6 except garage floors tabulated under class 5.	¾ ton uniformly distributed per foot width	2 tons uniformly distributed.
Garage floors tabulated under class 5.	1·5 × maximum possible combination of wheel loads, but each wheel load not less than 1 ton.	

Provided that beams and ribs spaced not further apart than two feet six inches between centres shall be calculated for the slab loads tabulated in this paragraph; provided also that non-load bearing beams such as beams solely employed as ties to columns shall be exempt from any load calculation under this paragraph.

The reactions due to the superimposed loads tabulated in this paragraph need not be allowed for in calculating the loads on columns, piers, walls or foundations.

(*d*) For the purpose of calculating the total load to be carried on columns, piers, walls and foundations in buildings of more than two storeys in height, and in which the loads and stresses are transmitted through each storey to the foundations:

(i) wholly by a skeleton framework of structural steel; *or*

(ii) partly by a skeleton framework of structural steel and partly by a party wall or party walls; *or*

(iii) wholly by a skeleton framework of reinforced concrete; *or*

(iv) partly by a skeleton framework of reinforced concrete and partly by a party wall or party walls:

the superimposed loads for the roof and topmost storey shall be calculated in full in accordance with the schedule of loading in paragraph (a) of this by-law, but for the lower storeys a reduction of the superimposed loads may be allowed in accordance with the following table :—

Next storey below topmost storey .	10 per cent. reduction of its superimposed load.
Next storey below	20 " " " "
Next storey below	30 " " " "
Next storey below	40 " " " "
Each succeeding storey below . .	50 " " " "

The above reduction may be made by estimating the proportion of floor area carried by each foundation, column, pier and wall. No such reductions shall be allowed on any floor tabulated in this by-law for a superimposed beam loading exceeding one hundred pounds per square foot.

(e) In any case where the superimposed load on any floor or roof is to exceed that hereinbefore specified for the floor or roof, such greater load shall be provided for in accordance with by-law 2.

In the case of any floor intended to be used for a purpose for which a superimposed load is not specified herein, the superimposed load to be carried on that floor shall be provided for in accordance with by-law 2.

(f) In cases where a superimposed load may move, proper provision in accordance with these by-laws to the satisfaction of the district surveyor shall be made for all effects of such movement, including vibration, impact, acceleration and deceleration.

5. In every storey the floor of which is constructed for superimposed loading exceeding one hundred pounds per square foot there shall be exhibited by the owner permanently in a conspicuous position in every room a notice in the following form stating the superimposed loading for which the floor has been constructed.

'LONDON BUILDING ACT (AMENDMENT) ACT, 1935.
NOTICE.'

The floor of this room is constructed for superimposed loading to an intensity not exceeding pounds on any square foot of its surface.'

6. A building shall be so constructed as to resist a wind pressure in each horizontal direction of not less than fifteen pounds per square foot on the upper two-thirds of its surface up to the general roof level or ridge which is or which may be exposed to wind pressure and an additional pressure in each horizontal direction of not less than ten pounds per square foot upon all projections above the general roof level or ridge. If the height of a building be less than twice the width (measured in a direction parallel with that of the wind pressure) of the base upon which the building depends for its resistance to the overturning action of the wind pressure in that direction and provided the district surveyor be satisfied that all loading due to wind pressure will be transmitted safely to the earth, the above wind pressure need not be calculated for the building as a whole; but provision shall be made in accordance with by-law 2 for all the local loading due to wind pressure.

7. Where loading is transmitted through plain concrete, brickwork or other material of similar consistency, the angle of dispersion of such loading through such material shall be taken as not more than forty-five degrees with the direction of such loading.

8. A building or any part thereof shall not be subjected to loading beyond its proper load-bearing capacity at any time when such loading is applied. This provision shall not apply to any loading which may be required by the district surveyor for the purpose of testing.

PART II.—MATERIALS OF CONSTRUCTION.

9. The following provisions shall apply to the aggregates for reinforced concrete :—

Aggregate shall be sand and gravel. or crushed natural stone. It shall be hard strong and durable and shall be reasonably clean and free from clay, organic matter, coal and coal residues (including clinker, ashes, coke-breeze, pan-breeze, slag and other similar material), copper slag, forge breeze, dross (and other similar material), soluble sulphates (including gypsum and other similar material), porous material and other materials liable to reduce the strength or durability of the concrete, or to attack the steel reinforcement.

Fine aggregate shall be of such a size that it will pass through a $\frac{3}{16}$-inch mesh. Not more than five per cent. by weight shall pass a No. 100 mesh.

Coarse aggregate shall be of such a size that it will be retained on a $\frac{3}{16}$-inch mesh and will pass a mesh of a size one-quarter of an inch less than the minimum lateral distance between the reinforcing bars.

Aggregate shall be so graded between the limits as to make a dense concrete of the specified proportions and consistence that will work readily into position without segregation and without the use of an excessive water content.

10. Aggregate for plain concrete shall consist of such materials as are specified in by-law 9 or of hard well-burned brick, hard well-burned tile, pumice or other material which the district surveyor may approve as of like suitability and shall be so graded and contain sand in such proportion as to produce a dense concrete.

11. Sand shall be clean and shall be composed of hard silicious grains reasonably free from clay or any animal, vegetable or bituminous matter. The grains shall be of such a size as to pass through a $\frac{5}{16}$-inch mesh.

12. Cement shall be Portland cement, Portland blast furnace cement or high alumina cement, but no two of such cements shall be used in combination.

Portland cement shall comply with the British Standard Specification for Portland Cement numbered 12—1931.

Portland blast-furnace cement shall comply with the British Standard Specification for Portland Blast-furnace Cement numbered 146—1932.

High alumina cement shall consist of aluminous and calcareous materials which have been fused to a molten state and ground to such a degree of fineness that the cement will not leave a residue of more than 12 per cent. by weight on a No. 170 mesh and not more than 1 per cent. on a No. 72 mesh. The cement shall contain not less than 35 per cent. by weight of alumina and the ratio of percentage by weight of alumina to that of lime shall not be less than 0·9. When gauged with 22 per cent. by weight of water it shall not begin to set before the expiration of two hours but shall begin to set within 6 hours of gauging and the final setting shall take place within 2 hours of the initial setting. The strength of high alumina cement shall be such that when a mortar is composed of one part by weight of high alumina cement to three parts by weight of white Leighton Buzzard sand graded to pass a No. 18 mesh and stop on a No. 25 mesh, and the whole is gauged with a weight of water equal to 8 per cent. of the dry materials, such mortar shall have a tensile strength of not less than 475 lb. per square inch within 24 hours after gauging and within seven days its tensile strength shall have increased and shall be not less than 550 lb. per square inch.

Wherever cement is used it shall not be moved or disturbed after one hour from the time it has come into contact with water until it has set hard.

13. Water used shall be clean and free from deleterious matter.

14. Concrete shall consist of aggregate mixed with cement. The proportions of fine aggregate to coarse aggregate to cement shall be as set out in Tables I and II or in any intermediate proportions in which the volume of coarse aggregate is twice that of the fine aggregate. Provided that in any particular case where specially authorised by the district surveyor the proportion of coarse aggregate may be varied within the limits of one-and-a-half and two-and-a-half times the fine aggregate. If in any particular case the district surveyor so requires, the proportion of coarse aggregate shall be varied within the aforesaid limits. Where the proportion of coarse aggregate to fine aggregate is so varied the requirements of this by-law shall be based on the ratio of the sum of the volumes of fine and coarse aggregates, each measured separately, to the quantity of cement and shall be obtained by proportion to the two nearest specified mixes. If the district surveyor so requires, the builder shall make tests in accordance with Schedules I and III of this Part of these by-laws as may be necessary to prove the quality of the concrete. The grades of concrete designated I, II and III in column I of Table I and mixed in the proportions set out in Column 2 of such Table against each such designation shall be deemed to be " ordinary concrete " and shall, within the period of twenty-eight days, possess the respective minimum resistance to crushing set out in Column 3 of such table against each such designation. Where intermediate proportions of cement to aggregate are used, as heretofore provided, the minimum crushing strength shall be in proportion to the prescribed minima crushing strengths of the two nearest specified mixes.

TABLE I.

(1)	(2)		(3)
Designation of Concrete.	Cubic Feet Aggregate per 112 lbs. of Cement.		Minimum Resistance to Crushing in lbs. per square inch within 28 Days after Mixing.
	Fine Aggregate.	Coarse Aggregate.	
I	1¼	2½	2,925
II	1⅞	3¾	2,550
III	2½	5	2,250
IV	7½		1,480
V	10		1,100
VI	12½		740
VII	15		370

The grades of concrete designated IA, IIA and IIIA in Table II shall be deemed to be ' Quality A concrete ' and when such concrete is to be used, if the district surveyor so requires, preliminary tests shall be made in accordance with Schedule II of this Part of these by-laws before the commencement of the work and subsequently whenever any change is to be made in the materials or in the proportions of the materials to be used. Works tests shall be made in accordance with Schedules I and III of this Part of these by-laws as and when the district surveyor shall require to prove the quality of the concrete. A record of such tests identifying them with the part of the work executed shall be kept by the builder on the works.

The grades of concrete designated IA, IIA and IIIA in column 1 of Table II and mixed in the proportions set out in column 2 of such Table against such designation shall, within the period of twenty-eight days, possess the respective minimum resistance to crushing set out in column 3 of such Table against each such designation. Provided that such concrete may possess a lesser strength but (not less than that required for ordinary concrete in Table I) subject to the appropriate maximum permissible stresses in such concrete being proportionately less than the maximum stresses specified in by-laws 99 and 101 of these by-laws.

TABLE II.

1	2		3	
Designation of Concrete.	Cubic Feet of Aggregate per 112 lbs. of Cement.		Minimum Resistance to Crushing in lbs. per square inch within 28 Days after Mixing.	
	Fine Aggregate.	Coarse Aggregate.	Preliminary Test.	Works Test.
IA	$1\frac{1}{4}$	$2\frac{1}{2}$	5,625	3,750
IIA	$1\frac{7}{8}$	$3\frac{3}{4}$	4,950	3,300
IIIA	$2\frac{1}{2}$	5	4,275	2,850

Concrete containing more than 10 cubic feet of aggregate per 112 lbs. of cement, or having resistance to crushing less than 1,110 lbs. per square inch, shall not be used in the construction of a building or any part thereof.

Concrete containing more than 15 cubic feet of aggregate per 112 lbs. of cement, or having resistance to crushing less than 370 lbs. per square inch shall not be used for any purpose in connection with the construction of a building or chimney shaft.

The quantity of water for making reinforced concrete shall be sufficient but not more than sufficient to ensure that the concrete shall surround, cover, embed and grip adequately all the reinforcement.

The quantity of water for making Portland cement concrete and Portland blast furnace cement concrete shall be sufficient but not more than sufficient to bring the entire mixture to a uniform colour and to ensure that the concrete shall be suitable for its intended purpose.

The quantity of water for making high alumina cement concrete shall be sufficient but not more than sufficient to produce a sound concrete and the concrete shall be kept wet for 24 hours after gauging.

Material shall be so mixed as to secure uniformity throughout the mixture.

The concrete shall be deposited without segregation of the materials and shall be properly consolidated by punning, rodding, vibrating or other means after depositing and before the cement begins to set.

After such consolidation, the concrete shall remain undisturbed and shall be protected from frost, heat, running water, evaporation, vibration or any other cause which may reduce its strength or tend to form voids in it.

During mixing, depositing and setting, the temperature of concrete shall not fall below 40 degrees Fahrenheit.

Where formwork is employed it shall be sufficiently rigid to retain the concrete in position and shape during depositing, punning and consolidating.

. . . .

25. The district surveyor may for the purpose of due supervision by notice require the builder or other person causing or directing the work, to furnish him with proof by means of adequate tests or otherwise that the materials used or to be used conform to the requirements of these by-laws, and no material shall be so used unless such material conforms to such requirements.

SCHEDULE I.

Standard method of test for consistence of concrete.

The test is to be used both in the laboratory and during the progress of the work for determining the consistence of concrete.

The test specimen shall be formed in a mould in the form of the frustrum of a cone with internal dimensions as follows:—Bottom diameter, 8 inches; top diameter, 4 inches, and height, 12 inches. The bottom and the top shall be open, parallel to each other, and at right angles to the axis of the cone. The mould shall be provided with suitable foot pieces and handles. The internal surface shall be smooth.

Care shall be taken to ensure that a representative sample is taken.

The internal surface of the mould shall be thoroughly clean, dry and free from set cement before commencing the test.

The mould shall be placed on a smooth, flat, non-absorbent surface, and the operator shall hold the mould firmly in place, while it is being filled, by standing on the foot pieces. The mould shall be filled to about one-fourth of its height with the concrete which shall then be puddled, using 25 strokes of a ⅝ inch rod, 2 feet long, bullet pointed at the lower end. The filling shall be completed in successive layers similar to the first and the top struck off so that the mould is exactly filled. The mould shall then be removed by raising vertically, immediately after filling. The moulded concrete shall then be allowed to subside and the height of the specimen measured after coming to rest.

The consistence shall be recorded in terms of inches of subsidence of the specimen during the test, which shall be known as the slump.

SCHEDULE II.

Standard method of making preliminary cube tests of concrete.

The method described applies to compression tests of concrete made in a laboratory where accurate control of materials and test conditions is possible.

Materials and proportioning.—The materials and the proportions used in making the preliminary tests shall be similar in all respects to those to be employed in the work. The water content shall be as nearly as practicable equal to that to be used in the work, but shall be not less than the sum of 30 per cent. by weight of the cement and 5 per cent. by weight of the aggregate unless specially authorised by the district surveyor. For porous aggregates additional water shall be used to allow for the amount absorbed by the aggregates.

Materials shall be brought to room temperature (58° to 64° F.) before beginning the tests. The cement on arrival at the laboratory shall be mixed dry either by hand or in a suitable mixer in such a manner as to ensure as uniform a material as possible, care being taken to avoid intrusion of foreign matter. The cement shall then be stored in air-tight containers until required. Aggregates shall be in a dry condition when used in concrete tests.

The quantities of cement, aggregate and water for each batch shall be determined by weight to an accuracy of 1 part in 1,000.

Mixing concrete.—The concrete shall be mixed by hand or in a small batch mixer in such a manner as to avoid loss of water. The cement and fine aggregate shall first be mixed dry until the mixture is uniform in colour. The coarse aggregate shall then be added and mixed with the cement and sand. The water shall then be added and the whole mixed thoroughly for a period of not less than two minutes and until the resulting concrete is uniform in appearance.

Consistence.—The consistence of each batch of concrete shall be measured, immediately after mixing, by the slump test made in accordance with the method of test for consistence of concrete given in schedule I. Provided that care is taken to ensure that no water is lost the material used for the slump tests may be re-mixed with the remainder of the mix before making the test specimen.

Size of test cubes.—Compression tests of concrete shall be made on 6-inch cubes. The mould shall be of metal with inner faces accurately machined in order that the opposite sides of the specimen shall be plane and parallel. Each mould shall be provided with a metal base, having a smooth machined surface. The interior surfaces of the mould and base shall be slightly oiled before concrete is placed in the mould.

Compacting.—Concrete test cubes shall be moulded by placing the fresh concrete in the mould in three layers, each layer being rammed with a steel bar 15 inches long and having a ramming face of 1 inch square and a weight of 4 lbs. For mixes of 1½ inches slump or less, 35 strokes of the bar shall be given for each layer; for mixes of wetter consistence the number may be reduced to 25 strokes per layer.

Curing.—All test cubes shall be placed in moist air of at least 90 per cent. relative humidity and at a temperature of 58° F. to 64° F. for 24 hours (± ½ hour) commencing immediately after moulding is completed. After 24 hours the test cubes shall be marked, removed from the moulds, and placed in water at a temperature of 58° to 64° F. until required for test.

Method of testing.—All compression tests on concrete cubes shall be made between smooth plane steel plates, without end packing, the rate of loading being kept approximately at 2,000 lbs.

per square inch per minute. One compression plate of the machine shall be provided with a ball seating in the form of a portion of a sphere, the centre of which falls at the central point of the face of the plate.

All test cubes shall be placed in the machine in such a manner that the load shall be applied to the sides of the cubes as cast.

Distribution of specimens and standard of acceptance.—For each age at which tests are required, three cubes shall be made and each of these shall be taken from a different batch of concrete.

The acceptance limits are a difference of 15 per cent. of the average strength between the maximum and minimum recorded strengths of the three cubes. In cases where this is exceeded repeat tests shall be made, excepting where the minimum strength test result does not fall below the strength specified.

SCHEDULE III.

Standard method of making works cube tests of concrete.

The method described applies to compression tests of concrete sampled during the progress of the work.

Size of test cubes and moulds.—The test specimens shall be 6-inch cubes. The moulds shall be of metal, with inner faces accurately machined in order that opposite sides of the specimen shall be plane and parallel. Each mould shall be provided with a metal base plate, having a smooth machined surface. The interior surfaces of the mould and base shall be slightly oiled before concrete is placed in the mould.

Sampling.—Wherever practicable concrete for the test cubes shall be taken immediately after it has been deposited in the work. Where this is impracticable samples shall be taken as the concrete is being delivered at the point of deposit, care being taken to obtain a representative sample. All the concrete for each sample shall be taken from one place. A sufficient number of samples, each large enough to make one test cube, shall be taken at different points so that the test cubes made from them will be representative of the concrete placed in that portion of the structure selected for tests. The location from which each sample is taken shall be noted clearly for future reference.

In securing samples the concrete shall be taken from the mass by a shovel or similar implement, and placed in a large clean pail or other receptacle, for transporting to the place of moulding. Care shall be taken to see that each test cube represents the total mixture of concrete from a given place. Different samples shall not be mixed together, but each sample shall make one cube. The receptacle containing the concrete shall be taken to the place where the cube is to be moulded as quickly as possible and the concrete shall be slightly re-mixed before placing in the mould.

Consistence.—The consistency of each sample of concrete shall be measured, immediately after re-mixing, by the slump test made in accordance with the method of test for consistence of concrete given in schedule I.

Providing that care is taken to ensure that no water is lost the material used for the slump tests may be re-mixed with the remainder of the mix before making the test cube.

Compacting.—Concrete test cubes shall be moulded by placing the fresh concrete in the mould in three layers, each layer being rammed with a steel bar 15 inches long and having a ramming face of 1 inch square and a weight of 4 lbs. For mixes of 1½ inches slump or less, 35 strokes of the bar shall be given for each layer; for mixes of wetter consistence the number may be reduced to 25 strokes per layer.

Curing.—The test cubes shall be stored at the site of construction at a place free from vibration, under damp sacks for 24 hours ($\pm$ ½ hour), after which time they shall be removed from their moulds, marked and buried in damp sand until the time for sending to the testing laboratory. They shall then be well packed in damp sand or other suitable damp material and sent to the testing laboratory, where they shall be similarly stored until the date of test. Test cubes shall be kept on the site for as long as practicable and for at least three-fourths of the period before test, except for tests at ages less than seven days.

The temperature of the place of storage on the site shall not be allowed to fall below 40° F., nor shall the cubes themselves be artificially heated.

Record of temperatures.—A record of the maximum and minimum day and night temperatures at the place of storage of the cubes shall be kept during the period the cubes remain on the site.

Method of testing.—All compression tests on concrete cubes shall be made between smooth plane steel plates without end packing, the rate of loading being kept approximately at 2,000 lbs per square inch per minute. One compression plate of the machine shall be provided with a ball seating in the form of a portion of a sphere, the centre of which falls at the central point of the face of the plate.

All test cubes shall be placed in the machine in such a manner that the load shall be applied to the sides of the cubes as cast.

Part IV.—Walls and Piers.

Section 1—General Requirements.

39. Every building shall be enclosed with walls. Provided that openings may be made in such walls subject to the following conditions—(1) That the total elevational area of openings in any such wall above the soffit of the first floor do not exceed one-half the elevational area of such wall measured from the soffit of the first floor of the building to the roof; (2) that the total elevational area of openings in any storey-height of such wall above the soffit of the first floor of the building do not exceed two-thirds of the total area of such wall within such storey-height; (3) that the total width of openings at any level above the soffit of the first floor do not exceed three-quarters of the total length of the wall at that level. For the purposes of this by-law, the expression 'walls' shall be deemed to include piers and for the purpose of this by-law and of by-laws 43 and 51 (*g*) any glazing or glass in the thickness of such walls shall be deemed to be an opening.

. . . .

43. . . . No reinforced concrete external wall nor reinforced concrete part or panel of an external wall shall be of less thickness in any part than four inches exclusive of plastering, rendering, rough cast or other applied covering. No reinforced concrete party wall shall be of less thickness in any part than eight inches.

. . . .

Part VI—The use of Reinforced Concrete.

92. Concrete shall comply with these by-laws and shall not be relied upon to support, collect, or transmit loading otherwise than as provided in these by-laws.

Reinforced concrete shall be, as regards composition and quality, not inferior to that designated III in by-law 14.

93. Construction which will support or transmit loading supported, collected or transmitted by reinforced concrete shall comply with the requirements of these by-laws.

94. Loading supported, collected or transmitted by reinforced concrete shall be distributed upon the earth by concrete which shall:—

(*a*) comply with the requirements of by-law 32 in the same manner as is required for concrete which is to support walls or piers;

(*b*) if plain, be of composition and quality not inferior to that designated V in by-law 14. The angle of dispersion through such plain concrete shall be taken as not less than forty-five degrees with the horizontal; and such plain concrete shall not be relied upon to resist shearing or tensile stresses otherwise than in accordance with this by-law; and

(*c*) if reinforced, comply with the requirements of these by-laws.

The pressure upon such distributing concrete shall be calculated, and such concrete, if plain, shall comply in all respects with the requirements of by-law 35 in the same manner as is required for plain concrete which is to support walls or piers.

95. Where metal is used in combination with concrete which supports, collects or transmits loading in a building or part thereof, or which distributes such loading upon the earth, proper protection shall be provided to prevent such damage to the metal as would, in the opinion of the district surveyor, affect adversely the stability of such building or of any part thereof.

96. Reinforcement shall be of structural steel complying with these by-laws so combined with the concrete that the reinforcement will be sufficient to provide, in accordance with these by-laws, all necessary:—

(*a*) resistance to tension;

(*b*) assistance for the concrete to resist shearing actions; and

(*c*) assistance for the concrete to resist compression.

Reinforcement shall, immediately before being placed in the concrete, be free from loose mill scale, loose rust, oil or other matter which might affect adversely the proper combination of such reinforcement with such concrete.

97. Reinforcement shall have concrete cover, and the thickness of such cover (exclusive of plaster or other decorative finish) shall be:—

(*a*) for each end of a reinforcement rod or bar which is anchored otherwise than by means of a hook, not less than 2 inches, nor less than twice the diameter of such rod or bar beyond such anchorage;

(*b*) for a longitudinal reinforcement rod or bar in a column, not less than 1½ inches, nor less than the diameter of such rod or bar;

(*c*) for a longitudinal reinforcement rod or bar in a beam, not less than 1 inch, nor less than the diameter of such rod or bar;

(*d*) for tensile, compressive, shear or other reinforcement in a slab, not less than half an inch, nor less than the diameter of such reinforcement;

(*e*) for any other reinforcement (not being a binding), not less than half an inch, nor less than the diameter of such reinforcement.

98. The following by-laws 99 to 112 inclusive shall relate only to the use of reinforced concrete in a building wherein the loads and stresses are transmitted through each storey to the foundations wholly by a skeleton framework of reinforced concrete or partly by a skeleton framework of reinforced concrete and partly by a party wall or party walls.

99. The compressive, shearing and bond stresses in reinforced concrete shall be calculated, and, subject to the requirements of by-law 101, such stresses shall not exceed those shown as appropriate for each designation of concrete in Tables IX and X following:—

TABLE IX—*Ordinary Concrete.*

Designation of Concrete.	Modular Ratio.	Permissible Concrete Stresses. Lbs. per square inch.			
		Compression.		Shear.	Bond.
		Due to Bending.	Direct.		
I	15	975	780	98	123
II	15	850	680	85	110
III	15	750	600	75	100

Where other proportions of fine to coarse aggregate are used the permissible concrete stresses shall be based on the ratio of the sum of the volumes of the fine and coarse aggregates, each measured separately to the quantity of cement, and shall be obtained by proportion from the two nearest designations.

TABLE X—*Quality A Concrete.*

Designation of Concrete.	Modular Ratio.	Permissible Concrete Stresses. Lbs. per square inch.			
		Compression.		Shear.	Bond.
		Due to Bending.	Direct.		
IA	15	1,250	1,000	125	150
IIA	15	1,100	880	110	135
IIIA	15	950	760	95	120

Where other proportions of fine to coarse aggregate are used the permissible concrete stresses shall be based on the ratio of the sum of the volumes of the fine and coarse aggregates, each measured separately, to the quantity of cement, and shall be obtained by proportion from the two nearest designations.

Provided that where reinforcement in the form of plain bars is used to resist tensile stresses induced by bending action the calculated bond stress due to a variation in tensile stress shall not exceed twice that shown as appropriate for each designation of concrete in tables IX and X above in this by-law.

Provided also that the 'punching shear' stress in a footing (or similar construction) of reinforced concrete which complies with the requirements of these by-laws shall be not more than twice the permissible shearing stress shown as appropriate for each designation of concrete in tables IX and X above in this by-law.

100. The tensile and compressive stresses in steel reinforcement of reinforced concrete shall be calculated, and, subject to the requirements of by-law 101, such stresses shall not exceed those shown as appropriate for each designation of stress in Table XI following.

TABLE XI.

Designation of Stress in Steel Reinforcement.	Maximum Permissible Stress, in Pounds per Square Inch.
Tension in helical reinforcement in a column . . .	13,500
Tension other than in helical reinforcement in a column .	18,000
Longitudinal compression in a beam where the compressive resistance of the concrete is not taken into account.	18,000
Longitudinal compression, direct or due to bending where the compressive resistance of the concrete is taken into account.	The calculated compressive stress in the surrounding concrete multiplied by the modular ratio.

101. The maximum permissible stresses in a reinforced concrete column or part thereof having a ratio of effective column length to least radius of gyration not exceeding 50 shall be as specified in by-laws 99 and 100.

The maximum permissible stresses in a reinforced concrete column or part thereof having a ratio of effective column length to least radius of gyration between 50 and 120 as shown in Table XII following shall not exceed those which result from the multiplication of the appropriate maximum permissible stresses specified in by-laws 99 and 100 by the coefficient shown as appropriate for each ratio of effective column length to least radius of gyration in Table XII following :—

TABLE XII.

Ratio of Effective Column Length to Least Radius of Gyration.	Coefficient.
50	1·0
60	0·9
70	0·8
80	0·7
90	0·6
100	0·5
110	0·4
120	0·3

For any ratio of effective column length to least radius of gyration between 50 and 120 not shown in Table XII above, the appropriate coefficient shall be determined on the basis that the coefficient varies in proportion with the ratio of effective column length to least radius of gyration between those shown as consecutive in Table XII above.

A reinforced concrete column or part thereof shall not have a ratio of effective column length to least radius of gyration more than 120.

102. The effective column length to be assumed in determining the working load per square inch in accordance with by-laws 99, 100 and 101 shall be as follows :—

	Type of Column.	Effective Column Length.
Columns of one storey.	Properly restrained at both ends in position and direction.	0·75 of the actual column length.
	Properly restrained at both ends in position but not in direction.	Actual column length.
	Properly restrained at one end in position and direction and imperfectly restrained in both position and direction at the other end.	A value intermediate between the actual column length and twice that length depending upon the efficiency of the imperfect restraint.

	Type of Column.	Effective Column Length.
Columns continuing through two or more storeys.	Properly restrained at both ends in position and direction.	0·75 of the distance from floor level to floor level.
	Properly restrained at both ends in position and imperfectly restrained in direction at one or both ends.	A value intermediate between 0·75 and 1·00 of the distance from floor level to floor (or roof) level, depending upon the efficiency of the directional restraint.
	Properly restrained at one end in position and direction and imperfectly restrained in both position and direction at the other end.	A value intermediate between the distance from floor level to floor (or roof) level and twice that distance, depending upon the efficiency of the imperfect restraint.

The effective column length values given above are in respect of typical cases only and embody the general principles which shall be employed in assessing, to the satisfaction of the district surveyor, the appropriate value for any particular column.

103. The maximum permissible stresses in reinforced concrete and in its reinforcement may exceed these specified in by-laws 99 and 100 respectively by not more than 33⅓ per cent., provided such excess is solely due to stresses induced by wind loading, and provided that such excess shall not apply to secondary floor beams, nor to the stresses in roof construction above the topmost floor level in a building.

104. A reinforced concrete column shall have longitudinal steel reinforcement, and the cross-sectional area of such reinforcement shall not be less than 0·8 per cent., nor more than 8 per cent., of the gross cross-sectional area of the column required to transmit all the loading in accordance with these by-laws.

A reinforced concrete column having helical reinforcement shall have also at least six bars of longitudinal reinforcement within such helical reinforcement. Such longitudinal bars shall be in contact with such helical reinforcement and equidistant around its inner circumference.

At a splice in a longitudinal reinforcement, the spliced bars shall overlap longitudinally through a distance not less than 24 times the diameter of the upper bar, or a sufficient distance to develop the force in the bar by bond, whichever is the lesser.

105. A reinforced concrete column shall have transverse or helical reinforcement so disposed as to provide all necessary restraint against buckling of the longitudinal reinforcement; and the ends of such transverse reinforcement shall be anchored properly.

The diameter of such transverse reinforcement shall not be less than one-fourth of an inch.

The pitch of such transverse reinforcement shall not be more than the least of the three following distances:—

(1) the least lateral dimension of such column;

(2) twelve times the diameter of the smallest longitudinal reinforcement in such column;

(3) 12 inches.

Helical reinforcement shall be of regular formation, with the turns of the helix spaced evenly; and its ends shall be anchored properly. The pitch of the helical turns shall be not more than 3 inches nor more than one-sixth of the core-diameter of such column; and such pitch shall be not less than 1 inch nor less than three times the diameter of the steel forming such helix.

106. The diameter of a steel reinforcement in reinforced concrete shall be not more than 2 inches.

The diameter of a longitudinal steel reinforcement in a reinforced concrete column shall be not less than ½ inch.

The diameter of a main steel reinforcement in a reinforced concrete beam or slab shall be not less than ¼ inch.

The diameter of a steel reinforcement in reinforced concrete other than a longitudinal reinforcement in a column or a main reinforcement in a beam or slab, and the diameter of steel forming a tie, helix, stirrup or the like, shall be not less than $\frac{3}{16}$ inch.

The diameter of steel forming a mesh-reinforcement for the purpose of resisting tension in reinforced concrete shall be not less than $\frac{1}{8}$ inch.

107. The distance between two steel reinforcements in reinforced concrete shall be not less than the greatest of the three following distances :—

(a) the diameter of either bar if their diameters are equal ;

(b) the diameter of the larger bar if their diameters be unequal ;

(c) ¼ inch more than the greatest size of the coarse aggregate comprised in such concrete.

Provided that the vertical distance between two horizontal main steel reinforcements, or the corresponding distance at right angles to two inclined main steel reinforcements, shall be not less than ½ inch, except at a splice and except where one of such reinforcements is transverse to the other.

The pitch of distributing bars in a reinforced concrete solid slab shall be not more than four times the effective depth of such slab.

A mesh-reinforcement shall be of such dimensions, shape, proportions and arrangement as will afford proper combination of such reinforcement with such concrete.

108. Where the concrete alone is not sufficient to resist, in accordance with by-law 99 the shearing action in reinforced concrete, the whole of such shearing action shall be provided for by the tensile resistance of shear reinforcement acting in proper conjunction with the compressive resistance of the concrete ; but the magnitude of such shearing action to be so provided for shall not exceed *four* times that which the concrete alone could resist in accordance with by-law 99.

109. A stirrup in reinforced concrete shall pass round, or be secured adequately otherwise to, the appropriate tensile reinforcement ; and such stirrup shall have both its ends anchored properly.

110. A reinforced concrete solid slab spanning in one direction shall have distributing bars at right angles to the main tensile reinforcement of such slab ; and the aggregate cross-sectional area of such distributing bars shall not be less than one-tenth of the aggregate cross-sectional area of such main tensile reinforcement associated therewith.

111. Where the compressive resistance of concrete in beams is taken into account, the compression reinforcement where it is required shall be effectively anchored over the distance where it is required at points not further apart centre to centre than twelve times the diameter of the anchored bar.

Where the compressive resistance in concrete is not taken into account the compressive reinforcement shall be effectively anchored laterally and vertically over the distance where it is required at points not further apart centre to centre than eight times the diameter of the anchored bar. The subsidiary reinforcement used for this purpose shall pass round or be hooked over both the compression and tensile reinforcement.

112. Hooks and other anchorages of reinforcement in reinforced concrete shall be of such form, dimensions and arrangement as will ensure their adequacy without overstressing the concrete or any other material.

113. Where reinforced concrete is used in the construction of a building wherein the loads and stresses are not transmitted through each storey to the foundations wholly by a skeleton framework of reinforced concrete nor partly by a skeleton framework of reinforced concrete and partly by a party wall or party walls, the standard of stability shall, to the satisfaction of the district surveyor, be not inferior to that required for compliance with by-laws 99 to 112 inclusive.

114. Reinforcement in reinforced concrete shall not be connected by welding, except in accordance with conditions prescribed by the Council in each particular case.

Provided that round or square bars not more than 0·4 inch diameter and transverse to each other forming a mesh reinforcement in a solid slab may be connected by electrically fusing the metal of such rods at their points of contact if such fusion be executed at the works where such mesh is fabricated and if the district surveyor be satisfied as to its suitability.

115. Reinforced concrete subjected to bending actions in a building shall possess adequate stiffness to prevent such deflection or deformation as might, in the opinion of the district surveyor, affect adversely the stability of such building or of any part thereof.

116. Reinforced concrete subjected to compression in a building shall possess adequate stiffness, or be provided with adequate restraint, to prevent such lateral flexure as might, in the opinion of the district surveyor, affect adversely the stability of such building or of any part thereof.

117. The fabrication and erection of reinforced concrete shall be such as will ensure that the assumptions upon which the stresses in such concrete and in its reinforcement have been calculated shall be fulfilled adequately at all times in the building of which such reinforced concrete forms part.

118. Where the district surveyor finds substantial reason for doubt as to the sufficiency or suitability of the reinforced concrete for its purposes under these by-laws, the builder shall make such test or tests on such concrete as the district surveyor may require ; and if such testing proves, in the opinion of the district surveyor, that such concrete is insufficient or unsuitable for its purposes under these by-laws, such concrete shall be removed and replaced with reinforced concrete which complies with these by-laws.

LONDON COUNTY COUNCIL

London Building Acts 1930 & 1935

Building By-Laws—Computation of Stresses

. . . .

LOADING.

. . . .

3. For ordinary construction, the weight of reinforced concrete may be assumed as 144 lb. per cubic foot.

. . . .

REINFORCED CONCRETE.

5. *Basic assumptions.*—Design of reinforced concrete to resist bending should be based upon the assumptions :—

(i) that both steel and concrete are elastic within the range of the permissible stresses ;
(ii) that all tensile stresses are taken by the reinforcement ; and
(iii) that plane sections remain plane.

Stresses due to shrinkage or expansion of the concrete need not be calculated.

6. *Moment of inertia.*—In the absence of conditions rendering such a course unjustifiable, the moment of inertia may be calculated on :—

(i) the entire concrete section, ignoring the reinforcement ;
or (ii) the entire concrete section, including the reinforcement on the basis of the modular ratio;
or (iii) the compression area of the concrete section, combined with the reinforcement on the basis of the modular ratio.

These methods should not be changed or combined in a design. One method having been adopted, that method should be applied throughout.

. . . .

Beams and Slabs.

8. *Effective span.*—The effective span of a beam or slab should be taken as either :—

(i) the distance between the centres of support ;
or (ii) the clear distance between supports plus the effective depth of the beam or slab.

9. *Lateral stiffness.*—The ratio of length between adequate lateral restraints of a beam to the breadth of its compression flange should not exceed :—

$$20\left\{3 - 2\left(\frac{\text{calculated compressive stress}}{\text{permissible compressive stress}}\right)\right\}$$

10. T-*beams and* L-*beams.*—In T-beams the breadth of the flange assumed as taking compression should not exceed the least of the following :—

(i) one-third of the effective span of the T-beam ;
(ii) the distance between the centres of the ribs of the T-beams ;
(iii) the breadth of the rib plus twelve times the thickness of the slab.

In L-beams, the breadth of the flange assumed as taking compression should not exceed the least of the following :—

(i) one-sixth of the effective span of the L-beam ;
(ii) the breadth of the rib plus one-half of the clear distance between ribs ;
(iii) the breadth of the rib plus four times the thickness of the slab.

When a part of a slab is considered as the flange of a T-beam or L-beam, the reinforcement in the slab transverse to the beam should cross the full width of the flange ; and where the slab is assumed to be spanning independently in the same direction as the beam, such reinforcement should be near the top surface of the slab.

11. Bending moments in beams and slabs should be calculated for the effective span and all loading thereon.

The bending moments to be provided for at a cross-section of a continuous beam or slab should be the maximum positive and negative moments at such cross-section for the following arrangements of superimposed loading :—

(i) alternate spans loaded and all other spans unloaded ;
(ii) any two adjacent spans loaded and all other spans unloaded.

Nevertheless, provided the maximum positive moments so obtained in any two adjacent spans are increased by an amount not exceeding 15 per cent. of the maximum intermediate support moment, the latter may be reduced by the same numerical amount and the positive moments elsewhere in the span increased accordingly.

The computation of bending moments in flat slabs is dealt with later in this memorandum.

12. *Beams and slabs spanning in one direction.*—Provided the fabrication and erection of the reinforced concrete be such as will ensure that the assumptions upon which the stresses in such concrete and in its reinforcement have been calculated will be fulfilled adequately at all times in the building of which such reinforced concrete forms part, the bending moments in beams and slabs spanning in one direction may be calculated on one of the following assumptions:—

(i) Beams may be designed as members of a continuous framework, with monolithic connection between beams and columns, and the bending moments calculated taking into account the resistance of the columns to bending; or

(ii) Beams and slabs may be designed as continuous over supports and capable of free rotation about them; or

(iii) The total bending moments in all cases of uniformly distributed or other symmetrica loading over a number of approximately equal spans may be assumed to have the following relations to those induced in a freely supported span similarly loaded:—

Near Middle of End Span.	At Support next to End Support.	At Middle of Interior Spans.	At Other Interior Supports.
$+\frac{8}{10}$	$-\frac{8}{10}$	$+\frac{8}{12}$	$-\frac{8}{12}$

Two spans may be considered as approximately equal when they do not differ by more than 15 per cent. of the longer.

13. *Slabs spanning in two directions at right angles*—

(i) *General.*—To estimate the bending moments in a solid slab spanning in two directions at right angles, the slab may be assumed to act as perfectly elastic thin plate, Poisson's Ratio being assumed equal to zero.

(ii) *Slabs simply supported on four sides.*—The bending moments at the centre of a rectangular solid slab spanning in two directions at right angles, with loading uniformly distributed, and simply supported on four sides, may be assumed to have the values given by the following equations (1) and (2):—

$$M_x = Z_x\left(\frac{wl_x^2}{8}\right) \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

$$M_y = Z_y\left(\frac{wl_y^2}{8}\right) \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where M_x and M_y are the bending moments on strips of unit width and spans l_x and l_y respectively;

w is the total load per unit area;

l_y is the length of the longer side (see fig. 1);

l_x is the length of the shorter side (see fig. 1);

and Z_x and Z_y are coefficients shown in Table A following.

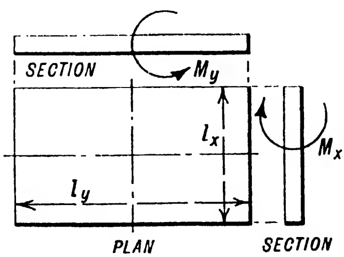

FIG 1.

TABLE A.

l_y/l_x	1·0	1·1	1·2	1·3	1·4	1·5	1·75	2·0	2·5	3·0
Z_x .	0·500	0·594	0·675	0·741	0·794	0·835	0·904	0·941	0·975	0·988
Z_y .	0·500	0·406	0·325	0·259	0·206	0·165	0·096	0·059	0·032	0·022

(iii) *Slabs fixed at or continuous over four sides.*—The negative bending moments at the supports of a rectangular solid slab spanning in two directions at right angles, with loading uniformly distributed, and fixed at or continuous over four sides, may be assumed to have the values given by equations (1) and (2) above, taking the values for Z_x and Z_y shown in Table B following; and the positive bending moments near mid-span may be assumed to have values not less than 80 per cent. of those given by equations (1) and (2) above, taking the values for Z_x and Z_y shown in Table B following :—

TABLE B.

l_y/l_x	1·0	1·1	1·2	1·3	1·4	1·5	1·75	2·0	2·5	3·0
Z_x .	0·295	0·358	0·419	0·477	0·532	0·581	0·681	0·757	0·869	0·940
Z_y .	0·295	0·237	0·191	0·154	0·127	0·107	0·071	0·051	0·032	0·022

14. *Resistance to shear*—

(*a*) *General.*—(i) The shear stress s at any cross-section in a reinforced concrete beam or slab should be calculated from the following equation (3) :—

$$s = \frac{S}{ba} \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

where S is the total shearing force across the section;

b is the breadth of a rectangular beam or the breadth of the rib of a T-beam;

and a is the arm of the resistance moment.

(ii) Where at any cross-section the shear stress, as calculated from equation (3) above, exceeds the permissible shear stress for the concrete, the whole shearing force should be provided for by the tensile resistance of the shear reinforcement acting in proper combination with the compression in the concrete. Moreover, even with the whole shearing force so provided for, the shearing stress as calculated from equation (3) above should not exceed four times the permissible shear stress for the concrete alone.

(*b*) *Shear reinforcement.*—(i) Tensile reinforcement which is inclined and carried through a depth of beam equal to the arm of the resistance moment may be considered as shear reinforcement provided it is anchored sufficiently.

(ii) Where two or more types of shear reinforcement are used in conjunction the total shearing resistance of the beam may be assumed to be the sum of the shearing resistances computed for each type separately.

(iii) The spacing of stirrups should not exceed a distance equal to the arm of the resistance moment. The resistance to shear 'S' should then be calculated from the following equation (4) :—

$$S = \frac{t_w A_w a}{p} \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

where t_w is the permissible tensile stress in the shear reinforcement;

A_w is the cross-sectional area of the stirrup;

a is the arm of the resistance moment;

and p is the pitch or spacing of stirrups.

(iv) The resistance to shear at any section of a beam reinforced with inclined bars may be calculated on the assumption that the inclined bars form the tension members of one or more single systems of lattice girders in which the concrete forms the compression members. The shear resistance at any vertical section should then be taken as the sum of the vertical components of the tension and compression forces cut by the section.

15. *Bond and anchorage.*—(i) A plain bar in tension should extend from any section for a distance not less than n times the diameter of the bar, where :—

$$n = \frac{\text{the tensile stress in the bar}}{\text{four times the permissible bond stress}}$$

In no case should n be taken at less than 12. That is, an anchorage of at least 12 bar diameters should be provided beyond the section at which tension commences theoretically.

(ii) When reinforcement in the form of plain bars is used to resist stresses induced by bending, the bond stress s_b due to a variation in tensile stress, calculated from the following equation (5) should not at any point exceed twice the appropriate permissible bond stress.

$$s_b = \frac{S}{ao} \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

where S is the total shear across the section less the resistance to shear provided by the inclined bars.

a is the arm of the resistance moment;

and o is the sum of the perimeters of the bars in the tensile reinforcement.

In members of other than uniform depth the effect of the change in depth on the bond stress should also be taken into account.

(iii) A hook at the end of a bar should be of the form indicated in fig. 2, and its inner diameter should be not less than four times the diameter of the bar; except that when the hook fits over a main reinforcing or other adequate anchor bar the diameter of the hook may be equal to the diameter of such main reinforcing or anchor bar. A bend in a reinforcing bar may be assumed to increase the bond strength of the bar by an amount equivalent to that of a length of bar equal to four times the diameter of the bar for each 45 degrees through which the bar is bent; provided that:—

(*a*) the radius of the bend be not less than twice the diameter of the bar;

(*b*) the length of the straight part of the bar beyond the end of the curve be at least four times the diameter of the bar; and

(*c*) whatever be the angle through which the bar is bent, the assumed increase in the bond strength shall not be taken as more than that of a length of bar equal to sixteen times the diameter of the bar.

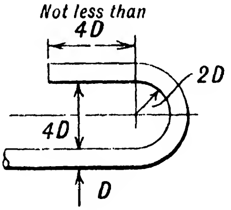

FIG. 2.

(iv) When an attachment is used in place of a hook, the permissible stress in the concrete may be increased to three times the value permitted for the concrete in direct compression, provided the end anchorage is of such form as to prevent local failure of the concrete.

(v) Notwithstanding any of the above notes, in the case of secondary reinforcement such as stirrups and binding, complete bond length and anchorage may be deemed to have been provided when a bend in the bar through an angle of at least 90 degrees passes round a bar of at least its own diameter and the bar is continued beyond the end of the curve for a length of at least eight diameters.

Columns.

16. *Short columns with lateral ties.*—The axial load P permissible on a short column reinforced with longitudinal bars and lateral ties should not exceed that given by the following equation (6):—

$$P = c(A_c + mA) \quad . \quad . \quad . \quad . \quad . \quad (6)$$

where c is the permissible stress for the concrete ;

A_c is the cross-sectional area of concrete excluding any finishing material applied after the casting of the column ;

m is the modular ratio (15).

and A is the cross-sectional area of the longitudinal steel.

17. *Short columns with helical reinforcement.*—Where helical reinforcement is used, the axial load P permissible on a short column should not exceed that given by equations (6) or (7), whichever is the greater :—

$$P = c(A_k + mA) + 2t_b A_b \quad . \quad . \quad . \quad . \quad . \quad (7)$$

where A_k is the cross-sectional area of concrete in the core ;

t_b is the permissible stress in the helical reinforcement ;

and A_b is the equivalent area of helical reinforcement (volume of helix per unit length of the column).

The sum of the loads contributed by the concrete in the core and by the helix should not exceed $0 \cdot 5uA_c$, where u is the crushing strength of the concrete required from the works test.

When, in a column having helical reinforcement, the permissible load is based on the core area, the radius of gyration also should be based on the core area of the column.

18. *Long columns.*—The permissible working load for a long column should not exceed that calculated as above for a short column, multiplied by the appropriate buckling coefficient.

19. *Bending in columns.*—Bending moments in internal columns supporting an approximately symmetrical arrangement of beams and loading need not be calculated.

Bending moments in external columns and in internal columns supporting an arrangement of beams and loading not approximately symmetrical should be calculated and provided for.

Unless more exact methods are preferred, the bending moments in external (and similarly loaded) columns may be estimated from the following equations (8), (9), (10) and (11) :—

Moment at foot of upper column . $M_e\left(\frac{K_u}{K_l + K_u + 0 \cdot 5K_b}\right)$ for a frame of one bay . . (8)

Moment at foot of upper column . $M_e\left(\frac{K_u}{K_l + K_u + K_b}\right)$ for frames of two or more bays . (9)

Moment at head of lower column . $M_e\left(\frac{K_l}{K_l + K_u + 0 \cdot 5K_b}\right)$ for a frame of one bay . . . (10)

Moment at head of lower column . $M_e\left(\frac{K_l}{K_l + K_u + K_b}\right)$ for frames of two or more bays . (11)

where M_e is the bending moment at the end of the beam framing into the column, assuming fixity at the connection ;

K_u is the stiffness of the upper column ;

K_l is the stiffness of the lower column ;

and K_b is the stiffness of the beam.

The equations for the moment at the head of the lower column may be used for columns in a topmost storey by taking K_u as zero.

For the purposes of these equations, the 'stiffness' of a member may be taken as the quotient obtained by dividing the moment of inertia of a cross section by the length of the member, provided the member be of constant cross-section throughout its length.

20. *Combined axial and bending stresses.*—The maxima stresses on longitudinal reinforcement and concrete due to combination of direct load and bending action should not exceed the permissible stresses for bending, multiplied by the appropriate buckling coefficient.

Code of Practice for the Use of Reinforced Concrete in Buildings.

The Codes of Practice Committee, formed under the ægis of the Ministry of Works, has recently issued a British Standard Code of Practice, C.P. 114 (1948), for the structural use of normal reinforced concrete in buildings. For concretes made with approved aggregates (B.S. 882), this code recommends even higher permissible stresses than those allowed for quality. A concrete in the L.C.C. By-laws. Where the aggregates do not comply with B.S. 882, the permissible stresses are based on the actual cube strengths in preliminary and works tests. The code assumes a modular ratio of 15.

The Memorandum on Bridge Design and Construction No. 577, issued by the Ministry of War Transport, like the D.S.I.R. Code of Practice which preceded it, assumes a variable modular ratio equal to 40,000 divided by three times the permissible concrete bending stress, expressed in pounds per square inch.

SYSTEMS OF REINFORCED CONCRETE CONSTRUCTION.

Although there exists a considerable number of so-called independent systems of reinforced concrete construction, the principles underlying the same are in every way similar, and it is only in the manner in which these principles are carried out that any difference arises. The several systems can be readily divided into groups, and the following notes will be sufficient here to indicate wherein one differs from another :—

Systems which make use of Plain Steel Rod Reinforcing Bars.

In the Hennebique system, the main bars are set parallel to the lower or tension face of the beam, some being, where necessary, bent or cranked upwards towards the upper face (as where the beam is continuous over a support). In addition to these bars, flat stirrups are hooked at intervals over the lower bars, and carried upwards towards the upper part of the beam; these bind the concrete and steels securely together, and assist largely in resisting the shearing stresses. For columns or piles, the rods are grouped symmetrically about the centre of the pile, and are tied together at intervals by means of straps or wire lacing.

The Coignet system is in many respects very similar to the Hennebique, except that generally a number of smaller rods are used, these being in turn bent upwards as they approach the ends of the beam. A continuous top bar is also provided, to which the bent-up members are securely tied or laced. Any additional stirrups or binding ties which are necessary are formed of small section round bars, varying from $\frac{3}{16}$ in. to $\frac{1}{4}$ in. diameter; these are laced or tied between the lower or main tension bars and the upper bar.

In the Considère system, the portions of any structure under compression are provided with a close-set spiral of steel wire or small-section steel rod, which, by surrounding the concrete and preventing its displacement, enables the enclosed portion to resist safely very high compressive stresses.

A number of other systems in which plain bars are used have recently appeared, the difference between them being in the manner in which the several bars are connected together, and the method of providing for shearing stresses, and for connecting the shear bars to the main bars.

Reinforced Concrete or Fire-Resisting Floors.

Numerous systems of these are on the market, but they can be grouped together into types, of which the following may be noted :—

(1) A series of hollow or solid blocks of fireclay, concrete, or other material are laid at short distances apart, and the space between same filled up with concrete or cement grouting, with steel rods embedded in same. In this way a series of reinforced concrete beams are formed surrounding the blocks. Where the area to be covered is approximately square, or the proportion of length to breadth does not much exceed 2 to 3, these reinforced concrete beams can be formed on all four sides of the blocks; but where hollow blocks are used, the open ends must be closed up, or provision made to prevent the concrete finding access into the hollows which are intended to lighten the weight of the floor. Of this type may be mentioned the 'Kleine,' the 'Fram,' Diespeker's 'Bigspan,' etc.

(2) Hollow blocks, usually of arched formation, and of a width or span of from 2 to 3 feet, or over, are laid between and supported by lines of rolled steel beams, or of reinforced concrete beams, these latter being made either at works, and delivered and erected complete, or formed *in situ* during the construction of the floor. A level floor surface is obtained by a light filling of breeze concrete over the blocks. Where steel beams or finished reinforced concrete beams are used, the floor can be erected without the use of centering. The dispensing with large masses of wet concrete minimises all trouble due to dripping from the new floor, and allows it to be used immediately after it has been erected.

A modification of this floor consists in the use of half-arch shaped blocks, which are set into the webs of steel beams, and brought together at the centre where they are lightly grouted at their meeting edges. A levelling-up covering of breeze concrete completes the floor. This type is represented by the 'Fram' arched floor, the 'Carlisle' tubular arch floor, etc.

(3) Concrete tubes of various sections and of considerable lengths may be formed, and reinforced where necessary with steel rods or wire. By placing these close together, it is only necessary to grout in between the joints in the several tubes to complete the floor ready for any top finish; the advantage of a dry laid floor is thus secured. The 'Siegwart,' etc., provide this type of floor.

(4) Floors may be formed of solid concrete slabbing reinforced with plain or special section bars as required, and supported by rolled-steel beams or reinforced concrete beams. Such types are supplied by any reinforced concrete contractor.

(5) Floors provided with a continuous mesh reinforcement :—The floors provided by the Expanded Metal Company and by the Lock Woven Mesh Company may be taken as examples of this class.

Other types of floors are to be met with, each possessing some particular qualification or arrangement peculiar to itself.

DESIGNING REINFORCED CONCRETE STRUCTURES.

Concrete is very strong under compression, but weak under tension. Good average concrete will safely resist a compressive stress of from 600 to 1,000 lbs. per square inch of section; its tensile strength does not exceed about one-tenth of this value, and may altogether disappear through the formation of minute cracks.

Concrete and steel possess practically the same coefficient of expansion, and therefore expand and contract together under changes of temperature, without developing internal stresses.

Concrete adheres strongly to a clean surface of steel; the average safe adhesion can generally be taken as about 100 lbs. per super. inch. It is thus possible to form a practical and economical combination of concrete and steel, the former material being utilised to resist the compressive stresses, with the necessary steel bars embedded at the points where tensile stresses occur. In certain cases, where the concrete alone cannot provide all the necessary compressive resistance, steel rods are added to assist the concrete; but from an economical point of view this should be avoided whenever possible, for the following reason :—

Steel possesses, on an average, about fifteen times the elasticity of concrete; where steel bars are embedded in concrete to assist in resisting compression, it follows that when the concrete around the bars has been stressed up to its limit, the steel has been compressed to fifteen times that of the concrete only, and is still far from its limit. Notwithstanding this want of economy, it is frequently necessary to utilise steel in this way, as, for instance, in the case of columns, arches, etc., and in beams when sufficient depth, or area of concrete in the compression flange, cannot be obtained.

Steel is very perfectly protected from deterioration by a covering of concrete, and many instances could be quoted to show that a covering of less than 1 inch of good concrete is sufficient to preserve steel almost indefinitely.

In many cases reinforced concrete forms an almost ideal method of construction, particularly where great strength and durability are essential. The strength of the concrete increases with age, and there is no cost of upkeep, as in the case of steelwork, which requires regular inspection, painting, etc.

All structures can have their several members resolved into three types or into combinations of these three types—namely, beams or girders, struts or stanchions, and ties. Beams or girders support loads which act at right angles to their length, and tend to cause bending or deflection of the member. In struts or stanchions the loads act in the direction of the length, and tend to compress the members; in long and slim compression members, however, stresses similar to those in beams may also arise, through bending or side-yielding when the load exceeds a particular value. In ties the load acts in the direction of their length, as in struts, but here the tendency is to produce tension or stretching in the member.

Composite members may be represented by struts or ties which are not placed vertically, and consequently tend to bend by their own weight, and to this latter extent act as beams. Arches also are generally subjected to bending stresses in addition to that of compression.

Beams or Girders.

The bending moment and shearing force values are calculated exactly as in the case of ordinary beams, and reference may be made to pages 216 and 217 for information on this point. Owing to the composite nature of a reinforced concrete beam, however, the determination of the internal stresses, or of the scantlings of any beam necessary to limit the tension and compression stresses to some specific maximum, are distinctly more complex than in the case of beams formed of a homogeneous material.

The following assumptions, which are practically correct within the usual limits of safe stress and ordinary conditions, are generally admitted, and form the basis on which the formulæ are built up :—

(*a*) The coefficient of elasticity in compression of good concrete is constant throughout the working limit of stress, and for an average 1 : 2 : 4 mixture may be taken as $\frac{1}{15}$ that of the steel reinforcement. For any distance from the neutral axis, therefore, the stress per square inch on the steel is fifteen times that on the concrete.

(*b*) The tensional resistance of concrete is ignored.

(*c*) The stress on the concrete varies uniformly from zero at the neutral axis to a maximum at outer edge ; the stress on the area of the steel is constant.

(*d*) The bond, or adhesion, between the concrete and the steel is sufficient to transmit any stress arising between these two materials.

Considering, in the first instance, a beam formed of some homogeneous material, supported at each end, and loaded so that it tends to deflect, the compressive stress at the upper edge of the beam will be exactly equal to the tensile stress at the lower edge, and these values will gradually diminish towards the centre of the depth, where they will altogether disappear ; this plane of no stress is called the neutral axis.

Assuming that the stresses vary uniformly, fig. 3 may be taken to represent the stresses in any section of the beam, the horizontal distance between the vertical line and the inclined line at any point above the neutral axis will be proportionate to the compressive stresses at the given point ; similarly, the horizontal lengths below the neutral axis will be proportionate to the tensile stress.

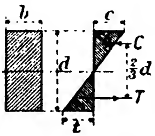

FIG. 3.

The total resistance to compression or extension would be represented by the area of either triangle. The resultant of either of these stresses would act through the centre of gravity of these triangles, or at a distance equal to $\frac{1}{3}$ the perpendicular depth from the base, giving the distance between the two resultants, or the lever arm of the resistance couples, as equal to $\frac{2}{3}d$.

The corresponding diagram for a simple reinforced concrete beam would be that of fig. 4. Here the compressive resistance, which occurs above the neutral axis, is represented, as before, by a triangle ; while the tensile resistance, being that of the steel reinforcement only, is represented by a line (the tensile strength of the concrete is ignored). The position of the resultant of the compressive resistance would pass through the centre of gravity of the triangle, or at $\frac{1}{3}n$ from the upper surface ; the lever arm in this case would equal $d - \frac{n}{3}$.

Where double reinforcement is adopted—that is to say, where a certain amount of steel is introduced into the upper or compression area of the beam to assist the concrete (fig. 5)—the total compressive resistance would, in addition to that of the concrete, include the compressive resistance of the steel ; the combined resultant of these two resistances would equal the sum of the two, and would act at some point between the two independent resistances, the exact position depending on the relative values of these two resistances.

In the case of T beams, or those in which the upper or compression flange is formed in part of the flooring slabs with which the beam proper is combined, two cases arise : the one in which the distance from the neutral axis to top of beam (n) is *not greater* than the thickness of the floor slab (d_s), and the other in which this value (n) is *greater* than the thickness of the slab (d_s). Since the compressive stress is assumed as being resisted by the concrete alone, the first case naturally falls under the same condition as that of a simple beam (fig. 4), except that the breadth of the beam must now be taken, not as the breadth of the reinforced beam only (b_r), but must include a certain portion of the slab at each side of the main beam, or b_s.

The difference between the first and second cases referred to will be obvious by a comparison between figs. 6 and 7. In the former the compression resistance is represented by a triangle, with a resultant acting $\frac{1}{3}n$ from the upper surface; while in the latter case the compressive resistance is represented by the area of a trapezoid, the point of action being through the centre of gravity of this figure. It should be noted that in this latter case the compressive value of the concrete in the main beam between the bottom of slab and the neutral axis is ignored, as its value is very slight, and the formulæ are much simplified by doing this.

Two extensions of the above two cases are shown in figs. 8 and 9, where double reinforcement is adopted ; the treatment in these two cases is modified generally, as previously noted when referring to figs. 4 and 5 for rectangular beams.

The following series of formulæ for the several types of single and double reinforced beams just referred to will enable the scantlings for any such members to be readily calculated or the designs for these checked with the minimum of trouble.

Rectangular Beams with Single Reinforcement.

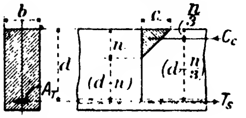

FIG. 4.

$$n=\frac{1}{1+\frac{t}{cm}} \quad . \quad . \quad . \quad (1)$$

$$r=\frac{1}{\frac{2t}{c}\left(1+\frac{t}{cm}\right)} \quad . \quad . \quad . \quad (2)$$

$$t=c\frac{(1-n)m}{n} \quad . \quad . \quad . \quad (3)$$

$$c=t\frac{n}{(1-n)m} \quad . \quad . \quad . \quad (4)$$

$$A_T=\frac{B}{td\left(1-\frac{n}{3}\right)} \quad . \quad . \quad . \quad (5)$$

$$n=\sqrt{(mr)^2+2mr}-mr \quad . \quad . \quad (6)$$

$$R=bd^2\left[tr\left(1-\frac{n}{3}\right)\right] \quad . \quad . \quad (7)$$

$$R=bd^2\left[\tfrac{1}{2}cn\left(1-\frac{n}{3}\right)\right] \quad . \quad . \quad (8)$$

SYMBOLS.

n = Ratio of distance of neutral axis from compression edge of beam to effective depth.
r = Ratio of area of steel to area of concrete $= A_T/bd$
t = Tensile stress intensity on steel.
c = Compressive stress intensity on concrete.
m = Modulus ratio $= E_s/E_c$.
A_T = Area of tensile reinforcement.
B = Bending moment of external forces.
R = Resistance moment of internal stresses.
b = Breadth of beam.
d = Effective depth of beam.

DESIGNING.—Decide values for m, t, c, and trial dimensions for b and d. Calculate n by (1) and r by (2); then value of A_T by (5). R is got from (7) or (8). If any other value of r is used than is given by (2), calculate n by (6) and R by (7) and (8), the lesser of these two values being adopted.

CHECKING A DESIGN.—Calculate r $(=A_T/bd)$, and with this determine n from (6); test t and c by (3) and (4). If t exceeds the safe stress, get R from (7); if c exceeds the safe stress, get R from (8), in each case using the maximum safe stress for t or c.

Note.—Where more than one bar is used to form the reinforcement, measure d to the centre of gravity of the group.

Usual Dimensions.—d = one-twelfth to one-sixteenth of span; b = one-half to two-thirds d.

Rectangular Beams with Double Reinforcement.

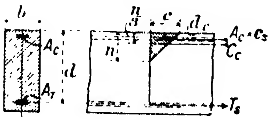

FIG. 5.

$$c_s=\frac{(n-d_c)}{n}m\times c \quad . \quad . \quad . \quad (9)$$

$$c_s=\frac{(n-d_c)}{(1-n)}t \quad . \quad . \quad . \quad (10)$$

$$A_c=\frac{B-\left[\tfrac{1}{2}cnbd^2\left(1-\frac{n}{3}\right)\right]}{c_s d(1-d_c)} \quad . \quad (11)$$

$$A_T=\frac{B-\left[A_c c_s d\left(\frac{n}{3}-d_c\right)\right]}{dt\left(1-\frac{n}{3}\right)} \quad (12)$$

$$n=\sqrt{m^2(r_t+r_c)^2+2m(r_t+r_c d_c)}-m(r_t+r_c) \quad (13)$$

$$R=bd^2\left[tr_t\left(1-\frac{n}{3}\right)+c_s r_c\left(\frac{n}{3}-d_c\right)\right] \quad (14)$$

$$R=bd^2\left[\tfrac{1}{2}cn\left(1-\frac{n}{3}\right)+c_s r_c(1-d_c)\right] \quad (15)$$

ADDITIONAL SYMBOLS.

c_s = Compressive stress intensity on steel.
d_c = Ratio of depth to centre of compression reinforcement to effective depth.
A_c = Area of compression reinforcement.
r_t = Ratio of area of steel in tension to area bd.
r_c = Ratio of area of steel in compression to area bd.

DESIGNING.—Calculate n by (1), then c_s by (9) or (10); the area of Compression Steel is got from (11), and the area of Tension Steel from (12). The Resistance Moment is got from (14) or (15).

CHECKING A DESIGN.—Calculate r and r_c from scantlings given, and n from (13). c_s is got from (9) and (10), the smaller value being adopted. R is obtained from (14) and (15), the former assuming the concrete, and the latter the steel as stressed to their respective safe limits; the least value of R from (14) and (15) must consequently be taken as the maximum safe R.

T Beams with Single Reinforcement.

Class I.—n not greater than d_s.

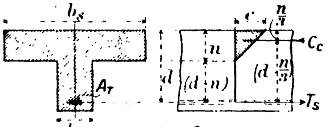

FIG. 6.

$$n = \frac{1}{1+\frac{t}{cm}} \quad . \quad . \quad . \quad . \quad . \quad (16)$$

$$r = \frac{b_s}{\frac{2t}{c}\left(1+\frac{t}{cm}\right)b_r} \quad . \quad . \quad . \quad . \quad (17)$$

$$t = c\frac{(1-n)m}{n} \quad . \quad . \quad . \quad . \quad (18)$$

$$c = t\frac{n}{(1-n)m} \quad . \quad . \quad . \quad . \quad (19)$$

$$A_T = \frac{B}{td\left(1-\frac{n}{3}\right)} \quad . \quad . \quad . \quad . \quad . \quad (20)$$

$$n = \sqrt{\left(mr\frac{b_r}{b_s}\right)^2 + 2mr\frac{b_r}{b_s}} - mr\frac{b_r}{b_s} \quad . \quad (21)$$

$$R = b_r d^2\left[tr\left(1-\frac{n}{3}\right)\right] \quad . \quad . \quad . \quad (22)$$

$$R = b_s d^2\left[\tfrac{1}{2}cn\left(1-\frac{n}{3}\right)\right] \quad . \quad . \quad . \quad (23)$$

SYMBOLS.

n = Ratio of distance of neutral axis from compression edge of beam to effective depth.
r = Ratio of area of steel to area ($b_r d$).
t = Tensile stress intensity on steel.
c = Compressive stress intensity on concrete.
m = Modulus ratio = E_s/E_c.
A_T = Area of tensile reinforcement.
B = Bending moment of external forces.
R = Resistance moment of internal stresses.
b_s = Breadth of T slab.
b_r = Breadth of rib.
d = Effective depth of beam.

DESIGNING.—Decide values for m, t, c, and trial dimensions for b_r, b_s, and d. Calculate n by (16) and r by (17), then value of A_T by (20). R is got from (22) or (23). If any other value of r is used than is given by (17), calculate n by (21) and R by (22) and (23), the lesser of these two values being adopted.

CHECKING A DESIGN.—Calculate r ($=A_T/b_r d$), and with this determine n from (21). Test t and c by (18) and (19). If t exceeds the safe stress, get R from (22), if c exceeds the safe stress get R from (23), in each case using the maximum safe stress for c or t.

T Beams with Single Reinforcement.

Class II.—n greater than d_s

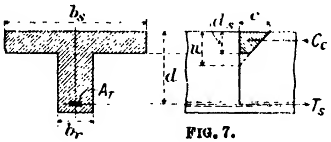

FIG. 7.

$$r = \frac{nd_s\left(1-\frac{d_s}{2n}\right)b_s}{(1-n)mb_r} \quad . \quad . \quad . \quad . \quad . \quad (24)$$

$$A' = \frac{B}{td\left(1-\frac{3nd_s-2d_s^2}{6n-3d_s}\right)} \quad . \quad . \quad . \quad . \quad (25)$$

$$n = \frac{d_s^2\frac{b_s}{b_r}+2mr}{\frac{b_s}{b_r}+2mr} \quad . \quad . \quad . \quad . \quad . \quad (26)$$

$$R = bd^2\left[\left(1-\frac{d_s}{2n}\right)cd_s\left(1-\frac{3nd_s-2d_s^2}{6n-3d_s}\right)\right] (27)$$

$$R = b_r d^2\left[tr\left(1-\frac{3nd_s-2d_s^2}{6n-3d_s}\right)\right] \quad . \quad . \quad (28)$$

ADDITIONAL SYMBOL.

d_s = Ratio of depth or thickness of slab to effective depth of beam.

DESIGNING.—Decide values for m, t, c, and trial dimensions for b_r, b_s, and d. Calculate n by (16) and r by (24), then value of A_T by (25). R is got from (27) or (28). If any other value of r is used than is given by (24), calculate n by (26), and R by (27) and (28), the lesser of these two values being adopted.

CHECKING A DESIGN.—Calculate r ($=A_T/b_r d$), and with this determine n from (26). Test t and c by (18) and (19). If t exceeds the safe stress get R from (28), if c exceeds the safe stress get R from (27), in each case using the maximum safe stress for c or t.

T Beams with Double Reinforcement.

Class I.—n not greater than d_s.

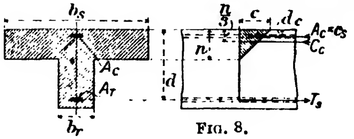

FIG. 8.

$$n=\frac{1}{1+\frac{t}{cm}} \quad . \quad . \quad . \quad . \quad (29)$$

$$t=c\frac{1-n)m}{n} \quad . \quad . \quad . \quad (30)$$

$$c=t\frac{n}{(1-n)m} \quad . \quad . \quad . \quad . \quad . \quad (31)$$

$$c_s=\frac{(n-d_c)}{n}m\times c \quad . \quad . \quad . \quad . \quad (32)$$

$$c_s=\frac{(n-d_c)}{(1-n)}t \quad . \quad . \quad . \quad . \quad . \quad (33)$$

$$A_c=\frac{B-\left[\frac{1}{2}cnb_sd^2\left(1-\frac{n}{3}\right)\right]}{c_sd(1-d_c)} \quad . \quad . \quad (34)$$

$$A_t=\frac{B-\left[A_cc_sd\left(\frac{n}{3}-d_c\right)\right]}{td\left(1-\frac{n}{3}\right)} \quad . \quad . \quad (35)$$

$$n=\sqrt{\left[\frac{m(r_t+r_c)b_r}{b_s}\right]^2+\left[\frac{2m(r_t+r_cd_c)b_r}{b_s}\right]}-\left[\frac{m(r_t+r_c)b_r}{b_s}\right] \quad . \quad (36)$$

$$R=b_rd^2\left[tr_t\left(1-\frac{n}{3}\right)+c_sr_c\left(\frac{n}{3}-d_c\right)\right] \quad . \quad (37)$$

$$R=d^2\left[\frac{1}{2}cnb_s\left(1-\frac{n}{3}\right)+c_sr_cb_r(1-d_c)\right] \quad (38)$$

SYMBOLS.

n=Ratio of distance of neutral axis from compression edge of beam to effective depth.
t=Tensile stress intensity on steel.
c=Compressive stress intensity on concret
c_s=Compressive stress intensity on steel.
m=Modulus ratio=E_s/E_c.
A_t=Area of tensile reinforcement.
A_c=Area of compression reinforcement.
b_s=Breadth of T slab.
b_r=Breadth of rib.
d=Effective depth of beam.
d_c=Ratio of depth to centre of compression reinforcement to effective depth of beam.
r_t=Ratio of area of steel in tension to area b_rd.
r_c=Ratio of area of steel in compression to area b_rd.
B=Bending moment of external forces.
R=Resistance moment of internal stresses.

DESIGNING.—Calculate n by (29), then c_s by (32) or (33), the area of Compression Steel is got from (34), and the area of Tension Steel from (35). The Resistance Moment is got from (37) or (38).

CHECKING A DESIGN.—Calculate r_t and r_c from scantlings given, and n from (36). c_s is got from (32) and (33), the smaller value being adopted. R is obtained from (37) and (38), the former assuming the Steel and the latter the Concrete as stressed to their respective safe limits. The least value of R from (37) and (38) must consequently be taken as the maximum safe R.

T Beams with Double Reinforcement.

Class II.—n greater than d_s.

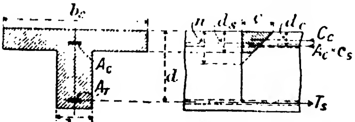

FIG. 9.

$$A_c=\frac{B-\left[\left(1-\frac{d_s}{2n}\right)cdb_sd^2\left(1-\frac{3nd_s-2d_s^2}{6n-3d_s}\right)\right]}{c_sd(1-d_c)} \quad (39)$$

$$A_t=\frac{B-\left[A_cc_sd\left(\frac{3nd_s-2d_s^2}{6n-3d_s}-d_c\right)\right]}{td\left(1-\frac{3nd_s-2d_s^2}{6n-3d_s}\right)} \quad . \quad . \quad (40)$$

$$n=\frac{d_s^2b_s+2m(r_t+r_cd_c)b_r}{2d_sb_s+2m(r_t+r)b} \quad . \quad . \quad . \quad (41)$$

$$R=d^2\left[\left(1-\frac{d_s}{2n}\right)cd\,b_s\left(1-\frac{3nd_s-2d_s^2}{6n-3d_s}\right)+c_sr_c(1-d_s)r\right] \quad . \quad (42)$$

$$R=b_rd^2\left[tr_t\left(1-\frac{3nd_s-2d_s^2}{6n-3d_s}\right)+c_sr_c\left(\frac{3nd_s-2d_s^2}{6n-3d_s}-d_c\right)\right] \quad . \quad (43)$$

ADDITIONAL SYMBOL.

d_s=Ratio of depth or thickness of slab to effective depth of beam.

DESIGNING.—Calculate n from (29), then c_s by (32) or (33), the area of Compression Steel is got from (39) and the area of Tension Steel from (40). The Resistance Moment is got from (42) or (43).

CHECKING A DESIGN.—Calculate r_t and r_c from scantlings given, and n from (41), c_s is got from (32) and (33), the smaller value being adopted. R is obtained from (42) and (43), the former assuming the Concrete and the latter the Steel as stressed to their respective safe limits. The least value of R from (42) and (43) must consequently be taken as the maximum safe R.

Note.—In many cases of double reinforcement the compression reinforcement can be placed at the centre of gravity of the compression area; the formula for R could then be somewhat simplified.

Shearing Stresses and Diagonal Tension in Beams.

These stresses and the methods of resisting them require careful consideration in all cases. At any point in a beam, the horizontal and vertical shearing stresses are of equal value, and these stresses may be looked upon as the connecting link between successive increments of tension in the reinforcement and corresponding increment of compression in the concrete; also, in the case of double reinforcement, in connecting up the increments of tension and compression in the two forms of reinforcement. The tendency of the longitudinal shearing stress is to destroy the adhesion between the concrete and steel, and it is necessary to calculate this value to ensure that no slipping or failure takes place from this cause.

If S represents the total vertical shear, which is equal to the rate of change of the bending moment from point to point along the beam; s_b the shearing stress between concrete and steel; O the periphery of reinforcement, whether one bar or a number of bars; the shearing stress round the bars per unit surface of reinforcement is approximately equal to:—

$$s_b = \frac{S}{O \times 0{\cdot}86d} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (44),$$

and this same stress per unit length may be written—

$$s_b O = \frac{S}{0{\cdot}86d} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (45).$$

The fraction 0·86*d* in the above equations represents the approximate average length of the lever arm, or distance between the centre of tension in the steel and the centre of compression in the concrete; and these equations may therefore be used to give practical values for rectangular or T beams, either with single or double reinforcement.

If *s* represents the unit horizontal shearing stress in the concrete, the shearing stress per unit length on any width *b* of a beam is as follows:—

$$s \times b = \frac{S}{0{\cdot}86d} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (46).$$

This last formula not only gives the value of the horizontal shearing stress, but also that of the vertical shearing stress at the same point, since both these stresses are always of equal value.

Failure by *diagonal tension* is the cause of numerous mishaps, which are frequently attributed to shear. The maximum diagonal tension in a reinforced concrete beam is largely governed by the amount of the horizontal tension in the concrete as well as that of the shearing stress at the same point. From practical experiments and data it would appear that, with average concrete, beams with no web reinforcement are liable to fail by diagonal shear when the vertical shearing stress intensity, at point of failure, averages about 120 lbs. per square inch. Accepting a factor of safety of 4, the shearing stress intensity given by formula (**46**) should not exceed 30 lbs. per square inch. With the same factor of safety, the shearing stress calculated by this formula in beams with web reinforcement may be taken at 120 lbs. per square inch.

Web Reinforcement.

This generally consists either of vertical or diagonal stirrups, alone or in conjunction with inclined bars, these latter generally consisting of a portion of the main reinforcing bars bent upwards as required.

The sectional area of steel to withstand the total shearing force at any vertical section, when the shear bar is inclined at an angle ϕ with the horizontal, should be as follows:—

$$\text{Sectional area required} = \frac{S}{t \times \sin\phi} \quad . \quad . \quad . \quad . \quad (47),$$

t being the tensile strength per square inch of the steel.

The resistance to shear and to diagonal tension in a T beam is practically similar to that for rectangular beams, if the breadth in the former be taken as the breadth of the rib (b_r), this value being compared with the breadth (b) of the rectangular beam.

The breadth of rib in T beams (b_r) will usually be found sufficient to resist any horizontal shear when of a size to give sufficient practical space for embedding the steel reinforcing bars, but to allow for any excessive shear, and for diagonal tension, it is well to keep this breadth of ample size.

Inverted Beams.

Where a beam is continuous over one or more intermediate supports, or where a single span beam is securely fixed or built in at its ends, the effect on the continuous beam over the supports or at the ends of the single span beam is to produce reverse bending, and consequently an inversion of the stresses; the upper portion now being in tension, while the lower portion is in compression. To meet this change in stress, it is usual to bend up a number of the lower reinforcing bars as they approach the ends, and for partial fixing this may be sufficient, but it will generally be found that additional reverse stress bars (sometimes called 'continuity bars') must be added to provide the full area of reinforcement necessary at the upper portion of the beam.

In the case of inverted T beams, it will usually be found that the neutral axis falls outside the slab, and it may therefore be calculated as for an ordinary rectangular beam, of **a breadth (b) equal to the breadth of rib (b_r).**

Deflection of Reinforced Concrete Beams.

An ingenious method of calculating the approximate deflection of a reinforced concrete beam or slab was suggested by Mr. Eli White in the 'Engineering Record' for November 9, 1907. The following explanations are based on this method:—

The deflection of a reinforced concrete beam being proportionate to the elongation of the steel tensile reinforcement, this deflection will be similar in amount, for similar tensile stress intensities, to that of a symmetrical beam, whose flanges are each of an area equal to the tensile reinforcement in the reinforced concrete beam, and are placed at a distance apart equal to twice that of

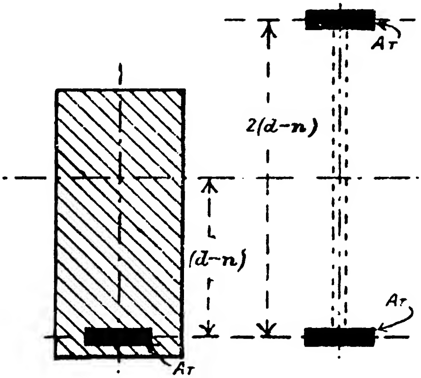

FIG. 10.

the distance between the tensile steel and the neutral axis in the reinforced concrete beam. Fig. 10 indicates to the left a sketch section of a reinforced concrete beam, with tensile reinforcement equal to A_T, and the sketch to the right indicates the section of an imaginary symmetrical steel beam, whose two flanges are each equal in area to A_T and are placed at $2(d-n)$ apart. If t = tensile stress intensity on steel, the

$$\text{Resistance Moment of this symmetrical beam} = 2(d-n) \times A_T \times t. \quad . \quad (48).$$

When any beam is carrying a load, it is obvious that the resistance moment must be equal to the bending moment of the external force acting on the beam.

For this symmetrical beam, the

$$\text{Approximate Moment of Inertia value} = 2A_T \times (d-n)^2 \quad . \quad . \quad . \quad . \quad (49).$$

and taking E at 30,000,000 lbs., the deflection formulæ given in the tables on pages 216 and 217 can be applied to calculate the approximate deflection in any single or double reinforced concrete beam, the correct value for $(d-n)$ being used in the above formulæ.

It should be noted that in the above formulæ the tensile resistance of the concrete has been entirely neglected, and that the formulæ for deflection on pages 216 and 217 are those for beams of uniform section (reinforced concrete beams only more or less approach this condition); for these reasons the calculated deflection will generally be distinctly higher than the actual values, which may at times be found as much as 10 to 15 per cent. less than given by these calculations.

The tables on pages 216 and 217 may prove of service in determining *graphically* the bending moment and shearing stress values for various types of loading; and since these diagrams show clearly the *change of values* they can frequently be used in arranging the main reinforcement and the points where these bars may be bent up to resist shear; independent shear members can also be set out by the same means.

PIPES, CIRCULAR RESERVOIRS OR BINS, ETC.

SYMBOLS USED IN THE FOLLOWING FORMULÆ.

A_h = Sectional area of hoop reinforcement.
C = Direct compressive stress on the shell.
b_r = Breadth of ring under consideration, in inches.
d = Diameter of pipe or reservoir, in inches.
t = Tensile stress in lbs. on steel reinforcement.
p_1 = Pressure in lbs. per sq. in. on shell.
H_w = Head of water, in feet.

When under Internal Pressure.

(Concrete neglected.)

Consider any circumferential strip or ring, then :—

$$A_h = \frac{p_1 \times d \times b_r}{2t} \quad . \quad . \qquad (50)$$

The total area thus found is divided up into any suitable number of hoops or rings.

Where water pressure has to be resisted :—

$$A_h = \frac{0 \cdot 216 H_w \times d \times b_r}{t} \quad . \quad . \quad . \qquad (51)$$

In addition to the hoop or spiral reinforcement determined above, longitudinal bars are necessary to strengthen the concrete shell between each hoop to resist the pressure they have to sustain; the shell here acts as a fixed ended beam or slab of a span equal to the distance between the hoops, and the scantlings calculated by the formulæ previously given for such a type of beam.

Practical considerations generally decide the thickness of the concrete shell, which is usually 1¼ to 2 ins. thick for pipes up to 9 or 10 ins. diameter, and seldom exceeds 3 to 3½ ins. even for large diameter pipes. In vertical reservoirs or bins the thickness towards the base must also be such as will safely carry the weight of the shell.

NOTE.—The required reinforcements for circular bins or silos may be determined by calculating 'p' from formulæ (54) or (55) on next page, for two levels say 12 ins. apart; the difference of the two values thus got will give the pressure per lin. foot and per one foot in height between these levels. Dividing this value by 12×12 (144) will give the average pressure per sq. in., and formula (50) above will at once decide the necessary hoop reinforcement.

When under External Pressure.

(Concrete and hooping both effective.)

$$C = \frac{p_1 d}{2} \quad . \quad . \quad . \quad . \quad . \quad . \qquad (52)$$

The safe load which the shell will sustain depends on the proportion of the steel hooping, and is obtained from formulæ (6), page 396. A few trials with varying thicknesses and proportions, of reinforcements may be required. The minimum practical thickness of shell is that necessary to give complete protection to the steel rods, and to permit of safe transport and handling.

Longitudinal reinforcement is provided under the same conditions as in the last case.

STORAGE BINS OR SILOS.

SYMBOLS USED IN THE FOLLOWING FORMULÆ.

h = Depth of bin in feet, or height of material above any point.
b = Breadth of rectangular bin, in feet.
l = Length of rectangular bin, in feet.
d = Diameter of circular bin, in feet.
p = Pressure against sides of bin in lbs. per lin. foot of horizontal perimeter.
w = Weight per cubic foot of material in bin.
μ = Coefficient of friction within the material stored.
μ_1 = Coefficient of friction between material and sides of bin.
(For values of the last three items, see table below.)

Bins can be conveniently divided into two classes, as follows :—

First.—Shallow Bins, where the plane of rupture (or the plane along which the material would tend to slide if the sides yielded) passes out through the material itself before it meets the opposite side of the bin, and

Second.—Deep Bins, where the plane of rupture meets the opposite side of the bin within the mass of the contained material.

The particular depth forming the dividing point between the above two classes is obtained by the following formulæ.

$$h = b \times \left[\mu + \sqrt{\mu \frac{1 + \mu^2}{\mu + \mu_1}}\right] \quad . \quad . \quad . \quad . \quad . \quad . \qquad (53)$$

All depths less than the above value would indicate shallow bins, all greater depths would be classed as deep bins.

For square bins:—

$$\textit{First Class.}\text{—}p = \tfrac{1}{2}wh^2\left[\frac{1}{\sqrt{\mu(\mu+\mu_1)}+\sqrt{1+\mu^2}}\right]^2 \quad . \quad . \quad . \quad . \quad (54)$$

$$\textit{Second Class.}\text{—}p = \tfrac{1}{2}wb^2\left[\frac{\sqrt{\frac{2h}{b}(\mu+\mu_1)+(1-\mu\mu_1)}-\sqrt{1+\mu^2}}{\mu+\mu_1}\right]^2 \quad . \quad (55)$$

The total pressure on bottom of bin =

(Total weight of material) − ($\mu_1 \times p \times$ perimeter of bin in feet) . (56)

The maximum pressure on the bottom of a bin occurs when

$$h = \frac{b}{2}\left[\frac{1+\mu^2}{\mu+\mu_1}\left(\frac{4\mu_1}{3\mu_1-\mu}\right)^2 - \frac{1-\mu\mu_1}{\mu+\mu_1}\right] \quad . \quad . \quad . \quad . \quad . \quad . \quad (57)$$

For Rectangular Bins the values given by formulæ (54) and (55) will be different for the sides and the ends, since in the latter case the value *l* would replace that of *b*.

For Circular Bins substitute *d* for *b* in formulæ (53), (55), and (57).

These formulæ are not applicable to the inclined sides of Hopper bins, nor to the conical or spherical bottoms of shallow bins.

Nature of Grain, etc.	Weight per Cubic Foot in Pounds.	Coefficients of Friction.

RETAINING WALLS.

Symbols used in the following Formulæ and Diagrams.

h = Height of wall in feet.
w = Weight of a cub. foot of earth in lbs.
e = Angle of surface of earth with horizontal; + when *above*. − when *below* horizontal.
ϕ = Angle of repose of earth.

(*a*) Back of wall vertical, and surface of earth inclined at an angle *e*.

$$\textit{Resultant Pressure} = \frac{wh^2}{20}\left[\text{Cos.}\,e\,\frac{\text{Cos.}\,e - \sqrt{\text{Cos.}^2 e - \text{Cos.}^2 \phi}}{\text{Cos.}\,e + \sqrt{\text{Cos.}^2 e - \text{Cos.}^2 \phi}}\right] \quad . \quad . \quad (58)$$

The *direction* of the resultant pressure is parallel to earth surface, and acts at $\frac{1}{3}h$ from base of wall.

(*b*) Back of wall vertical, and surface of earth horizontal,

$$\textit{Resultant pressure} = \frac{wh^2}{2} \times \frac{1-\sin\phi}{1+\sin\phi} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (59)$$

(*c*) Water pressure.

$$\textit{Resultant pressure} = 31 \cdot 25h^2 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (60)$$

The direction of resultant pressure in (*b*) and (*c*) is horizontal, and acts at a point $\frac{1}{3}h$ from base.

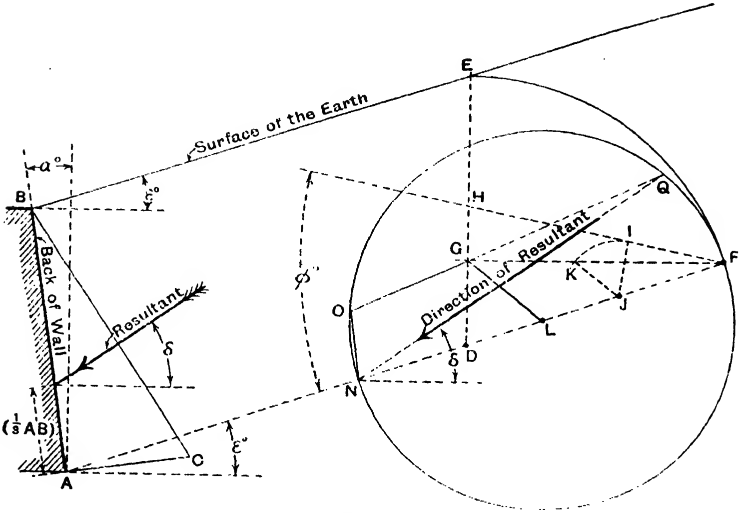

FIG. 11.

To construct this Diagram :—

Draw A F parallel to B E, and at any point D lay off D F = vertical height D E.

Draw F G horizontal, and set off F H, making angle D F H = ϕ.

From any point J in D F describe arc I K tangent to F H, and draw G L parallel to K J.

With L as centre and radius L F, describe circle A D in N.

From N draw N O parallel to A B, cutting circle in O, and join O G.

At A draw A C = O G, and normal to A B.

The area of the triangle A B C multiplied by w will give the resultant pressure on the wall.

The point of action of the resultant is at $\frac{1}{3}$ A B from A.

To find the direction of the resultant pressure, produce O G to Q and join Q N, the direction of the line Q N is that of the resultant pressure

DOMES AND CONICAL COVERINGS.

The following graphic method of determining the stresses in domes is only correct for thin coverings of true spherical or conical section, and formed of a material of uniform weight per unit of surface, and capable of resisting both tension and compression. The majority of reinforced concrete domes approximate to these conditions.

For a detailed explanation of the following statements and formulæ, &c., a reference may be made to a Paper by Mr. W. Dunn, Assoc.M.Inst.C.E., F.R.I.B.A., published in the 'Transactions of the Royal Institute of British Architects,' May 21, 1904.

To construct Figs. 12 and 13. Divide centre line of dome (fig. 12) into any convenient number of parts, and draw the horizontal lines to shell, as 1A, 2B, &c. Draw load line 0–12 (fig. 13) and from O draw radial lines parallel to tangents on the curve at points A, B, &c., till they meet the corresponding horizontal lines; from these meeting points verticals are drawn to the adjacent horizontal lines to complete the zigzag lines shown. If correctly set out, the outer meeting points will lie on a regular curve as shown.

Select a scale such that the length 0–12 corresponds with the total weight of the dome; then the several heights between any two horizontal lines can be scaled off direct to give the weight of the portion between these two lines. To same scale, the radial lengths from O (fig. 13) to any point A, B, C, &c., indicate the total pressure on any horizontal section; the horizontal lengths A1, B2, &c., to same scale, give the total horizontal or radial thrust; the shorter full lines drawn from A, B, &c., give the variation in the radial thrust between the adjoining section lines.

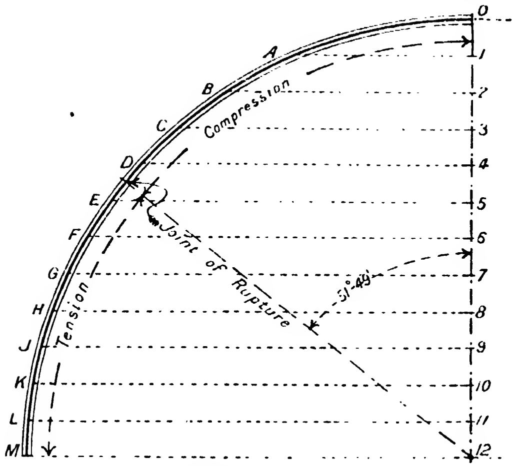

FIG. 12.

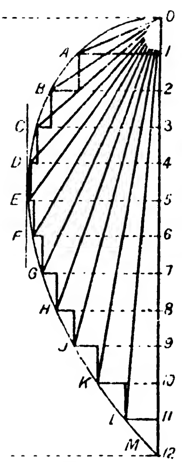

FIG. 13.

To determine the hoop stress, or that acting at the vertical face of any section, the radial thrust must be divided by 6·28 $\left(= \dfrac{\text{Radius}}{\text{Circumference}}\right)$, or by choosing a scale such that the height

0–12 = $\dfrac{1}{6 \cdot 28}$ × total weight of dome, the horizontal lengths to this scale will give the radial thrust direct.

The pressure per lineal unit on any horizontal section is equal to the length of the radial line from O to the particular section measured by the modified scale just mentioned, divided by the radius length at this section.

The position of the joint of rupture is at an angle of about 51¾° with the vertical, or where the tangent to the curve in fig. 12 is parallel to the loadline 0–12; this is also the point of no hoop stress.

The addition of a lantern, or other load, at apex of dome will raise the point O in load line, and also the joint of rupture; the formation of a central opening will depress the point O to level of edge of opening, and lower the joint of rupture.

This graphic method will similarly apply to conical coverings.

ARCHES.

The designing of concrete arched bridges as a rule should be undertaken only by experts, as the accurate determination of the stresses, and the economical arrangement of concrete and steel to resist those stresses, calls for a large amount of skill and experience. The following diagrams and brief explanations will serve to indicate the manner in which such arches can be designed, or the strength of existing arches calculated.

Arched bridges may be divided into three general types :—

1. That in which a continuous arch is provided, without joints or hinges, and connected rigidly to the abutments.

2. Where the arch is hinged or jointed at each abutment, but is continuous between these two points.

3. Where the arch is hinged or jointed not only at the abutments, but also at the centre.

The existence of a hinge or joint implies that any stress in the arch ring must pass through the centre of the joint, and it is necessary to keep this in view when drawing the equilibrium polygon, and to arrange that this polygon passes through the centre of all joints.

Analytical methods of determining the stresses in two-pin and in three-pin arches are described on pages 533 and 534. An analytical method of determining the line of thrust in a parabolic arch with fixed ends is given on page 535, and may be applied to a flat segmental arch which does not sensibly differ from a parabola.

Calculation of Stresses in Arches with Fixed Ends.

To make the solution complete, the derivation, from generally accepted principles, of the conditions to be satisfied, will be briefly indicated. In fig. 14 ds is an extremely short length of an arch

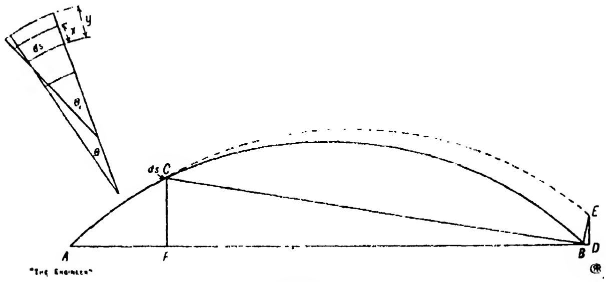

FIG. 14.

with fixed ends at A and B. Throughout this short length the bending moment may be supposed to be constant and equal to M. If the angle subtended by this length before bending is θ and due to the bending moment M is changed to θ_1, the length of a fibre distant x from the neutral axis will have changed from $ds + \theta x$ to $ds + \theta_1 x$, the difference being

$x(\theta - \theta_1)$ or $\frac{x(\theta - \theta_1)}{ds + \theta x}$ per unit of length. The maximum stress f, due to the bending moment M,

s $\frac{My}{I}$, where y is the distance of the extreme fibre from the neutral axis and I is the moment of inertia of the section. The stress on the fibre under consideration is

$$\frac{x}{y} \times \frac{M}{I} = \frac{Mx}{I}$$

Therefore, E, the modulus of elasticity, is:

$$\frac{Mx}{I} \div \frac{x(\theta - \theta_1)}{ds + \theta x}$$

$$\text{and } \theta - \theta_1 = \frac{M(ds + \theta x)}{EI} = \frac{Mds}{EI}$$

θx being negligible compared with ds.

If only this short length of the arch is subjected to bending and the end towards A is supposed to remain fixed, the effect of the bending will be to deflect the end B to a position E, the angle BOE being equal to $\theta - \theta_1$, and therefore equal to $\frac{Mds}{EI}$. As this angle is extremely small, the angle OBE is practically a right angle, and the triangle CFB is similar to the triangle BDE.

Therefore
$$\frac{CF}{OB} = \frac{BD}{BE}$$

or
$$BD = \frac{BE}{OB} \times CF$$
$$= (\theta - \theta_1)CF$$
$$= \frac{Mds}{EI} . CF \qquad . \quad . \quad . \quad . \quad . \quad (61)$$

Also
$$\frac{FB}{OB} = \frac{DE}{BE}$$

or
$$DE = \frac{BE}{OB} \times FB$$
$$= \frac{Mds.}{EI} FB \qquad . \quad . \quad . \quad . \quad (62)$$

In the fixed end arch with rigid abutments the ends are incapable of lateral or vertical movement, and therefore the sum of the quantities BD given by equation (61) is equal to zero, and the sum of the quantities DE given by equation (62) is also equal to zero. The bending of the short section ds is represented by $\theta - \theta_1 = \frac{M ds}{EI}$, and as the tangents at the ends of a fixed end arch remain unchanged, however the arch may be deformed due to bending, the sum of these quantities is likewise equal to zero.

These three conditions will now be applied to determine the resultant thrust line in the arch indicated in fig. 15. As space will not allow of a larger scale being used, the centre line of the arch

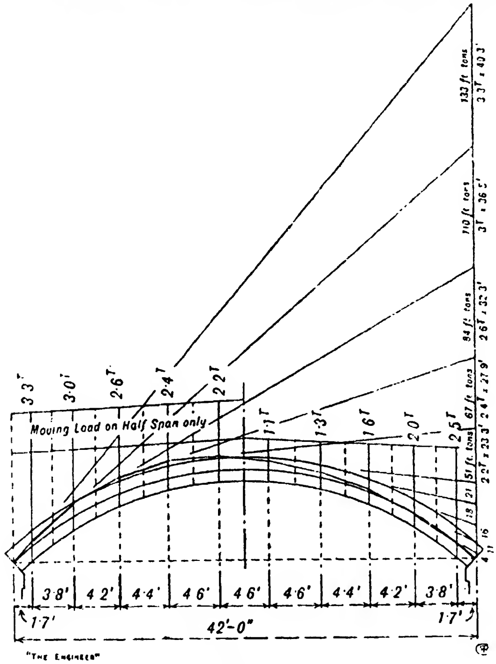

FIG. 15.

has been divided into ten equal parts, but in actual practice it would be preferable to draw the arch to a scale of not less than 4 ft. or 5 ft. to the inch, and to divide the centre line into twenty equal parts. The loads shown on the diagram which correspond to 1 ft. width of the arch, are assumed to be applied at the centre of each of the ten divisions. As the arch is of uniform thickness, the only variable quantity in the expression $\frac{M ds}{EI}$ is the bending moment M, which is equal to the horizontal thrust H multiplied by the vertical distance between the centre line of the arch and the resultant thrust line. By calculating the moment of each load about the right abutment, and plotting these moments consecutively from the springing upwards, as shown in fig. 15, an equilibrium polygon can be drawn, which intersects at the centre of each springing; but as the ends of the arch are not hinged but fixed, the resultant thrust line may intersect the verticals drawn through the centres of the springings above or below these centres. Let these vertical distances above or below the centres of the springings be y at the left abutment and y_1 at the right abutment, distances above the level of the springing being considered positive and distances below this level negative. The ordinates of the resultant thrust line are obtained by dividing the ordinates of the equilibrium polygon, measured from the base line which closes the polygon, by the horizontal thrust H. The respective ordinates of the equilibrium polygon are not altered whether the closure line at the base be horizontal or inclined, and as the calculation depends on small differences between the ordinates of the resultant thrust line and the ordinates of the centre line of the arch, the ordinates of the equilibrium polygon have been calculated for each division by taking moments of all the forces to the left of that division, having previously determined the vertical reaction at the left abutment for a two-hinged arch or simple beam subjected to the same loading, by dividing the sum of the moments of all the loads with reference to the right abutment by the span, *i.e.*, 515 foot-tons ÷ 42 ft. = 12·25 tons.

The expressions which follow represent the vertical distances between the resultant thrust line and the centre line of the arch for each of the ten divisions commencing from the left, and the sum of these expressions is zero.

$$y - \frac{1\cdot7}{42}(y - y_1) + \frac{20\cdot8}{\mathrm{H}} - 1\cdot55$$
$$y - \frac{5\cdot5}{42}(y - y_1) + \frac{54\cdot8}{\mathrm{H}} - 4\cdot23$$
$$y - \frac{9\cdot7}{42}(y - y_1) \times \frac{79\cdot8}{\mathrm{H}} - 6\cdot30$$
$$y - \frac{14\cdot1}{42}(y - y_1) + \frac{94\cdot5}{\mathrm{H}} - 7\cdot70$$
$$y - \frac{18\cdot7}{42}(y - y_1) + \frac{99\cdot0}{\mathrm{H}} - 8\cdot41$$
$$y - \frac{23\cdot3}{42}(y - y_1) + \frac{93\cdot0}{\mathrm{H}} - 8\cdot41$$
$$y - \frac{27\cdot9}{42}(y - y_1) + \frac{82\cdot2}{\mathrm{H}} - 7\cdot70$$
$$y - \frac{32\cdot3}{42}(y - y_1) + \frac{66\cdot2}{\mathrm{H}} - 6\cdot30$$
$$y - \frac{36\cdot5}{42}(y - y_1) + \frac{44\cdot1}{\mathrm{H}} - 4\cdot23$$
$$y - \frac{40\cdot3}{42}(y - y_1) + \frac{16\cdot6}{\mathrm{H}} - 1\cdot55$$

$$10y - 5(y - y_1) + \frac{651\cdot0}{\mathrm{H}} - 56\cdot38 = 0$$

or
$$y + y_1 + \frac{130\cdot2}{\mathrm{H}} = 11\cdot28 \quad . \quad . \quad . \quad . \quad (63)$$

The sum of these expressions, each multiplied by the respective distance from the left abutment, is also equal to zero and the results are as follows :—

$$1\cdot7y - \frac{1\cdot7^2}{42}(y - y_1) + \frac{35}{\mathrm{H}} - 2\cdot6$$
$$5\cdot5y - \frac{5\cdot5^2}{42}(y - y_1) + \frac{301}{\mathrm{H}} - 23\cdot3$$
$$9\cdot7y - \frac{9\cdot7^2}{42}(y - y_1) + \frac{774}{\mathrm{H}} - 61\cdot1$$
$$14\cdot1y - \frac{14\cdot1^2}{42}(y - y_1) + \frac{1332}{\mathrm{H}} - 108\cdot6$$
$$18\cdot7y - \frac{18\cdot7^2}{42}(y - y_1) + \frac{1851}{\mathrm{H}} - 157\cdot2$$
$$23\cdot3y - \frac{23\cdot3^2}{42}(y - y_1) + \frac{2167}{\mathrm{H}} - 196\cdot0$$
$$27\cdot9y - \frac{27\cdot9^2}{42}(y - y_1) + \frac{2294}{\mathrm{H}} - 214\cdot8$$
$$32\cdot3y - \frac{32\cdot3^2}{42}(y - y_1) + \frac{2138}{\mathrm{H}} - 203\cdot5$$
$$36\cdot5y - \frac{36\cdot5^2}{42}(y - y_1) + \frac{1610}{\mathrm{H}} - 154\cdot4$$
$$40\cdot3y - \frac{40\cdot3^2}{42}(y - y_1) + \frac{669}{\mathrm{H}} - 62\cdot4$$

$$210y - \frac{5996}{42}(y - y_1) + \frac{13{,}711}{\mathrm{H}} - 1183\cdot9 = 0$$

or
$$67\cdot2y + 142\cdot8y_1 + \frac{13{,}171}{\mathrm{H}} = 1183\cdot9 \quad . \quad . \quad . \quad (64)$$

The sum of the numerical coefficients in the first column is equal to five times the span. The values of the squares in the second column are taken from tables and the products figuring in the third and fourth columns are worked out using four-figure logarithms. As the same numbers occur two or three times in the various calculations, by working systematically the apparently laborious operations are very much simplified.

The sum of the original expressions, each multiplied by the respective ordinate of the centre line of the arch, is also equal to zero and results as follows :—

$$\begin{array}{l}
1\cdot55y - \frac{2\cdot6}{42}(y - y_1) + \frac{32}{H} - 2\cdot4 \\
4\cdot23y - \frac{23\cdot3}{42}(y - y_1) + \frac{232}{H} - 17\cdot9 \\
6\cdot30y - \frac{61\cdot1}{42}(y - y_1) + \frac{503}{H} - 39\cdot7 \\
7\cdot70y - \frac{108\cdot6}{42}(y - y_1) + \frac{728}{H} - 59\cdot3 \\
8\cdot41y - \frac{157\cdot2}{42}(y - y_1) + \frac{833}{H} - 70\cdot7 \\
8\cdot41y - \frac{196\cdot0}{42}(y - y_1) + \frac{782}{H} - 70\cdot7 \\
7\cdot70y - \frac{214\cdot8}{42}(y - y_1) + \frac{633}{H} - 59\cdot3 \\
6\cdot30y - \frac{203\cdot5}{42}(y - y_1) + \frac{417}{H} - 39\cdot7 \\
4\cdot23y - \frac{154\cdot4}{42}(y - y_1) + \frac{187}{H} - 17\cdot9 \\
1\cdot55y - \frac{62\cdot4}{42}(y - y_1) + \frac{25}{H} - 2\cdot4
\end{array}$$

$$56\cdot38y - 28\cdot19(y - y_1) + \frac{4372}{H} - 380\cdot0 = 0,$$

or

$$28\cdot19y + 28\cdot19y_1 + \frac{4372}{H} = 380 \quad . \quad . \quad . \quad . \quad (65)$$

These three equations—(63), (64) and (65) determine the values :

$$H = 11\cdot32 \text{ tons}$$
$$y = -0\cdot72 \text{ ft.}$$
$$y_1 = 0\cdot50 \text{ ft.}$$

The resultant thrust line can now be drawn following the procedure indicated in fig. 16. The value of $y = -0\cdot72$ ft. is set off below the centre of the left springing, and the value of $y_1 = 0\cdot50$ ft. above the centre of the right springing. From this point and vertically upwards, the values of the moments of each of the loads about the right abutment, divided by the horizontal thrust, are consecutively set off. This can be done graphically as follows :—The sum of the moments of all the loads with reference to the right abutment is 515 foot-tons, which, divided by the horizontal thrust, 11·32 tons, gives 45·4 ft. This distance PQ is set up vertically on the right abutment to the same scale as the drawing of the arch, starting from the point determined by $y_1 = 0\cdot50$ ft. At Q a horizontal line QR is drawn. The value 515 foot-tons is set off to a convenient scale on a diagonal line PR, and on this line the respective moments of each of the loads are plotted. By drawing horizontal lines through the points thus determined, the distance PQ is divided up into parts representing each moment divided by the horizontal thrust. By using the same construction as that employed in fig. 15, the true resultant thrust line is now completed

The absolute maximum deviations from the centre line of the arch occur at the abutments, and the maximum values within the span occur at divisions 4 and 7. Calculating the amount of the deviation at these divisions by substituting the values of y, y_1 and H in the corresponding expressions in the first summation, gives the values $+ 0\cdot34$ ft. at division 4, and $- 0\cdot35$ ft. at division 7. From these values the accuracy of the graph can be checked and the stresses in the corresponding sections of the arch truly calculated.

At division 7, for instance, the bending moment is 11·32 tons × − 0·35 ft. = − 3·96 foot-tons. The direction of the resultant thrust on the left abutment is clearly indicated in fig. 16, and as the horizontal thrust is uniform throughout the arch, the vertical component of the reaction at the left abutment is evidently

$$\frac{45\cdot4 \text{ ft.} + 0\cdot5 \text{ ft.} + 0\cdot72 \text{ ft.}}{42 \text{ ft.}} \times 11\cdot32^{T} = 12\cdot57 \text{ tons}$$

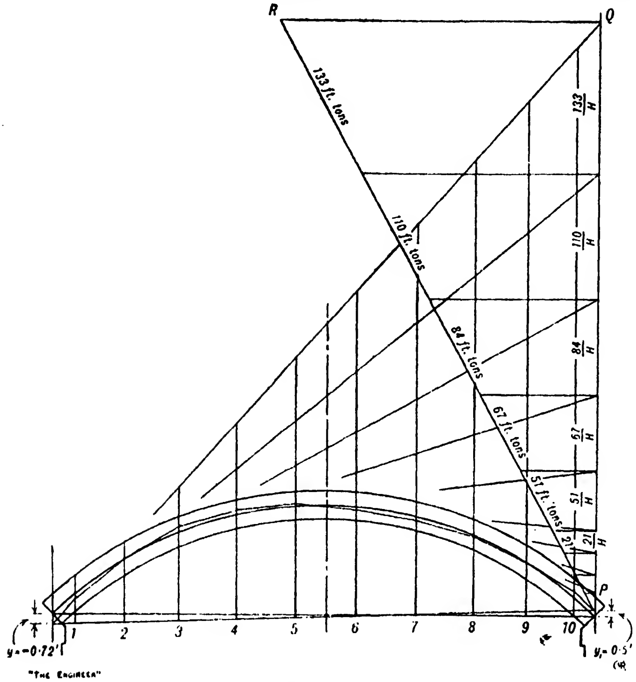

FIG. 16.

The total load is 22 tons and, therefore, the vertical component of the reaction at the right abutment is 9·43 tons. The vertical shear at division 7 is

$$(9\cdot 43^{T} - 2\cdot 5^{T} - 2^{T} - 1\cdot 6^{T} - \tfrac{1}{2} \times 1\cdot 3^{T}) = 2\cdot 68 \text{ tons},$$

and the resultant thrust at this division of the arch is therefore equal to

$$\sqrt{11\cdot 32^2 + 2\cdot 68^2} = 11\cdot 63 \text{ tons}.$$

The section of the arch at division 7 is thus subjected to direct compression of 11·63 tons, and to a bending moment of 3·96 foot-tons, the tension due to this bending being at the extrados of the arch.

The calculation described is for an arch of uniform section. If the section is not uniform, each of the expressions giving the vertical distances between the resultant thrust line and the centre line of the arch must be divided by the moment of inertia of the corresponding section before summing them, and these corrected expressions must also be used in proceeding to the second and third summations.

Specification for Reinforced Concrete Work.

The following sketch specification may be of assistance. It can be modified to any required extent to meet special conditions.

Specification for Reinforced Concrete Work to be executed in erecting New Premises at ………… for Messrs. …………

(Date) ……………

……………………………………

Engineer.

……………………………………

Architect.

General Description and Conditions.—The Structure will be erected in strict accordance with the Engineer's Drawings Nos. ...... and ...... and to any further Detail Drawings to be afterwards provided.

The Structure will consist of (*give general description*). The Foundations shall be taken out to (*the clay, ballast?*). The Maximum Load at this point must not exceed ...... tons per square foot. The average depth of foundations may be assumed as ...... below datum level.

The whole of the work included in this Contract shall be constructed of the best materials and workmanship, and shall be carried out to the entire approval of the Consulting Engineer, and be completed to his satisfaction.

No variations or alterations from Specification or Drawings shall be permitted unless same are approved in writing by the Consulting Engineer.

Immediately on acceptance of his tender, the Contractor must provide a complete and detailed Bill of Quantities (priced in ink) for this work. Should any variations or alterations occur during the carrying out of the work, the variations shall be measured up and priced according to the Bill of Quantities, and any necessary additions or deductions thereafter made from the quoted lump sum price. Any materials or labour required during the progress of the work which are not indicated in the Bill of Quantities shall be paid for at Rates or Prices to be agreed with the Engineer.

The Contractor will be responsible for meeting all requirements of the London County Council, or other Local Authorities, with regard to the mode of construction or the carrying out of same, and shall at once notify the Consulting Engineer should such requirements necessitate any modification in his designs or details.

The Contractor will be held responsible for setting out the Works, and for amending any errors due to inaccuracy, or other cause, at his own cost.

The Contractor must provide for these Works all labour, tools, tackle, boards, horsing, centering, scaffolding, cartage, water, etc.

The Contractor must provide and maintain proper sheds, latrines, and other accommodation for the use of workmen, and proper sheds and shelters for the protection of materials.

The Contractor will be held responsible for all losses, accidents, and damages that may happen to the Works, adjoining properties, or persons during the progress, and caused by the execution of the Works.

The Contractor will be bound to complete all the Works contained in this Specification, etc., within .... months of the date of signing the Contract or obtaining possession of site, under the penalty of .... per week or part of a week as liquidated and agreed damages, except the delay in the opinion of the Engineer arises from causes beyond the control of the Contractors, in which case the Engineer shall grant an extension of time in writing.

The Contractor must allow for making good at his own expense any defect or defects which may become noticeable in the Works during a period of twelve months after certified completion.

Samples.—Samples of all materials must be submitted to the Consulting Engineer, and approved by him in writing before same are used. All materials rejected must be removed immediately from the vicinity of the Works.

Cement.—The Cement used must be the best quality of British Portland Cement, of an approved make, and guaranteed to conform to the Specification of the British Standards Institution for slow-setting cement. Before being used all Cement must be tested, as required by the Engineer, at the Contractor's expense. The Cement should be delivered to the Site in sealed bags bearing the maker's name and the weight of the cement contained.

Cement shall be stored on the Site in such a manner as to permit of easy access for proper inspection and identification. The building used for same must be raised from the ground, and properly weatherproofed to protect the cement.

Sand.—The Sand used shall be clean, sharp, and coarse, composed of grains of various sizes up to particles which shall pass a ¼-inch square mesh, but of which at least 75 per cent. shall pass a ⅛-inch square mesh. It shall be free from all ligneous, organic, or earthy matter.

Aggregate.—This must be composed of Thames ballast; screened, broken stone of a hard close-grained quality; or gravel, cleaned free from organic matter, and angular, varied in size as much as possible, and to pass through a ¾-inch ring, but not through a ¼-inch ring.

Proportions of Concrete.—(*Here specify the composition of concrete, which for usual requirements, may be* 1 *part cement*, 2 *sand*, 4 *aggregate. Foundations are frequently made of a weaker mixture, say* 1 : 3 : 6.) These proportions are approximately correct, but in all cases sufficient sand must be added to fill the interstices. The proportioning should be done in an approved manner, as by means of a bottomless box, to ensure each of the materials being accurately measured.

Mixing of Concrete.—The concrete must be thoroughly well mixed in a suitable machine, sufficient clean water being added to convert the whole into a semi-liquid mass, which will quiver under the blows of the rammer. The water for each batch of concrete must be measured in a small tank, so as to ensure the same amount being used each time. When consent is given to mix any of the concrete by hand, it shall be done as follows:—The necessary quantity of the three materials—coarse aggregate, sand, and cement—shall be measured separately, 5 per cent. more cement being added in addition to the above specified amount. The materials should first be thoroughly mixed dry, then the necessary amount of water added, and the mixing continued till the concrete shows a uniform colour. As far as possible, the mixture shall always be brought to the same degree of wetness. A competent foreman must be in constant attendance at the mixer, to give his approval of every batch which leaves the machine.

Allowable Working Stresses.—(*Here specify maximum stresses desired.*)

Steel Reinforcement.—All steel used should have a tensile strength of not less than 60,000 lbs. per square inch of section, and an elastic limit of not less than 50 per cent., nor more than 60 per cent. of the ultimate tensile strength, with an elongation of not less than 20 per cent. in a length of 8 ins. Any bar must stand bending cold round a bar of its own diameter, through an angle of 180°, and should close down upon itself without fracture on the outside of the bent portion. All welding will be prohibited, unless where absolutely necessary, and must be done only with the sanction of the Consulting Engineer.

All bars shall be free from scale, flaws, or other imperfections, and from oil, but a slight coating of rust is not objectionable. Wherever cinder concrete is used, the bars before being placed in position should receive a coating of neat cement grouting.

Any temporarily protruding bars which shall be exposed to the weather for any period must be protected from rusting by a thin coat of cement grout.

Centering.—All centering must be of dressed timber with close joints, and must be true to line, and sufficiently braced and strutted to be rigid and free from measurable deflection when carrying the dead load of the concrete which is to be placed upon it. A slight camber of ½ in. per 10 ft. of span should be given to all beams, &c. It must also be without appreciable deflection when men are working upon it, and barrows, &c., are being wheeled over it. The joints must be tight, so as to prevent leakage of the liquid cement. The centering shall be arranged so that the sides of the columns can first be removed, then that at the side of beams, and below floor slabs, and finally that below the beams themselves. The time of removal of these several portions shall be arranged with the Consulting Engineer.

Placing of Reinforcement.—All bars must be accurately placed in the exact position shown on the detail drawings, and great care must be taken that they are not displaced during the process of packing the concrete around them. Where, for unavoidable reasons, it is necessary to stop the concreting work, care must be taken to place in position all the bars which will be embedded in the portion of the concrete work which is being executed.

Placing of Concrete.—Before any concrete is put in position a careful inspection of the centering must be made, to ascertain that no dirt, shavings, loose stones, etc., have been allowed to remain in or about the centering, and the woodwork should be well watered to avoid any danger of its sucking up too much moisture from the concrete.

All concrete shall be placed in its final position in the work as soon as possible after mixing. In no case must more than half-an-hour be allowed to elapse before this is done. The concrete must be placed gently into position, in layers not exceeding 6 inches thick, and must not be tipped or dropped from a height. It must then be thoroughly rammed into position, great care being taken to see that the steel reinforcement is thoroughly surrounded by the liquid cement, and that no voids or cavities are left. This can be ensured only by repeated ramming with a suitable tool.

In hot weather the concrete shall be continually moistened for at least a week after placing in position.

In beams and slabs, if any difficulty is found in getting the concrete to pass through the bars which have been placed in position in the bottom of the timber centering, the concrete at the bottom of the beam should be made of finer and more liquid consistency than that used elsewhere, so that it may freely pass between the bars.

Cessation and Recommencement of Work.—Stoppage of work in laying concrete in slabs, beams, etc., will be allowed only at the centre of the span of the slab, or a beam, and the joint with the new concrete should be a vertical plane at right angles to the direction of the span of beam or slab. No joint must be made towards the ends of beams or slabs, or close to a concentrated load.

Wherever a stop has been made in concreting, before recommencing the work, the surface of the existing concrete must be carefully washed with a stiff brush to remove loose particles and dust, and a thick grout of neat cement must be poured over it before the concrete is rammed against it.

Frosty Weather.—No concreting work should be done when the temperature is near or below freezing point. If a frost comes on shortly after any concreting work has been completed, this should be very carefully covered over with sawdust, straw, or sacking, and the centering must be allowed to remain up for at least as long a time after the complete disappearance of the frost as it would have been left in position if no frost had occurred.

Finish.—All concrete roofs and gutters must be laid with the necessary fall, and finished for asphalt, all as may be directed.

All floors shall be finished. (*Here state whether cement, granolithic, preparation for wood blocking, or other covering is desired.*)

The top surface of all outside walls to be weathered.

Tests.—The Maker's Certificate must be provided, when required, with each lot of steel reinforcing bars supplied, but in addition to this the Consulting Engineer shall choose whatever test pieces he may desire from the material delivered, and shall have same tested by Messrs. Kirkaldy, or other firm, and should the result not comply with Specification the right is reserved to condemn all bars included in same consignment.

The cement shall be tested as required, and must comply with the Specification. Cubes of concrete from the material used shall be made as and when directed, and these shall be tested for crushing strength by Messrs. Kirkaldy, or other firm.

The Consulting Engineer shall select at least one bay in each floor, or the equivalent, and these bays shall be tested to 1½ times the safe superimposed load, by means of bricks, cement bags, or in such other manner as the Engineer may decide. Should the deflection under this test exceed $\frac{1}{380}$th part of the span, or should the beam or floor slab fail to regain its normal position after the removal of the load, or show any indication whatever of weakness, the building shall be considered unsafe, and the contractor shall carry out at his own expense such additional work as the Engineer may consider necessary to make the building secure.

The cost of all such testing shall be borne by the Contractor.

Practical Notes.

Wood Strips.

Particularly long lengths of wood for nailing strips in concrete beams should be avoided; they have been known to absorb the moisture from the concrete, and cause serious cracks in the beams. Short plugs are the safest, and where a nailing strip must be used flush with beams, a moulded impress of the wood strip should be made and the strip then removed, and only fixed when the concrete beam is thoroughly dry, it being then secured by means of the plugs. (*Horobin.*)

Durability.

Reinforced concrete will last as long as plain concrete in any situation provided that certain special precautions are taken during its construction. The precautions to be taken are as follows: The materials (cement, sand, and stone) must be of good quality. They must be most carefully and thoroughly mixed and scientifically proportioned, so as to be practically water-proof and air-proof. The mixture must be fairly wet, and must be well punned into position so as to minimise voids. The aggregate should be as non-porous as possible, and any aggregate which is known to have a chemical action on steel should be avoided. The aggregate should all pass through a ¾ in. mesh. The concrete covering should in no case be less than ½ in., and it is suggested that if round or square bars be used the covering should not be less than the diameter of the bar. In structures exposed to the action of water or damp air the thickness of covering should be increased at least 50 per cent., or the size of the aggregate should be reduced so as to ensure a dense skin. In the case of structures exposed to very severe conditions the concrete might be covered with some impervious coating as an extra precaution. The reinforcement should be so arranged that there shall be sufficient space between one piece and its neighbour to allow the concrete to pass and to completely surround every part of the steel. All steel should be firmly supported during the ramming of the concrete, so as to avoid displacement. It should not be oiled or painted, and thick rust should be scraped and brushed off before placing. The scantling of the various members of the structure should be sufficient to prevent excessive deflection. If electric mains are laid down very great care must be taken that no current is allowed to pass through the reinforced concrete. Fresh water should be used in mixing, and aggregates charged with salt should be washed. These recommendations have regard only to the prevention of corrosion of steel and not to fire-resistance or any other property of reinforced concrete. (*Committee of the Concrete Institute.*)

Causes of Failures in Concrete Structures.

Owing to the failure of several reinforced concrete floors in the United States within ten or a dozen years of their construction, Prof. H. J. M. Creighton, of Swarthmore College, examined a large number of reinforced concrete structures in which cracks were developing, and found that in every case the cracks ran along the reinforcing rods, due to the deteriorating action of salt and brine on the concrete. Solutions of the chlorides reacted with the lime and the silicates in the concrete, and penetrating to the iron of the reinforcement converted it into oxide and hydrate, which occupy more space than the metal and force the concrete apart. It was therefore necessary to waterproof reinforced concrete structures which will be in contact with brine, to cease to use in the concrete beach gravel which has not been thoroughly washed with fresh water, and never to add salt to the concrete to prevent it freezing during building operations in cold weather.

Cracking.

According to a recent report, the cracking of reinforced concrete structures is markedly prevalent in the Philippine Islands. A study of this trouble has shown that not a single structure showing rusted steel has been free from salt, the percentage of which varies considerably. In view of this, engineers in the Philippines have been advised that not only is the use of salt water dangerous in concrete structures, but that beach sand and beach gravel should be employed only after having been thoroughly washed with fresh water. The foregoing, and many other similar pieces of evidence, indicate that salt and brine exert a deteriorating action on concrete.

Specification Notes.

Specifications governing concrete construction generally require that 1–2–4 concrete be used in the best class of reinforced concrete construction. In other reinforced concrete work, and in some mass concrete work, 1–3–5 concrete is specified, while in other mass work, such as dams, gravity retaining walls, etc., 1–3–6 concrete is generally required.

SECTION XIII

EARTHWORK — EXCAVATION — FOUNDATIONS — PILING — DAMS — SCAFFOLDING — STAGINGS — SHORING — TIMBERING EXCAVATIONS — RETAINING-WALLS — CHIMNEYS—STONE AND BRICK ARCHES—PIERS.

EARTHWORK.

To determine the Volume of Earth in a Cutting or Embankment.

First Method (By Simson's Rule).

Divide the length of the cutting or embankment into an even number of equal parts, not less than four, and take the areas of the transverse sections at the points of division. Number all the cross sections consecutively. Add together the areas of the extreme sections, twice the sum of the areas of the intermediate sections bearing odd numbers and four times the sum of the sections bearing even numbers and multiply by one-third of the common distance between the sections. The product will be the volume.

Second Method.

This, although somewhat less accurate than the First Method, is frequently used.

Divide the length of the cutting or embankment into any number of equal parts and take the areas of the transverse sections. Add together half the sum of the areas of the extreme sections and the areas of all the intermediate sections, and multiply by the common distance between the sections.

Third Method.

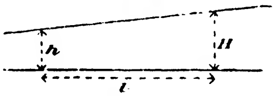

FIG. 1.

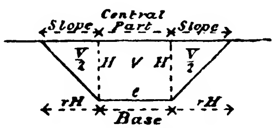

FIG. 2.

H, h = heights of section, in feet, at each end of a length, l, in feet (fig. 1).
rH = breadth of each slope at one end (fig. 2).
rh = breadth of each slope at other end.
(r = ratio of breadth of each slope to height = $\frac{\text{breadth}}{\text{height}}$).
e = base.
$\frac{A}{2}$ = area of each slope at one end.
$\frac{a}{2}$ = area of each slope at other end.
V = cubic contents of both slopes = $\frac{1}{3}(A + \sqrt{Aa} + a) \times l = \frac{1}{3}r(H^2 + Hh + h^2) \times l$.
V = cubic contents of centre = $\frac{1}{2}(H + h)e \times l$.
Q = cubic contents of length, l, in feet = $V + V$.

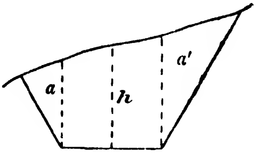
Fourth Method.

If the transverse section is on an incline, instead of horizontal, as in figs. 3 and 4, then, if A, A′, a, and a' are the respective areas of the ends of the slopes,

$$V = \tfrac{1}{6}(A + \sqrt{Aa} + a) \times l + \tfrac{1}{6}(A' + \sqrt{A'a'} + a') \times l. \qquad V = \tfrac{1}{2}(H + h)e \times l.$$

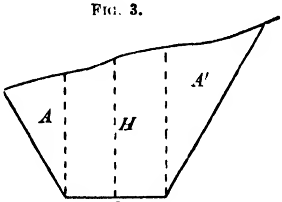
The longitudinal section of the line of railway, road, or canal, having been drawn, and the gradients laid off, the quantities of earthwork may be calculated as follows :—

If the ground is tolerably even, record the heights (or depths in cuttings) on the section at every 100 feet, or some other convenient distance. The sectional areas at each of these recorded heights (or depths) may then be calculated.



c

FIG. 3.



e

FIG. 4.

Let
A = area of section, s = s to 1 slope,
h = height or depth of section,
F = width at formation-level,

all expressed in feet ; then, if the slopes on both sides are the same, as is usually the case,

$$A = h(sh + F).$$

By this formula the areas of the first three sections of a series increasing in height regularly are calculated, and from them the remainder are at once written down by the method of second differences, as follows :

Assume heights to be 1, 2, 3, 4, 5 feet,

$$F = 10, \quad s = 2 \text{ to } 1.$$

Then

	Difference.	Second Difference.
A for 1 ft. = 12		
„ 2 „ = 28	16	4
„ 3 „ = 48	20	
„ 4 „ = 72..	$\frac{4}{24}$	—
„ 5 „ = 100..	$\frac{4}{28}$	—

and so on.

If the cross-slope of the ground is slight, and the areas of the sections do not differ very widely, the quantity of earthwork may be found by taking the mean of the two areas and multiplying by the distance between them, thus :

A′ = area of first section ; A″ = area of second section ; d = distance apart.

$$\text{Cubic contents} = d\,\frac{A' + A''}{2} \text{ feet.}$$

Where the surface of the ground is uneven, the cross slope considerable or the areas of the sections widely different, the best method of finding the volume is to obtain the areas of all the cross sections by means of a planimeter or otherwise and use these areas to obtain the volume by either the First or Second Method.

Earthwork Tables.*

(*H. R. Kempe.*)

The tables on pages 426 to 431 are for the purpose of facilitating the calculation of the volumes of earthwork.

V = cubic contents, in *yards*, of both slopes.
V = cubic contents, in *yards*, of centre part.

V is calculated from the formula

$$V = \tfrac{1}{3}r\,(H^2 + Hh + h^2) \times l,$$

r being = 1, l = 1 chain = 66 feet, and H and h being in *feet* ; so that

$$V = \tfrac{1}{3}(H^2 + Hh + h^2)\,66 \div 27 = \cdot814815\,(H^2 + Hh + h^2) \text{ cubic yards.}$$

V is calculated from the formula

$$V = \tfrac{1}{2}(H + h)e \times l,$$

e being = 1 foot ; so that

$$V = \tfrac{1}{2}(H + h)\,66 \div 27 = 1\cdot22222\,(H + h) \text{ cubic yards.}$$

For any slope other than 1 to 1 the values of V in Table I. must be multiplied by r, that is by $\dfrac{\text{breadth of slope}}{\text{height of slope}}$. Table II. gives the values of V and V for slopes of 1 to $1\tfrac{1}{2}$.

* Revised 1920.

Example.—The length of a cutting is 3 chains, the width 10 feet, the $\frac{\text{breadth of slope}}{\text{height of slope}} = 2$, the height at one end 20 feet, and at the other end 15 feet; what is the cubic content of the cutting?

From table (page 426), $V = 753{\cdot}70$, $\mathsf{V} = 42{\cdot}78$: then,

$$\text{total cubic content} = (753{\cdot}70 \times 2 + 42{\cdot}78 \times 10)3 = 5805{\cdot}60 \text{ cubic yards.}$$

Excavating Machinery.

Excavating machinery may be divided into the following types:—

(1) General purpose navvies.
(2) Trench diggers.
(3) Scrapers, bulldozers, etc.
(4) Power-driven hand tools.

Type (1) is illustrated in Figs. 5 to 9 inclusive, which show the machine in use as (5) a shovel, (6) a back-acting shovel, (7) a skimmer, (8) a drag line and (9) a grab and crane. Machines of this type can be adapted for almost any class of excavation provided timbering does not prevent their use.

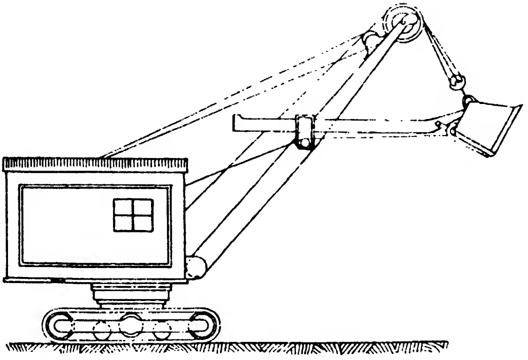


Fig. 5.—Shovel.

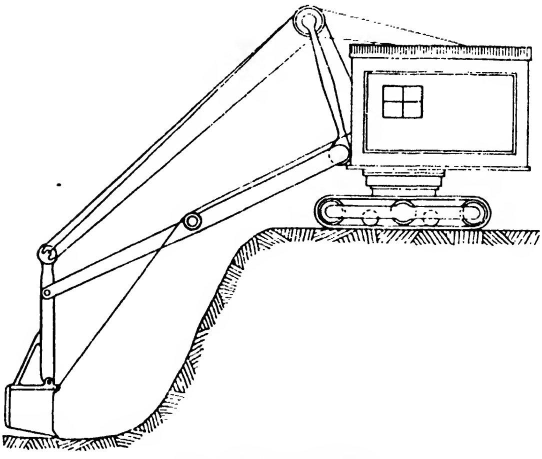

Fig. 6.—Back-Acting Shovel.

Type (2) consists of machines mounted on creeper tracks, which work on the same principle as continuous bucket dredgers. They are suitable for small trenches in ground which will stand for a short time unsupported and which does not contain many mains or service pipes.

Type (3) consists of various units which are pushed or pulled by tractors with creeper tracks. The ground to be excavated may, if very hard, be loosened by some form of plough or ripper drawn

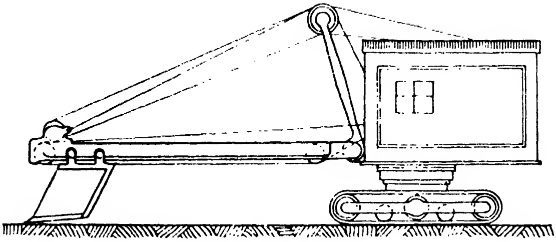

FIG. 7.—Skimmer.

by a tractor. It is then scooped up by a scraper which is, in effect, a shovel mounted on wheels the front end being depressed while scooping and raised for transporting. In some cases a sliding door retains the contents of the scraper which has at the back a plate capable of sliding forward to expel the contents when necessary. The scraper has large balloon tyres to enable it to travel on soft ground.

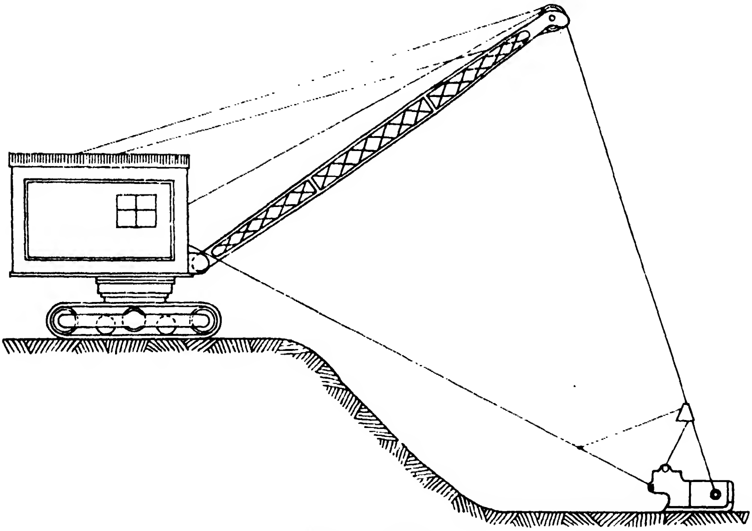

FIG. 8.—Dragline.

After the material has been tipped the surface can be levelled off by means of a bulldozer which is attached to the front of a tractor and consists of a steel plate at right angles to the line of travel of the tractor. This machine removes the material from mounds and deposits it in hollows. A similar machine in which the steel plate is fixed at a smaller angle to the line of travel of the tractor is known as an angledozer and is useful in some cases for moving material sideways to the direction of travel of the machine.

The machines of this type are suitable for levelling and grading large areas in cases in which the excavation is shallow and the material has to be deposited on or near the site. They are largely used in the construction of aerodromes.

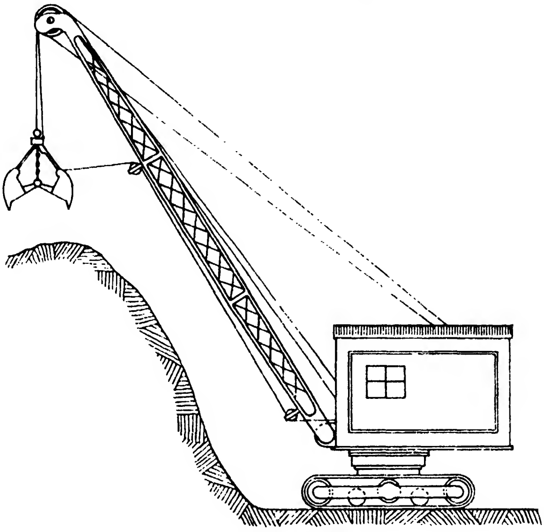

FIG. 9.—Grab and Crane.

Type (4) includes picks, drills, clay shovels, concrete breakers, rammers, etc., driven by compressed air, electricity or internal combustion. They are used where rock, concrete, tough clay or other hard material has to be broken up or where lack of space or other conditions render the use of the previous types impracticable.

Bulking and Shrinkage of Materials.

In estimating the relative amounts of excavation and filling required allowance must be made for the difference in volume of the material before excavation and after being tipped and consolidated. The volume after excavation will also have a bearing on the cost of transportation. Rock, after being broken up will increase in volume very considerably, possibly to the extent of 50 or 60 per cent. on account of the voids formed, but even after being consolidated and partially crushed it will never return to its original volume. On the other hand, loose soil bulks little when excavated, but if placed in an embankment it becomes compressed by the superincumbent weight and may shrink to the extent of 12 or 15 per cent. The relative volumes of other materials may be stated as depending generally upon the pressures to which they are subjected before being excavated and after being tipped and also upon their wetness or otherwise in both cases.

Transporting Earth.

The methods in use for transporting earth comprise barrow runs, horses and carts, motor lorries, tractors and trailers, and rail transport.

Motor lorries with double tyred rear wheels will, except in wet weather, run over ordinary ground without special tracks, but on soft ground tracks formed of old railway sleepers laid transversely are generally used.

Petrol tipping wagons have become very popular in recent years and are hopper wagons mounted on large balloon tyres. They can move at good speeds over soft ground.

Rail transport includes hand-propelled bogies, horse wagons and trucks drawn by locomotives or by ropes worked by stationary engines.

Gradients on transport ways increase cost if excessive. The following limits should not be exceeded except under special conditions: for barrows, 1 in 30; for horses and carts, 1 in 40; for motor transport, 1 in 30; temporary railway track, 1 in 60.

TABLE I. FOR CALCULATING EARTHWORK.

TABLE I. FOR CALCULATING EARTHWORK—(*continued*).

Slopes 1 to 1. Base = 1 foot. l = 66 feet = 1 chain. H and h in feet. V̄ and V in cubic yards.

H	h = 10 V̄	10 V	11 V̄	11 V	12 V̄	12 V	13 V̄	13 V	14 V̄	14 V	15 V̄	15 V	16 V̄	16 V	17 V̄	17 V	18 V̄	18 V	19 V̄	19 V

Barrow and Cart Runs.

The barrows used usually hold about one-tenth cubic yard, and are mostly run on planks, which should not be narrower than 11″, and 3″ thick, nor, as a rule, have a greater inclination than 1 in 12, unless aided by ropes or winding machinery. Box-horses (fig. 10) are the best supports on an incline, either singly or resting one on another; they are mostly from $1\frac{1}{2}'$ to 3′ square, made out of 11″ × 3″ planks. If a considerable height is required, trestles (fig. 11) are used, but boxhorses are stronger, and less likely to get out of repair.

A barrow run is 20 or 25 yards. Each foot of rise is considered equal to 6′ to 9′ additional run.

Wheeling is more economical than carting for distances under 100 yards.

An earth wagon holds as much as 20 or 30 wheelbarrows, and goes one-fifth faster—equal, therefore, to 24 or 36 barrows.

If loaded wagons have to be drawn up an ascent, and the temporary rails are in moderately good order, each foot of ascent may be considered equivalent to about 150 feet of additional horizontal distance.

BOXHORSE.

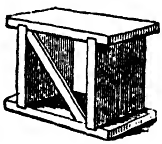

FIG. 10.

TRESTLE.

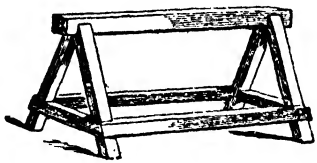

FIG. 11.

When the height exceeds 12 feet, a horse lift is better than wheeling.

For railway embankments and cuttings, locomotives are better than carting for distances over $1\frac{1}{2}$ miles.

Narrow Gauge Track and Tipping Wagons.

Whilst standard gauge track and large trucks are most suitable for railway work, narrow gauge track is often more serviceable for other engineering work for the following reasons:—

(1) It is more easily laid.

(2) It is more convenient for use in confined spaces where many changes of direction are needed.

(3) The trucks are of such a size as to be man-handled with ease when necessary.

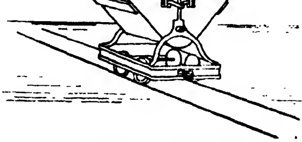

FIG. 12.—Tipping Wagon.

With light track the tipping hopper truck shown in fig. 12 is generally used. The gauge varies from 1 ft. 6 ins. to 2 ft. 6 ins. and the rails weigh from 16 to 20 lbs. a yard. The wagons hold from ½ yard to 3 yards and are of all metal construction.

Tip Wagons.

End Tip Wagons (figs. 13 and 14) will hold 2 yds. filled up to top of sides, as with gravel, 2½ yds. when heaped up with clay, &c., the most economical size. The lowness of sides is of great advantage in filling.

The sides, one end, and bottom of body are of elm 1½″ thick (the earth being confined at other end by movable tailboard), bound together with iron straps at angles, and with upright

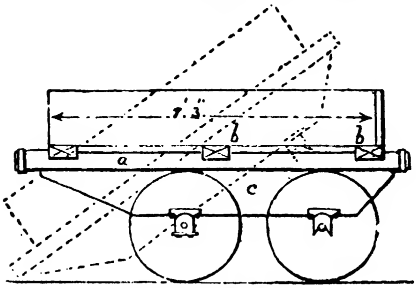

Fig. 13. Side Elevation.

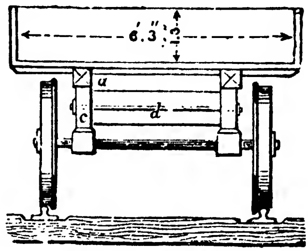

Fig. 14. Cross Section.

straps at sides and one end, all bolted through. The sole is the longitudinal piece, *a*, at each side, of elm, 5″ × 5″, upon which the bottom boards rest. At each end, and in middle of body, is a cross-piece of elm, *b*, 6″ × 3″, bolted down to the soles. The under soles, *c*, are of Memel, 12″ × 3″, between which from side to side are two distance-pieces, *d*, each 9″ × 3″, and alongside of each is a ¾″ bolt. The wheels are of cast iron, 2′ 6″ diam., with wrought-iron axles.

Weight of body of waggon, ¾ ton, of load, 3¼ tons; total load on axles, 4 tons. With well-greased axles, resistance will be about 10 lbs. per ton, but may be as high as 20. Resistance, 80 lbs. per waggon. A horse can draw 150 lbs. 2½ miles an hour for eight hours; a horse can therefore draw two waggons.

Temporary contractor's rails weigh from 25 lbs. to 30 lbs. per yard.

It is generally better to throw earth away than to lead it three miles.

Slopes of Excavations and Embankments.

Slopes of cuttings are often—

In gravel, 1 to 1 when not more than 20′ deep	**In clay, 2 to 1 when well drained**
„ 1½ „ 1 when greater depth	**„ 3 or 4 to 1 when wet**

Slopes of embankments are often—

In gravel, 1½ to 1 when not more than 30′ high	**In clay, 2 to 1 when not more than 40′ high**
„ 2 „ 1 when of greater height	**„ 2½ „ 1 when of greater height**

Chalk and rock will stand perpendicular, or with a slope of about ¼ base to 1 height.

In roads it is often better to make the sides of cuttings, especially on the south side, with greater slope than that they will stand at, to admit sun.

Earth in embankments should be laid in regular horizontal courses not more than 4′ thick. In high embankments they should be rather concave, to avoid slipping.

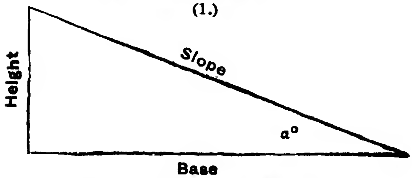
Form of Side Slopes.

The natural, strongest, and ultimate form of earth slopes is a concave curve, in which the flattest portion is at the bottom. This form is very rarely given to the slopes in constructing them; in fact, the reverse is often the case, the slopes being made convex, thus saving excavation for the contractor, and inviting slips.

In cuttings exceeding 10 feet in depth the formation of concave slopes will materially aid in preventing slips, and in any case it will reduce the amount of material which will eventually have to be removed when cleaning up. Straight or convex slopes will continue to slip until the natural form is attained.

Table of Angles and Lengths of Slopes.

(1.)



If Height = 1, then

$$\text{Base} = \cot a^\circ\ ;\ \text{Slope} = \sec a^\circ = \frac{1}{\cos a^\circ}.$$

FOUNDATIONS.

In cases where there is any doubt as to the ground being of too soft a nature to bear the weight of the proposed structure, a trial pit should be sunk, or borings made with boring-rods; samples of the underlying strata may thus be brought up and examined.

Where a soft stratum overlies firm ground, the foundation should, if possible, be carried down to the firm ground; if this is not possible, piles may be driven to the solid ground and the building supported on them, or a number of piers of brickwork, masonry, or iron cylinders sunk.

Where ground is soft to a great depth, a wide trench filled with concrete may distribute the weight over a sufficiently large area to support it, or the trench may be filled with carefully rammed sand, prevented, by sheet piling or some other means, from escaping laterally. Another method is to drive a number of piles, which, by the friction of their sides, would bear the weight of the building.

Foundations on different Soils.

In any structure begun at different levels larger blocks should be used for the deeper parts, if the material admits of it, so as to reduce the number of mortar joints and the risks of unequal settlement.

With Sand or Gravel Foundation overlying Clay on a Slope, intercept water by drain on upper side of building.

Least Depth to escape Effects of Heat and Frost, from 3′ to 6′, according to climate. Not less than 3′ in England for ordinary soils, and 4′ for clay.

Rock.—Good foundation, but must be level; should be levelled, if necessary, in steps. The uneven parts should be filled up with large stones, firmly built with strong cement, or with concrete.

Gravel.—The best foundation.

Sand.—Good foundation, if dry and not liable to be washed away, but this easily occurs; drains with leaky joints may cause a subsidence, or any disturbance of the water-level in the stratum, whether by natural or artificial means, such as pumping operations connected with deep foundations, even at a great distance.

Clay.—Generally very treacherous and damp; the foundation must be deep.

Hard overlying Soft Ground.—If care is taken that the pressure per unit of area is not greater than the firm layer will bear, it may be wiser to build on it, sinking into it as little as possible.

Soft Ground overlying Hard Ground.—If the stratum of soft ground does not exceed 15′ to 20′ it will generally be cheaper to sink down to the firm ground; if not more than about 30′, drive piles or sink wells of masonry. If of indefinite depth, the platform must be supported by friction against the sides, and be therefore of considerable thickness.

Made Ground should never be trusted for the support of much weight, even though it may have lain undisturbed for years.

Chemical Treatment of Foundation Soils.—A method of increasing the bearing power of soft, sandy soils is said to have been employed with conspicuous success in connection with the construction of the Metropolitan Railway, Berlin. On a site composed of alluvial and diluvial sands, two solutions, one rich in silicic acid, the other containing soluble salts or acids, were successively injected under pressure into the soil. The first solution served solely to impregnate the soil, the second, by chemical reactions, causing solidification through the formation of silicates. The method is particularly applicable to soils containing acids and saline solutions, which exert a favourable influence on the chemical reactions involved. Its relative economic advantages have yet to be determined, the cost, principally attributable to the quantity of chemical material required, varying according to the site, and being comparatively lower with damp than with dry, sandy soils.

Loads which Foundations will Bear.

Safe Loads on Ordinary Foundations.

	Tons per sq. ft.		Tons per sq. ft.
1. Hard rock	12 upwards	8. Dry sand	2 to 3
2. Moderately hard rock (strength of engineering bricks)	9	9. ,, ,, with clay	2
3. Very soft rock	2	10. Wet or loose sand	1
4. Hard chalk	4	11. Hard clay	4
5. Soft chalk	1½	12. Ordinary clay	2
6. Marl and firm shale	6	13. Soft clay	1
7. Compact gravel	4	14. Alluvial soil	½ to 1

Intensity of pressure on a rock foundation should at no point exceed one-eighth pressure which would crush the rock.

Safe Loads on Materials.

	Tons per sq. ft.		Tons per sq. ft.
Portland cement concrete, 6, 3, 1 mix	10	Blue bricks in cement mortar, 3 to 1	12
,, ,, ,, 4, 2, 1 ,,	15	Granite	15
Common bricks in lime mortar	3½	Sandstone	12
,, ,, in cement mortar, 3 to 1	5	Limestone	9
London stock bricks in cement mortar, 3 to 1	8	Rubble in cement mortar, 3 to 1	4

Safe Load on Stone Walls and Columns.

	Ashlar Walls, single bedstones. Columns diameter = ⅛ height. Lbs. per sq. in.	Block in course. Columns, diameter = $\frac{1}{12}$ height. Lbs. per sq. in.
Granite	712	570
Hard stone	356	280

Safe Loads on Floors.

London County Council Regulations.

In the area under the control of the London County Council floors must conform to the London Building Act (Amendment) Act, 1935, and the By-laws in connection therewith (see p. 318).

Piled Foundations.

There are two kinds of piled foundations:—

1. *When the soil is soft to a great depth*, area should be enclosed with sheet piling before main piles are driven, to consolidate the ground better. When the tops of the piles are connected by timber, cross-pieces (12 ins. × 9 ins. for 12-in. piles) running across breadth of foundation are first notched on to heads of piles, and longitudinals, or *string pieces*, 12 ins. × 9 ins., running parallel to length of foundation, over them. On these latter, 3-in. or 4-in. planking (better diagonal) is laid to carry masonry. In modern practice the piles are generally of reinforced concrete. After driving, the heads are broken away and the reinforcement bared. The beams and slabs are cast *in situ*, the reinforcement of the piles being incorporated with that of the beams to form a monolithic whole. The platform so formed may be part of the main structure or the latter may be built on it.

2. *When there is hard ground below.*—In this case, as each pile resists partly by resistance to buckling as a column, the cross-section should be greater in proportion to the depth. Maximum depth may be put at 30 ft. The number of piles must be proportional to weight carried.

TIMBER PILES.

Timber piles may be chosen from the following table according to the conditions under which they will be placed:—

(1) In sea-water where sea worms are to be resisted: Greenheart, jarrah, lignum vitae, Huon pine, African oak, teak, creosoted timbers.

(2) In the tropics where ants are to be resisted: Cedar, greenheart, ironwood, jarrah, lignum vitae, locust, Huon pine, pitch pine, teak.

(3) Where exposed to weather and alternately wet and dry: Cedar, cypress, greenheart, blue gum, hornbeam, ironwood, jarrah, larch, locust, oak, Huon pine, Kauri pine, northern pine, white poplar, teak.

(4) Where permanently wet: Beech, white cedar, Spanish chestnut, elm, larch, oak, Huon pine, Northern pine, American plane, teak.

(5) Durable only when kept dry: Ash, Norway fir, American red and yellow pine, grey and black poplar.

(6) Wet or dry, but not alternately: Beech, fir, mahogany, pitch pine, spruce.

Timber in sea-water is rapidly attacked by the wood borers *Teredo navalis* and *Limnoria terebrans*; creosoting will prevent their attack for a considerable time; it has also been suggested to cover piles with sheet copper or flat-headed copper nails. The head of the pile may be protected by a wrought-iron hoop, about 3 ins × 1 in., to prevent splitting when being driven. The lower end should be pointed, the length of the point being from 1½ to twice the diameter, and where the ground is hard, protected with an iron shoe. Piles protected by shoes should have a blunt end 4 to 6 ins. in diameter. The shoes should have a solid point; the base being properly fitted to the blunt end of the pile prevents splitting by bolts which secure the shoes.

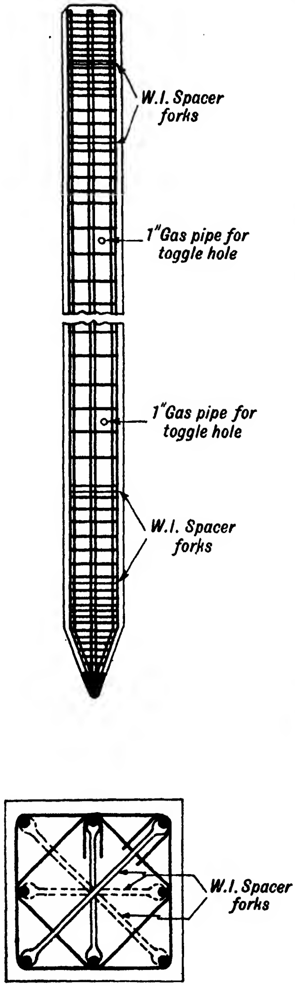

Fig. 15.

Concrete Piles.

(1) Pre-cast Piles.

Fig. 15 shows the commonest type of pile in general use, although other shapes of cross section may be used. In some cases the binding is helical at the same spacing as shown and often additonal longitudinal bars are placed along the centres of the sides, inside the binding, for the top 3 or 4 feet, with additional binding to prevent the bursting of the head of the pile. Toggle holes are left at convenient points for slinging and pitching. Piles should be matured for at least six weeks if made with ordinary Portland cement. If made with rapid hardening cement, however, they may be driven a week, or even less, after being cast. It is desirable to cast piles on the site to avoid damage in transit. A steel thimble-shaped helmet should be placed on the pile while it is being driven, to receive the blow of the monkey or hammer. A bag of sawdust, a pad of matting or old sacks, or a piece of soft timber should be placed in the top of the helmet to prevent the pile from being shattered. To lengthen piles *in situ* the heads are broken away, the reinforcement made up as for the original pile and the main bars overlapped 18 ins. or 2 ft. and tied in position with fine wire. The piles are then shuttered and the tops cast as in the case of columns.

(2) Cast in situ Piles.

Several proprietary methods are available. These have their individual merits and differences but share the general principle which consists of driving a circular steel tube fitted with a pointed cast-iron shoe to the required set. The required length of reinforcement is then assembled and lowered down the tube, concrete being afterwards poured in and the tube withdrawn, leaving a reinforced concrete pile in its place.

In cases where the required set cannot be attained at a reasonable depth by ordinary methods bulb toes are used. These are formed by depositing a small quantity of concrete, partially withdrawing the tube and tamping the concrete by means of a ram, thus causing it to spread. *In situ* piles can be used for lengths up to 70 or 80 ft. and they have the advantages that they can be constructed to the exact lengths required, thus obviating the necessity for splicing or removing surplus length, which often arises in the case of pre-cast piles; they can be formed with bulbs giving greater bearing value and they are not liable to be damaged in being handled or driven.

Loads Carried by Piles.

A timber or steel pile is usually of the same section throughout its length, and it is then only necessary to calculate the load borne by the greatest unbraced length of the pile, regarded as a strut or column. The part below ground may be regarded as held firmly or as quite free, according to the nature of the strata. Piles are often driven so closely together, or have to be of such strength for driving purposes, that they are more than strong enough for their loads. This also applies to piles which support their loads by skin friction only and are of ample section, or numerous, in order that the area subjected to skin friction may be great enough to support the loads. But it is often necessary for the sake of economy, especially when the piles are very long, to load them up to the safe limit.

The calculations of strength may then be made as follows :—

(1) If the pile is unbraced above the ground, the length measured from a few feet below the surface of the ground to the head of the pile is treated as a long column, and the section at the mid-point must be sufficient (see Column formulæ and 'Reinforced Concrete').

(2) If it is braced, the length taken is, in the case of a uniform pile, the longest unbraced length; that is, from a few feet below the ground to the point of bracing, or from the point of bracing to the head of the pile.

(3) If the pile is not uniform, the strength of the section at the mid-point of each of these lengths may have to be calculated separately, each length being treated as a long column.

(4) Bracing must not be considered effective unless it is effective in both directions, except in the following case:

(5) When the dimension of the pile is greater at right angles to the bracing than it is in the direction of the bracing, the two part lengths must be calculated as struts liable to cripple in the direction of the smaller diameter, and the whole length as a strut liable to cripple only in the direction of the larger diameter. If the formula for a square section of a reinforced concrete pile be used, the permissible load, expressed as a proportion of the short column load, may be thus modified. In each case modify the factor with l^2 in it, by multiplying by $\frac{r^2}{r_1^2}$ for the smaller dimension, and by $\frac{r^2}{r_2^2}$ for the larger dimension; where r = radius of gyration of a square section of the same area, r_1 = the smaller actual radius of gyration, and r_2 the larger actual radius of gyration. In the case of reinforced concrete piles, use the sums of the squares of the radii of gyration of the concrete and of the steel as in the formula (see 'Reinforced Concrete'). In this case the outside dimension might be the same, but the reinforcement stronger in one direction than in the other.

(6) For the portion of the pile below the ground :—

If the pile is in firm ground, or passes through a sufficient number of firm layers so that it is effectively steadied, any section of the pile should have sufficient strength, calculated as a short column; that is, it should take a load equal to the safe stress multiplied by the area. The load will be the whole load *less* an amount equal to the area of the pile above the section in question multiplied by the coefficient of friction. This will usually range from about 1 to 4 cwts. per square foot.

If the ground into which the pile is driven is soft and yielding, and is not regarded as effectively steadying the pile, the strengths at mid-points of each length l_1, l_2, . . . must be calculated as those of the mid-section of a long strut or column of that length. These lengths are measured from the head of the pile, or from the point of effective bracing, to successive points in the length of the pile, the last being measured to the tip. The load in each case is the whole load less the load carried by friction on the length of pile above the point in question. Unless the tip of the pile rests on a hard stratum, or is driven some way into a very firm stratum, the load vanishes before the point is reached, and very few calculations will actually be required.

(7) If the pile so rests upon a firm stratum that a large part of the load is carried from the lower end, the same procedure may be adopted, but the loads will, of course, be greater.

If the length of the pile below ground is small, and it is driven into or rests on a hard stratum, the whole length may have to be calculated as a strut carrying the whole load. Such length as is actually in firm ground should, however, be subtracted from the length for calculation.

In some cases the support given by the ground may not be regarded as equivalent to effective bracing, but may be considerable. The strength of any section may then be calculated in the first place as though the soil were quite firm and hard, giving a load W_1, and next as though the soil, though exerting the effect of skin friction, had no bracing effect, giving a load W_2. The actual load will be something between W_1 and W_2, depending upon the estimated value of the soil as a steadier of the pile. Even soft silt must be regarded as exerting a considerable steadying effect; but if there be progressive movement of silt, sand, or peaty ground, no steadying effect can be counted upon. Considerable movement, of course, demands the provision of special bracing, or, with short piles driven into a firm stratum, the calculation of a cantilever effect based upon the observed pressure as recorded by a torsion pressure meter or otherwise estimated.

Generally: to find the necessary strength at any section S, measure the distance upwards to the head or bracing, at A, and an equal distance downwards to a point B. Calculate the load P carried by skin friction above B, and (W — P) is the load carried by AB as a strut. The strength at S will be calculated as that of a short strut if most of the length BS be effectively steadied by the ground; if there be no such steadying the calculation will be that for a strut of length AB (but in no case any greater length). If the lower half of SB is in firm ground, or all of it in weak ground, the section may be calculated for a stress somewhere between that allowable as a short strut and that allowable on the length AB as a free strut.

The strength of the cross-sections of a pile does not change suddenly, and very few calculations need be made in actual practice; but any of the above may be necessary in a particular case.

The two most probable errors are, first, to calculate as free struts lengths which are really steadied by the ground, and, secondly, to neglect making for each section the reduction of load (regarding the section as the mid-point of a strut) due to skin friction from the surface of the ground to a point which is as far below the section as the bracing or head of the pile is above it. The load which the length in question itself carries by skin friction is imposed, upwards, upon some other mid-section nearer the head of the pile.

Loads on Reinforced Concrete Piles.

A well-designed reinforced concrete pile, 14 ins. by 14 ins. in section, will carry a load up to 100 tons (calculated). In actual practice such piles are carrying loads of 60 to 70 tons (at Bristol up to 65 tons; in the Thames, 15-in. × 15-in. piles, 70 tons).

Pile-sinking with the Water Jet.

In sinking piles the work may sometimes be much facilitated by the use of a water jet. In the case of hollow piles, the usual shoe may be replaced by a funnel-shaped end-piece, and the water pumped through the pile. In sinking cast-iron piles for bridge piers in New South Wales (*E. M. de Burgh*) it was found that a central nozzle with an aperture of 2 ins., and four holes of ½ in. diameter in the conical portion, gave good results in sand and soft clay, the piles being sunk through 14 ft. of sand in an average time of 6 minutes, and the actual rate of movement was about 8 ft. a minute. For sinking in sand not under water it was found expedient to flood the surface round the pile. In clay, the pile was loaded with 10 tons, and after 5 or 10 minutes pumping the pile would sink 6 to 9 ins. At a depth of 11 ft. in the clay, progress was very slow and practically ceased at 13 ft., with the 10-ton load. These piles had flanged joints.

Timber piles can be similarly sunk, the pipe being taken down the side of the pile. On the work referred to above, timber piles, 14 ins. in diameter at one end and 9 ins. at the other, were sunk 16 ft. on an average; the average time taken being 4 minutes, and the water pressure 5 to 7 lbs. per sq. in. in sand and 30 to 40 lbs. per sq. in. in clay. The pipe (2-in.) was taken to a 1½-in. augur hole in the point of the pile.

In driving steel sheet piling at Hodbarrow (*H.S. Bidwell*) a water jet was used in hard ground. Double ram pumps 5½ ins. and 6 ins. in diameter were used, with 10 to 14 h.p. boiler capacity, the water being delivered by a 5-in. pipe, diminishing to 3-in. and to 1½-in. From this a 1½-in. vertical pipe led to two ¾-in. jets. The jet pipes were kept working up and down, with a block and tackle, about level with or slightly below the point of the pile. After three or four tides, the ground had recovered its normal consistency.

Safe Load on Piles.

Rankine gives safe load on piles as follows :—

For piles driven till they reach firm ground, 1,000 lbs. per sq. inch of area of head.

For piles standing in soft ground, by friction, 200 lbs. per square inch of area of head.

Formulæ for Safe Load on Piles.

(1) *Wellington Formula.*

If P = safe load on a pile; h = height of fall in feet;

w = weight of ram; s = penetration per blow in inches.

(P and w must be in the same units—i.e. both in lbs. or both in tons, for example),

$$P = \frac{2wh}{s + 0\cdot1}$$

(2)

If P = safe load on pile in tons; a = sectional area of pile in sq. ft.;

w = weight of ram in tons; E = modulus of elasticity in tons per sq. in.

h = height of fall in ft.; x = weight of pile in tons;

s = depth driven by last blow in ft. l = length of pile in ft.

Rankine's formula,
$$P = \sqrt{\left(\frac{4Eawh}{l} + \frac{4E^2a^2s^2}{l^2}\right)} - \frac{2Eas}{l}.$$

Sanders' formula,
$$P = \frac{wh}{8s}$$

Dutch formula,
$$P = \frac{w^2h}{ks(w + x)}$$

k is a constant = 4 to 6 for concrete piles and 6 to 8 for timber piles.

In Rankine's formula the safe load is taken to be about $\frac{1}{5}$ of the greatest load; if there is a great vibration, the factor of safety should be increased to 8 or 9; where there is no vibration, a factor of safety of 3 or even less may be adopted.

'Engineering News' (U.S.A.) formula, $P = \dfrac{fwh}{p + 1}$

Where p is the average penetration in the last six blows; a factor ranging from 1 to 12 and recommended to be taken as 2.

Hiley's Formula (From the B.S.P. Pocket Book 1932).

A reliable pile driving formula for computing this resistance for all classes of piles and hammers has been obtained by A. Hiley, A.M.I.C.E. (*The Structural Engineer*, vol. 8, Nos. 7 and 8); it has shown satisfactory agreement with many actual loading tests, and is as follows:—

$$R = \frac{Wh\eta}{S + \frac{c}{2}} + (P + W) \quad \ldots \quad (1)$$

$$L = \frac{R}{F} \quad \ldots \quad (2)$$

Where R = resistance overcome in driving, expressed in tons.
W = weight of kinetic member or ram of hammer, in tons.
h = equivalent height of free fall of ram, in inches, taken as 80 per cent. of stroke for drop hammers, and 92 per cent. of stroke for B.S.P. single-acting hammers.
S = set, or penetration of pile per blow, in inches.
c = temporary compression of pile and cap, together with the temporary compression or 'quake' of ground beneath the pile point, in inches, caused by transmission of stress corresponding to R.
η = efficiency of hammer blow, representing the ratio the energy given out after impact bears to the striking energy of the ram.
P = weight of pile including helmet or anvil, in tons.
F = factor of safety against settlement, generally taken from 3 to 4.
and L = safe working load (including self weight of pile) which can be applied to the pile.

The value of η to suit given ratios of $\frac{P}{W}$ for typical conditions of pile driving, are set out in the following table:—

TABLE III.

Ratio of $\frac{P}{W}$	Case 1.	Case 2.	Case 3.	Case 4.
½	0·75	0·72	0·69	0·67
1	0·63	0·58	0·53	0·50
1½	0·55	0·50	0·44	0·40
2	0·50	0·44	0·37	0·33
2½	0·45	0·40	0·33	0·28
3	0·42	0·36	0·30	0·25
4	0·36	0·31	0·25	0·20
5	0·31	0·27	0·21	0·16
6	0·27	0·24	0·19	0·14

In using Table III, the ration of $\frac{P}{W}$ in the given case must first be ascertained.

Case 1 refers to double-acting hammers driving steel sheet piles or R.C. piles.
Case 2 refers to double-acting hammers driving timber piles.
Case 3 refers to single-acting and drop hammers driving timber piles, or R.C. piles fitted with helmet and wood dolly.
Case 4 refers to ditto, when the head of pile or cap is in poor condition.

Suitable allowances for temporary compression, *c*, in inches for typical cases of piles corresponding to medium driving conditions are given in the following table :—

TABLE IV.

Length of Pile.	Temporary Compression c in inches.							
Feet.	Sheet piles.		R.C. piles without helmet.		R.C. piles fitted with helmet and dolly.		Timber piles.	
	(1)	(2)	(1)	(2)	(1)	(2)	(1)	(2)
	in.	in.	in.	in.	in.	in.	in.	in.
20	0·04	0·08	0·27	0·39	0·47	0·79	0·36	0·57
30	0·06	0·12	0·33	0·51	0·53	0·91	0·44	0·73
40	0·08	0·16	0·39	0·63	0·59	1·03	0·52	0·89
50	0·10	0·20	0·45	0·75	0·65	1·15	0·60	1·05
60	0·12	0·24	0·51	0·87	0·71	1·27	0·68	1·21

TABLE V.

Item.	Size numbers of McKiernan-Terry hammers.								
	1	2	3	5	6	7	9B2	10B2	11B
Weight of ram in lbs.	21	48	68	200	400	800	1,500	2,500	3,625
Weight of anvil in lbs.	13	37	40	86	203	314	387	550	700
Weight of casing in lbs. . . .	111	258	567	1,214	2,297	3,886	4,873	6,950	8,860
Total weight of hammer in lbs. . .	145	343	675	1,500	2,900	5,000	6,760	10,000	13,185
Actual stroke in ins.	3·75	5·25	5·75	7·0	8·75	9·5	16·0	20·0	20·0
Average number of blows per minute .	500	500	400	275	230	195	130	105	110
Average kinetic energy of blow in ft.-lbs. . .	100	140	350	820	1,970	3,710	8,500	15,800	20,800

Columns 1 in Table IV refer to a medium driving resistance, assumed to correspond to a stress transmitted through the cross section of the pile of 4,000 lbs. per sq. in. for steel sheet piles; and 1,000 lbs. per sq. in. for R.C. or timber piles.

Columns 2 refer to a very hard driving resistance corresponding to stresses of 8,000 lbs. per sq. in. for steel sheet piles; and 2,000 lbs. per sq. in. for R.C. or timber piles on the cross sectional area.

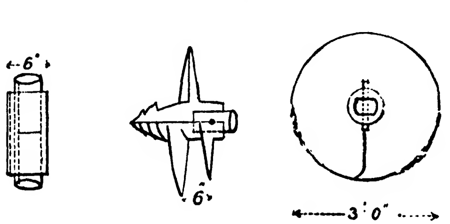
Intermediate values of c corresponding to other intensities of driving resistance between the values stated above, may be obtained by interpolation.

For McKiernan-Terry double-acting pile hammers, the energy Wh in the formula 1 should be expressed in inch-pounds: the resistance similarly will then be given in pounds.

The necessary particulars of these hammers and the kinetic energy (K.E.) given out when driving, are given in Table V.

Screw Piles.

Screw Piles, figs. 16 and 17, are either of wood or of cast or wrought iron; they are seldom less than 6, or more than 18 inches, in diameter. They should be cylindrical in section to enable them to be more readily turned. They are fitted with a screw disc at the foot of the pile, similar to an auger, which usually does not make more than one and a half turns. This



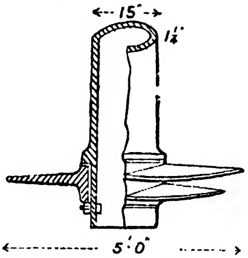


FIG. 16.—Wrought-iron pile with cast-iron disc. FIG. 17.—Cast-iron pile and disc.

disc is of cast-iron, which is made up to 6 feet in diameter. The piles are usually sunk by manual power acting on long levers fixed to a capstan head on the piles, so as to screw them down to a firm stratum. When screw piles have to be sunk through hard ground, a water jet may be used to facilitate sinking.

Cylinders.

Cylinders of cast-iron are sunk to a firm foundation by excavating inside and letting them sink by their own weight, or if that is not sufficient, adding additional weight. As the cylinder sinks, lengths are bolted on by means of flanges which are on the inside. When it is desirable to make the joints water-tight, a cloth strip saturated with thick paint, or a strip of bitumen cloth, is laid between the flanges.

Small cylinders from 4 to 10 feet in diameter are usually cast in lengths of from 5 to 10 feet, without any vertical joint, and from 1 to 1½ inches in thickness with 1½ or 2 inch internal flanges. The thickness in inches necessary to withstand the pressure of the water of small thin cylinders may be approximately found from the formula—

$$t = \cdot 001\, rh\,;$$

where r is the radius of cylinder, and h depth of water, both in feet, and assuming that the metal will stand with safety a compression of 5,000 lbs. per square inch. In no case should the thickness t be less than ½ inch. The inside of the cylinder is excavated by hand, or if the water cannot be kept out, by means of a grab, and is afterwards filled up with concrete or masonry.

At the St. Louis Bridge, U.S.A., the cylinders were 4, 6, and 8 feet in diameter, cast in 10-feet lengths, the metal being 1½ inch. thick with 2½-inch flanges.

The bottom cylinder of the Albert Bridge over the Thames was 21 feet in diameter and 4 feet 6 inches high, cast in one piece; on this was a reducing ring tapering to 15 feet in diameter; all the other rings were 15 feet in diameter and 6 feet high, also cast in one piece.

Brick or masonry cylinders built on an iron or wooden curb are frequently used instead of iron cylinders.

Pneumatic Process of Sinking Cylinders.

Cylinders and large caissons are often sunk by the pneumatic process. The cylinder is made as nearly as possible air-tight, and an air-lock or chamber, with two doors, one opening from the outer air and the other into the cylinder, is bolted on to it; both of these doors open downwards into the cylinder or against the pressure of the air. Air is pumped into the cylinder so as to drive the water out. The workmen then enter the air-lock, the door communicating with the outer air is closed, and the compressed air allowed to enter from the cylinder; when the pressure has become equal the door into the cylinder is opened and the workmen descend. The excavated material is carried up through the air-lock, or blown up through a tube by air pressure. The cylinder is buoyed up by the pressure of the air inside it, and when this is released it tends to sink. It has generally been considered that men cannot work in safety under a greater depth of water than 100 ft.; in the St. Louis Bridge 108 ft. was reached, and 147 ft. under mean low water is said to have been attained in the East River Gas Company's tunnel at New York.

Steel Sheet Piling.

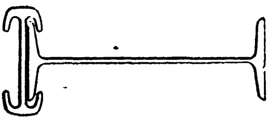

FIG. 18.—Universal Joist Section.

British standard joists are employed, having flanges 5 ins. wide and used in conjunction with a standard clutch or locking bar. The ranges of joists are 15 ins. by 5 ins., 12 ins. by 5 ins., 10 ins. by 5 ins., 8 ins. by 5 ins. and 6 ins. by 5 ins. The clutch is put on the flange of joist at works and the two driven as one. The section has great strength, and is very easily straightened for re-use and possesses high salvage value, as the joists can be used for constructional purposes. Supplied up to 65 ft. lengths.

In addition to the pattern shown above there are several proprietary steel sheet piles on the market. These have various sections, but in most cases consist of steel plates with interlocking grooves running their whole length. Most modern types are trough shaped in order to increase the stiffness of the piling by having most of the metal as far as practicable from the neutral axis.

Driving.

The driving of the steel sheeting is generally effected by means of double-acting pile hammers. The blows are given in rapid succession.

Light-weight sheeting, and also heavy piling, may at times be very advantageously driven with a water jet. Such material as mud, soft clay, and clear sand will ordinarily respond to the jet. If, however, the material is hard clay or a sand containing a heavy percentage of gravel, the water jet is an inadvisable adjunct. A supply pipe of 1 in. diameter and a $\frac{3}{4}$-in. nozzle will be suitable for moderate weights of piling having a width of, say, 12 ins. or less.

Pulling.

It is quite customary to pull piles that have been used in temporary service. The cost of pulling is considerable. While, in general, it is not as great as the cost of driving, still it is to be rated as equal to a large percentage of the expense of driving the very same piles which it is proposed to pull out again. This percentage may rise as high as 75, or even higher. Where the piling has been driven with a wooden maul, or could have been so driven, a simple lever may suffice. This lever may have attached to it metal straps or other devices to facilitate connecting the pile head with the lever. Simple perforations in the top of the pile serve for the introduction of bolts or pins. Ordinary hoisting arrangements may suffice for these piles and for still heavier sheeting. Hydraulic jacks have been used for rather difficult pulling. The jacks may be used mainly for starting the units. By setting up jacks on the heads of the adjacent piles they may be brought to bear beneath a head block provided with a slot through which the intermediate pile may pass on its way up. Another method that has been used simply sets up a framework provided with a strong cross-piece, to which blocks and tackle may be rigged. The line may be operated by hand or by power, as circumstances may require. For pulling piles which have been put down to a considerable depth, a percussion-piston pile-driving hammer may be hung upside down from a derrick boom and used thus to pull the piles. In pulling, the inverted hammer takes hold of the pile by means of the shackle, and steady tension is then exerted on the pile line, which pulls the shackle strap down upon the anvil block, and the hammer is placed in operation. Piles of 26 ft. penetration in clay, sand, and gravel have been withdrawn in from 2 minutes to 10 minutes each, without distortion. The Mc-Kiernan-Terry pile hammers can also be used for pulling purposes.

Timber Sheet Piling.

Timber sheet piles are usually from 9 ins. to 12 ins. wide and 3 ins. to 6 ins. thick. They have chisel-pointed shoes and the tops are bound with iron straps. The shoes are usually bevelled in order that each pile may be forced against the pile previously driven. The joints between the piles may be plain butt joints, rebated joints or of one of the forms shown in fig. 21, p. 448.

Reinforced concrete is sometimes used for sheet piles, the dimensions and method of use being much the same as in the case of timber sheet piles.

Uses of Sheet Piling.

Sheet piling is used for coffer dams, holding up the faces of excavations and similar temporary work and also for quay walls, retaining river banks, etc.

In the latter cases it may be used in the following ways :—

(1) Sheet piling alone driven deep and supporting the ground behind as a cantilever.

(2) As (1) but backed with concrete, in which case it serves as protection and shuttering for the concrete.

(3) As (1) but anchored back by means of tie rods fastened to walings across the front of the piles and to concrete anchor blocks buried in the ground some distance behind the piles. In this case the piles may be designed as simply supported slabs between walings and between the lowest waling and a point about two-thirds the distance between the river bed and the toes of the piles.

(4) Ordinary square piles are driven at regular intervals, walings are fixed behind these and sheet piles are driven at the back of the walings a relatively short distance into the river bed. The square piles, known as king piles, are anchored back to concrete blocks.

Caissons.

Very deep and large piers and abutments of bridges have recently been constructed with steel caissons braced internally so as to prevent them collapsing while sinking. These caissons are excavated and filled with concrete or masonry.

The foundations of the Hawksbury Bridge in Australia were sunk to a depth of 162 ft. below high-water level by dredging.

Frictional Resistance of Pneumatic Foundations (Schmott).

The foundation must be vertical, being kept in equilibrium by the friction of its surface.

According to Mr. F. W. Sweeney in the *Journal of the Western Society of Engineers*, experience in sinking concrete caissons for bridge foundations has shown that building the walls with a batter is not only of no particular advantage in reducing the sinking friction, but it is positively detrimental to the proper guiding of the caisson. It is considered the best practice to have a perfectly plumb wall. When the depth of water will permit, it is generally cheaper to build up a river caisson on shore in the form of a wooden shell, launch it, tow it into position between guide piles and sink it by filling with concrete.

Freezing Process of Sinking Foundations.

The Freezing Process has been used to sink large foundations in treacherous material, especially quicksand. Pipes 10-inch in diameter, open at the bottom, are sunk vertically about 3 feet apart round the ground to be excavated ; inside of these 8-inch pipes, closed at the bottom, are lowered, and again within the latter small pipes. The freezing material is pumped into the smaller pipes, and returns to the cooling tank through the large ones. A solid cylinder of frozen ground is gradually formed round the pipes ; these frozen cylinders unite, forming a solid ring round the place to be excavated. The material to be removed will, of course, be frozen solid, and therefore much more difficult to excavate. An example, at Swansea, was described in detail in *The Engineer* of May 26, 1933. A chemical process of consolidation was also introduced a few years ago. (See p. 436.)

DAMS.

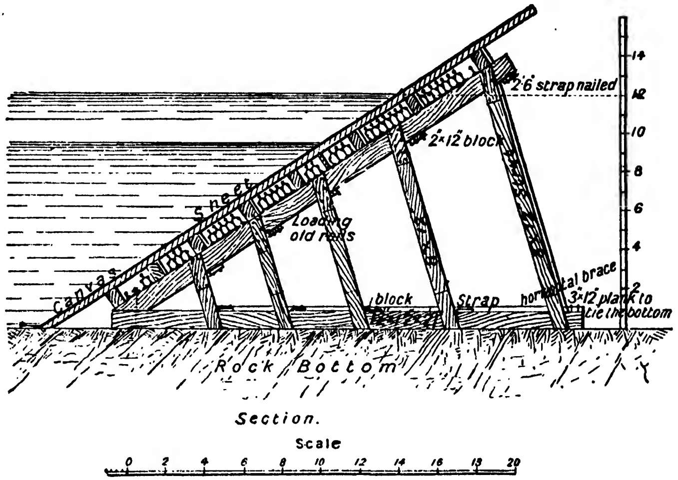

FIG. 19.

If the depth of the water does not exceed 4 feet, the bottom moderately firm, and there is no current, a dam of clay puddle about 3 feet wide on top may be formed round the space to be enclosed; before the dam is commenced care should be taken to remove all loose porous material

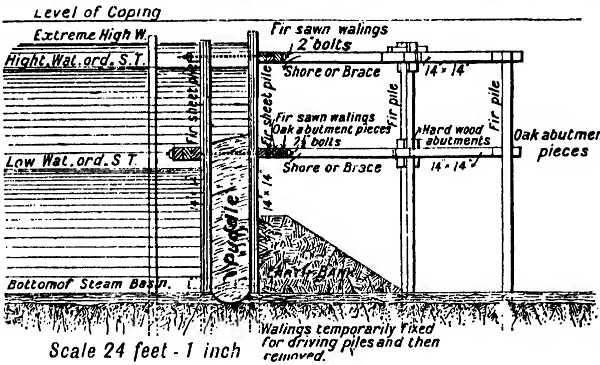

FIG. 20.

and roots from the site, and, if possible, excavate a trench for its foundation. Long lengths of waterproof canvas, sewn together and weighted with a chain stitched to the ends so as to keep it in place, have also been used. The canvas should be supported by a framework of timber (see fig. 19). These frameworks are spaced about 8 feet apart and sheeted with boarding between. The ground should be dredged level to receive them.

Puddle Dams.

Coffer dams of puddle usually consist of two parallel rows of sheet piling, the intervening space between them being filled in with puddle; sometimes three or even four rows, with a puddle wall between each, have been adopted in order to give greater stability and make the dam more watertight.

It is always desirable to make the puddle wall as thin as possible; it is seldom more than 4½ or 5 feet in thickness. Bolts through coffer dams should be avoided as far as possible, as the puddle in settling leaves vacant spaces along them, causing leaks; to remedy this, iron discs through which they pass have been used; these discs are embedded midway in the puddle wall. In coffer dams made for the construction of the East London Railway through the docks, through bolts were entirely dispensed with, their place being taken by buttress piles driven at intervals on the outside which withstood the pressure of the puddle.

Fig. 20 shows a coffer dam used at Portsmouth Dockyard extension. The shoring piles were driven 9 ft. centre to centre, and 12-in. by 12-in. struts, one horizontal and one inclined, were fixed to each.

Puddle.

(Alfred B. Searle.)

Puddle is a highly plastic paste made by mixing 'clay' with about one-fifth of its weight of water, the precise amount depending on the plasticity and dryness of the 'clay.' A perfectly pure 'clay' does not usually produce good puddle, as it is either deficient in plasticity (like china clay) or it shrinks excessively. The former defect can only be remedied by the use of a more highly plastic material; excessive shrinkage may be prevented by mixing a suitable proportion of sand with the clay. For the best results, a piece of puddle when dried should not shrink more than 1¼ in. per linear foot; on the other hand, it should not shrink less than ¾ in. per linear foot or it will probably not be sufficiently impermeable to water.

The materials used must be carefully selected and thoroughly well mixed; some contractors are very careless in this respect and will use anything which has been passed through a pugmill. The correct consistency for good puddle is that at which that paste can be squeezed easily in the hand without any appreciable quantity adhering to the latter when the pressure is released. Puddle made of the consistency of porridge is much too soft for best work, though it is better than an over-dry or badly mixed stiff paste.

Where possible, the materials used for making puddle should, before being mixed with water, be passed between a pair of rollers placed not more than ¼ in. apart, so as to crush any stones or coarse gravel present. It is also desirable that all roots and large stones should be picked out before sending the 'clay' to the mixer.

The usual method of preparing puddle is to mix the local 'clay' with sufficient water to form a soft paste, a pugmill being used for the mixing. The 'clay' may consist of a sandy loam with 50 per cent. of sand and, therefore, incapable of producing a mass impermeable to water except within extremely narrow limits of consistency, which are seldom investigated. On the other hand, it may be so rich in colloidal matter as to have an abnormally high shrinkage on drying; this is a very objectionable property, as puddle which shrinks greatly usually cracks and becomes unreliable. It may be prevented by using a plastic mixture of 'clay' and very fine sand which is well rammed into position, the proportion of sand being such that the puddle, when fully dried, has a shrinkage not exceeding 1 in. per linear foot. No definite figures can be equally suitable for all cases, but two parts of clay to one part of fine sand is often suitable, though much depends on the nature of the clay.

Too much water should not be used in making puddle; it is often better to use moist clay mixed with sand rather than to add sand to a clay-slurry in order to stiffen it. The stiffer puddle must be mixed mechanically in a powerful pugmill, and it must be rammed in position by mechanical rammers. Under these conditions it produces excellent results.

To produce a really satisfactory puddle, it is not sufficient to proceed along 'cookery-book' lines. The available materials should be mixed in different proportions, and each mixture should be tested in a hydraulic press to ascertain its permeability. A useful 'holder' for the puddle is a hollow cylinder made of Portland cement and sand, or even a 4-in. salt-glazed drain-pipe, into one end of which the puddle is placed. The cylinder or pipe is then placed vertically on a flat bed and the pressure applied. A little skill is required to make the puddle fit properly, but once this has been acquired, the test is easy to make.

The worst kind of puddle is that made by preparing a liquid slip, wash, or slurry of clay, and letting this settle. The sand and other non-plastic material normally present is removed in this method of preparing the slip, and the product has too great a shrinkage.

In trenches filled with properly made puddle, there appears to be no advantage in using a 'reinforcement' of strings of jute, as the plain puddle is quite impermeable when properly prepared. A mixture of wood-wool and clay makes an excellent puddle, but requires a machine for its production.

Permeability of Different Puddles.

Tests made under hydraulic pressure to determine the permeability of different puddles showed that it is possible to produce mixtures which, when only 6 ins. thick, will withstand 50 lbs. per sq. in. water-pressure for 5 hours without showing any signs of seepage. Puddles free from sand stood this test the best because of their greater density, but those containing sand are so much less liable to crack that, on the whole, they are the most suitable for general use.

Single Balk Dams.

Dams have also been most successfully constructed of single rows of sheet piling grooved and driven between waling pieces. Fig. 21 is the more usual arrangement; the piles are from 9 to 12 inches in thickness; a groove about 2 inches wide and 2 inches deep is cut out of each

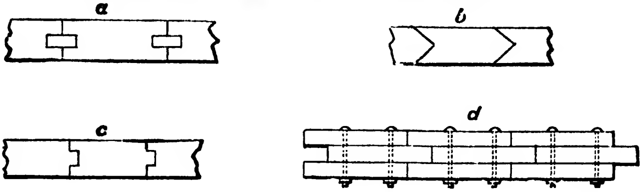

FIG. 21.

pile; into this is fitted a tongue, which is cut to the exact size to fit it. Sheet piles should be sawn die-square with the grooves perfectly straight and true. They should be of sufficient thickness to withstand the water pressure without bulging between the waling pieces. Small leaks at the joints may be stopped by caulking with oakum.

Cribs.

Timber cribs or boxes, which are usually made watertight and floated into position and then sunk, have been largely used in America for foundations of bridges on rock, or in places where there is no fear of undermining by the currents. They are filled with concrete.

Scaffolding.

(Note: Tubular steel scaffolding is now extensively used.)

Standards are upright poles, generally of spruce, 20′ to 50′ long, 5″ to 8″ diam. at butt; those under $2\frac{1}{2}''$ at tips are termed *rickers*, and run about 22′ long. They are firmly fixed in the ground (or in tubs filled with earth, if excavation is inconvenient), 4′. 6″ from wall, 10′ to 12′ apart. When greater lengths are required, two are lashed together, tip to butt, and tightened with wedges To these, on the side next the wall, are lashed horizontal *ledgers*, or *runners*, parallel to the wall at vertical intervals of 3′ 0″ to 5′. They support the *putlogs*, of squared timber (usually birch), 4″ × 3″, 6′ long, one end of which rests on the ledgers, the other in a hole in the wall left by omitting a brick header; they are about $3\frac{1}{2}'$ or 4′ apart, and support the *scaffold boards*, usually 9″ × $1\frac{1}{2}''$, sometimes 3″. Poles called 'braces,' lashed diagonally across every three or four standards, stiffen the scaffold. Masons often use a second row of standards and runners, close to the wall, to prevent the masonry being disfigured by putlog holes.

Fig. 22 (from Spon's 'Dict. of Eng.') shows the arrangement of a bricklayer's scaffold. When the scaffold has to be carried to a considerable height, other poles are lashed to the standards with ropes tightened by wedges. Poles are also lashed diagonally across every three or four standards in the shape of a St. Andrew's cross; these are called braces, and they serve to stiffen or brace the scaffold longitudinally.

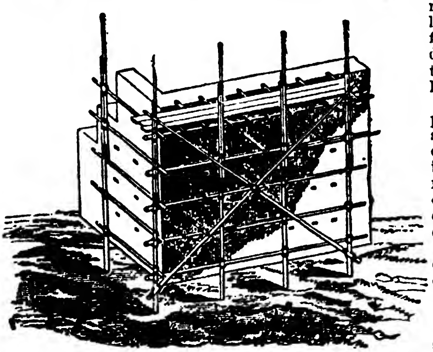

FIG. 22.

In buildings which do not admit of putlog holes in the walls, as where rubble stone or ashlar facing is used, and which do not require heavy machinery for hoisting, or strong timbers in the scaffold, two rows of standards with ledgers are used, one row being close to the wall, and the other at the usual distance, so that both ends of the putlogs may rest on the ledgers. Scaffolds such as we have just described are sometimes used for heights of 90′ or 100′ from the ground, as in building church steeples and similar work. In the erection of houses it is usual to construct a staging about 10′ square on the outside of the scaffolding, for the purpose of hoisting materials, and from which they are distributed for use.

This staging is usually formed with standards and ledgers in the same manner as the scaffold to which it is connected.

Scaffolding Knots.

The principles of a good knot are its facility in tying, its freedom from slipping, and its being easily untied. All knots will jam more or less when subject to a strain. The knots in fig. 23 are shown open before being drawn taut, in order to show the position of the parts. The names usually given, and their uses, are as follows :—

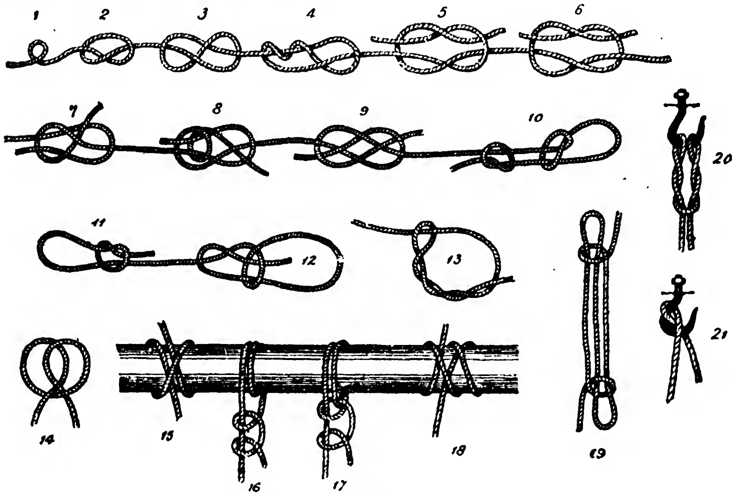

FIG. 23.

1. Bight of a rope.
2. Overhand, or thumb, knot, to prevent a rope running through the sheave of a block.
3. Figure of eight knot, used as No. 2.
4. Stevedore knot: is useful when the rope passes through an eye. It is easily untied after being strained.
5. Square, or reef, knot. This is a most useful knot for joining two ropes of same size. However tightly it jams, it is easily 'upset' and undone.
6. Granny, or thief, knot. This should not be used, as it will jam tightly but not slip (as erroneously supposed), will not 'upset' and consequently is difficult to undo.
7. Single sheet bend, or weavers' knot, used principally for joining two ropes of unequal sizes more securely than a reef knot.
8. Double sheet bend, more secure than No. 7.
9. Carrick bend, for fastening the four guys to a derrick.
10. Flemish loop.
11. Slip knot.
12. Bowline, for making a loop that will not slip. After being strained, this knot is easily untied. Commence by making a bight in the rope, then put the end through the bight and under the standing part, pass the end again through the bight, and pull taut. This knot should be tied with facility by everyone who handles ropes.
13. Timber hitch ; the greater the strain the more tightly it will hold.
14. Clove hitch, consisting of two half-hitches.
15. Clove hitch, as No. 14, showing its application around a pole.
16. Round turn and two half-hitches, for securing a rope to a ledger or for fastening the guys of derricks, shear legs, &c.
17. Fisherman's bend, used when a thick rope, such as a fall, is made fast to a ring.
18. Rolling hitch, used in a variety of ways, chiefly in making fast one rope to another that is held taut.
19. Sheepshank, for shortening a rope when the ends are inaccessible.
20. Catspaw. An endless loop, and used where great power is required.
21. Blackwall hitch. Easily applied, but requires watching; has a tendency to slip.
22. Square lashing. See p. 450.
23. Diagonal lashing. See p. 450.

Square Lashing.—This is used to fix a ledger to a standard and is made as follows: A clove hitch is first made round the standard just below the ledger. The short or running end of the rope is disposed of by twisting it round the long or standing end and the latter is then passed up in front of the ledger, horizontally behind the standard, down in front of the ledger and again horizontally behind the standard. Three more similar turns round the spars are then taken. Two turns known as frapping turns are next taken in a vertical plane between the two spars, round the four turns just mentioned, these being well beaten in and the frapping turns pulled as taut as possible. The lashing is completed by making two half hitches (equivalent to a clove hitch) on the ledger.

Diagonal Lashing.—Used for fixing diagonal braces to standards or to each other. It is made in the following way: A timber hitch is made round both spars diagonally across their intersection and three complete turns, exclusive of the timber hitch, are then taken round them in the same plane. Three turns are next taken across the other diagonal and the lashing is completed with two frapping turns and two half hitches as in the case of the square lashing.

Shoring Buildings.

A plank (fig. 24), C, 9 ins. wide, 3 ins. thick, the length varying with height of building, is placed against upper part of wall to be supported. In this rectangular holes are cut to admit of timber 'needles,' D, from 4 ins. × 6 ins. × 6 ins., and about 12 ins. long. These are let into

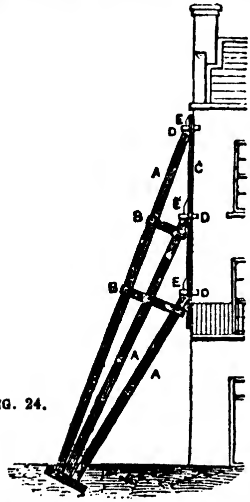

FIG. 24.

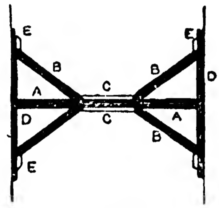

FIG. 25.

the wall about 4½ ins., and project beyond the plank about 4½ ins. to receive the ends of the 'shores,' A.

A cleat, E, is usually nailed to the plank on the upper side of each needle.

The struts, A, are from 6 ins. × 4 ins. in very small buildings to 12 ins. × 9 ins. or 12 ins. in very large; usually half timbers 12 ins. × 6 ins. They are fixed to a footing block, F.

The outer strut is called a 'top raker,' the inner the 'bottom shore,' the centre the 'middle raker.'

Short pieces, B, about 1 in. thick and from 6 ins. to 9 ins. wide are nailed on each side of the shores.

Struts between Houses.

A (fig. 25), horizontal strut, 6 ins. × 4 ins. to 9 ins. × 4 ins.

B, raking strut, 6 ins. × 4 ins.

C, straining-piece, 6 ins. × 3 ins.

D, plank, 9 ins. × 3 ins.

E, cleats.

The horizontal strut, A, is at height above ground equal to about two-thirds height from ground to eaves.

The Timbering of Trenches and Shafts.

Excavations must be timbered where the ground will not stand without support, in order to render possible the construction of the work in hand, to ensure the safety of the men engaged upon it, and to prevent settlement which may result in damage to adjacent buildings or other structures, mains of various kinds and road surfaces. Any 'loss of ground' may, in addition to causing damage, result in movement of the timbering because disturbance of the ground, if of a loose nature, may exert on the timbering pressure far in excess of that of the undisturbed ground. Movement of the timbering may result in insufficient room being available for the permanent work and necessitate 'poling back,' *i.e.* setting back the timbering to the required position—an operation which under some conditions is tedious and costly.

The amount of timbering needed in any excavation depends upon the nature of the ground and the length of time during which the excavation is to remain open, and may range from an occasional support to timbering completely covering the excavated faces. In extreme cases it is necessary even to timber the bottom of the excavation in order to prevent the ground from being squeezed upwards by the pressure at the sides.

It is very important that the area of ground which may be at any time temporarily unsupported during the fixing of timber should be restricted to safe limits. Although in many cases the ground will stand with little or no support for a short time, heavy timbering may be required if the excavation is to remain open for a long period.

In view of the difficulty of fixing timbering perfectly plumb and of the possible reduction in the size of the excavation due to pressure and in some cases the swelling of the ground, it is desirable, when permanent work is to be accommodated, to take out the excavation to dimensions somewhat in excess of those actually required.

The timber actually in contact with the ground consists either of poling boards or of long timbers called runners which are driven down as excavation proceeds. Unless the ground is of a strongly cohesive nature any cavities behind the timbering should be filled either with loose material rammed in or with bricks, wood or other suitable packing.

In the case of loose sand, especially if water be present, the passage of the particles through the small openings between the timbers is often prevented by 'stemming,' *i.e.* the insertion of hay, straw or similar material. This, although it does not prevent the flow of water, stops much of the sand which would otherwise accompany it.

Poling boards and runners are generally of spruce, although pitch pine is preferable and possibly cheaper in the long run on account of the longer period during which it will remain serviceable; heavier squared timber is usually of pitch pine; round bars of larch and wedges of beech or other hard wood, pitch pine being, however, frequently used.

TRENCHES.

(*a*) *Poling Boards.*—The boards are usually from 3 ft. 6 ins. to 4 ft. 6 ins. long and 1 in. to 1½ in. thick. In all cases they are held against the ground by longitudinal timbers called walings, between which and the boards pages (small wedges) are driven. Walings vary from 4 ins. by 2 ins. to 12 ins. by 12 ins., according to requirements, and when of rectangular section they are fixed with the longer dimension vertical for convenience, although this is not the most economical way of resisting lateral bending. The walings are held apart by struts, the best section for which is square, their function being to resist compression. Round and rectangular timbers are, however, frequently used. In most cases strips of wood, called lips, are nailed to the tops of the struts at the ends to hold them level with the walings while they are driven into position. See fig. 26. Large wedges, called driving wedges, are generally used to tighten up the struts, but in some cases slack blocks, as shown in fig. 27, are used, these being more easily removed.

When considerable pressure on the timbering occurs it frequently happens, especially when the timber has been in position for a long time, that the struts cannot subsequently be knocked out on account of their having been forced into the walings which have been partially crushed. When this is anticipated 'cutting-out pieces,' fig. 27, are inserted between the struts and the walings when these timbers are fixed. Cutting-out pieces are removed in the manner indicated by their name and the waste of valuable timber thus avoided.

Struts are fixed at both ends of the walings and as many intermediate struts as necessary are added, the distance apart of the struts depending on the nature of the ground, the size of the walings and the working room required between the struts. Two opposite walings with the struts between them form a complete frame. See fig. 28.

In order to prevent the dropping of the walings, vertical props, called puncheons, are wedged between them, as in fig. 26, the feet of the puncheons resting on the lips of the struts, if any. Lacing boards are also nailed vertically to the faces of the walings near their ends. It is essential that, as the excavation proceeds, the lowest walings should be securely propped from the bottom of the excavation. Should the bottom of the trench be very soft it is sometimes necessary to prevent the settlement of the timbering by slinging it from timbers laid transversely across the top of the trench.

In order to prevent the settlement of the timbering in deep trenches it is usual to insert at intervals, possibly under every third or fourth frame, midway between the struts, raking or back props, as shown in fig. 29, these being fixed as the excavation proceeds, resting on foot blocks securely driven into the ground.

There are three methods of fixing poling boards in general use, these being known as the middling board, tucking board and piling board systems.

Middling Boards.—In this method, shown in fig. 30, each setting of boards is held in position by a single waling. It is only used in fairly good ground and has the disadvantage that it does not readily lend itself to the adoption of the piling board method, to be described later, if bad ground is met with below. In fixing the first setting, the trench having been excavated to the requisite depth, the walings are placed in position resting on temporary supports with poling boards behind them opposite the points at which the struts are to be fixed. Packing pieces, called 'chogs,' are put in between the boards and the walings to allow room for the pages in front

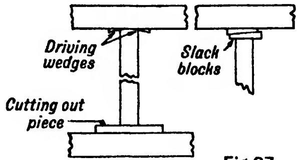

Fig.27

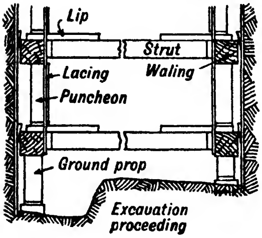

Fig.26

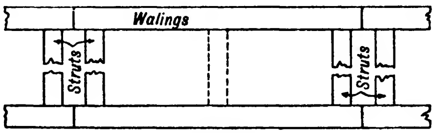

Fig.28

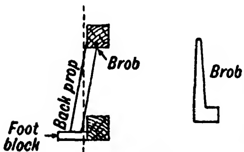

Fig.29

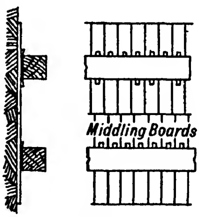

Fig.30

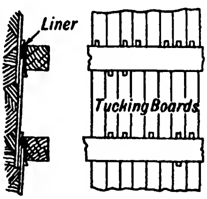

Fig.31

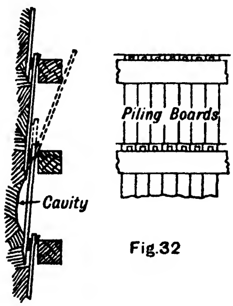

Fig.32

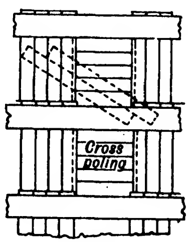

Fig.33

of the boards to be subsequently inserted. The struts are then fixed. The remaining boards are finally placed behind the walings and held against the ground by means of pages driven in behind the walings, usually at the top only but sometimes also at the bottom. In cases in which the ground is good enough to permit it open poling is frequently adopted. This consists of inserting the boards with spaces between. In the second and lower settings the whole of the boards may be placed in position before the walings are fixed, the lower ends being toed into the ground or kept in position by pegs or pages driven into the ground and the tops held by nails driven obliquely into the boards above.

Tucking Boards.—In this system, shown in fig. 31, which is used when the ground is not good enough for middling boards or where bad ground necessitating piling boards is expected to be met with below, the poling boards are held at both ends. The walings, with the exception of those at the top frame, have nailed to them liners of the same thickness as the boards. The poling boards above the walings pass behind the liners and their lower ends are about level with or slightly below the bottoms of the walings. The boards of the setting below are subsequently 'tucked' into the space below the liners. The method of fixing the frames is as described for middling boards except that the temporary support of the top walings while the struts are inserted is usually afforded by raking ground props which do not interfere with the fixing of the frame below.

Piling Boards.—These are illustrated in fig. 32 and are used in bad ground. The boards are usually bevelled off as shown at the lower ends and are in most cases driven as indicated by dotted lines. Distance pieces or chogs are, in the first place, inserted between the liners and the walings and these are taken out as the driving of the boards proceeds. The piling board method has the advantage that the sides of the trench can be supported during the whole of the time excavation is proceeding, the toes of the boards being kept slightly below the level to which the bottom has been excavated. Driving is commenced at a considerable angle from the vertical, and the boards assume the right batter as they are driven. In order to prevent them from approaching too near the veritcal chogs, are placed between them and the boards above. A small cavity behind the boards is inseparable from this method of driving and sometimes the method shown in fig. 33 is adopted to avoid this. In this case the boards are driven in on the slant laterally and are gradually righted. When only a small gap is left between the boards when driving has been done in opposite directions towards the same point, the gap is filled with cross poling as shown. If it is found necessary to resort to the use of piling boards after tucking boards, this is effected by removing the liners from the walings of the lowest tucking frame.

(*b*) *Runners*, shown in fig. 34, are frequently used in bad ground instead of poling boards. They are long timbers up to 20 ft. and occasionally more in length and from 2 to 3 ins. thick by 6 to 9 ins. wide. The lower ends are toed or bevelled off and the heads are usually bound with hoop iron. The runners are driven down behind the frames which are from 3 to 5 ft., apart the pages being loosened to enable this to be done. As in the case of piling boards the toes of the runners are kept slightly below the bottom of the trench and the sides are never unsupported. Sometimes runners are used for the full depth of the trench, in which case the top frame may be at the surface, a guide being fixed at a higher level to ensure the runners being driven vertically. A scaffold or other means whereby the men are enabled to drive the runners may be required, but it is sometimes possible to dispense with driving until the runners are some distance in the ground. Frequently a setting of poling boards is used at the surface as shown in fig. 34 to obviate the use of the guide above ground and reduce the height of the scaffolding (if any). This method is also adopted when the depth of the trench is slightly greater than can be reached by one or more sets of runners.

Whenever runners are used below either poling boards or another set of runners, an internal frame is needed to enable the runners to be driven in front of the frames above. This necessitates the taking out of the upper part of the trench to a width sufficient to allow for any internal frames which may be required.

It is obvious that gaps must occur between the runners below the struts and, if the nature of the ground permits, these small spaces are left until the fixing of the frames below enables boards to be inserted. Should it be found undesirable to leave these areas unsupported, cross poling may be inserted behind the runners as excavation proceeds. See fig. 35.

Occasionally horizontal runners are used, in most cases in small trenches as shown in fig. 36. Sufficient ground is excavated to enable a pair of runners on opposite sides to be placed in position on edge and temporarily strutted. When several runners have been put in vertical, walings, sometimes called 'soldiers,' are placed in position and strutted apart, one or more struts being used for each pair.

SHAFTS.

Shafts may be regarded as short lengths of trench timbered at the ends, and the methods of timbering hitherto described are applicable. The purpose of shafts is, in many cases, to enable tunnels to be driven from them, and they have therefore generally to be sunk to greater depths and to remain open for longer periods than trenches. It is necessary therefore that in these cases even greater care than usual should be taken in the timbering. In deep shafts raking or back props as previously described are of great importance.

The struts are fixed across the short dimension in a small rectangular shaft and the struts at the ends have, in addition to fulfilling their usual function of keeping the walings in position, to act themselves as walings. These end struts are sometimes referred to as 'stretchers.' Then lateral movement is prevented by means of either cleats or straining pieces spiked on to the walings, both being shown in fig. 37, the latter being preferable. The walings also act as struts, being subjected to compression as well as to bending. In the case of a shaft sufficiently large to require strutting in both directions as, for example, that shown in fig. 38, the transverse struts are usually continuous timbers, the longitudinal struts being inserted between them in short lengths.

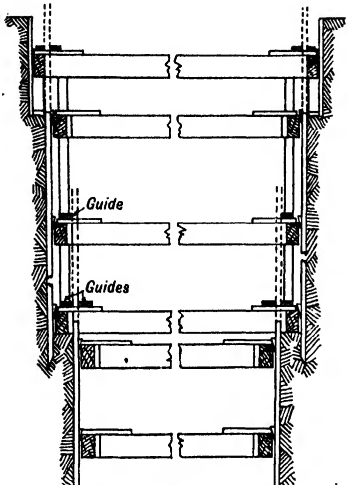

Fig. 34

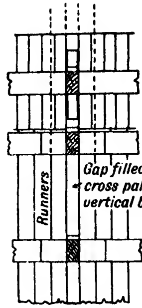

Fig. 35

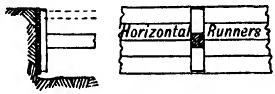

Fig. 36

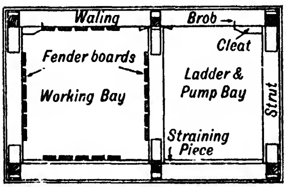

Fig. 37

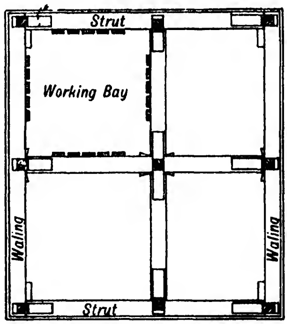

Fig. 38

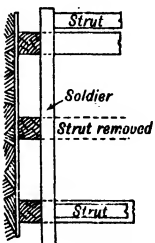

Fig. 39

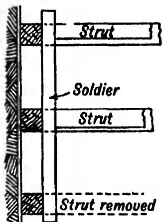

Fig. 40

In designing the timbering of a shaft it is important not to arrange for timbers of such lengths that, owing to the struts of the frames above that for which they are intended, they cannot be readily placed. In some cases walings instead of being the full length of a shaft, as is usual when practicable, have to be in sections. Sometimes it is possible to omit struts or to fix temporary ones in suitable positions until the timbers of the frame below have been placed in position. Props are fixed between the struts of adjacent frames at the points of intersection of transverse and longitudinal struts.

In a shaft divided into bays by struts it is necessary to have a working bay large enough to provide for the passage of skips, brick boxes and the like, and it is frequently necessary therefore to have bays of different sizes. Vertical fenders are nailed between the frames in the working bay to prevent the skips, etc., from being caught by the timbers. Provision must be made in the other bays for ladders, pipes of various kinds and pumps as may be necessary. It is desirable to keep the struts clear of the centre line of a tunnel to be driven from a shaft, in order to facilitate setting out.

In large shafts, in which great pressure is expected to be exerted on the timbering, it is necessary to prevent the upward buckling of the struts by means of raking struts fixed between them and convenient frames above.

Sheet Piling.

In bad ground timber sheet piling is sometimes employed in both trenches and shafts. The method is essentially similar to the use of runners, as sheet piles may be regarded as large runners. The toes of the piles are shod with iron and are cut diagonally so that each pile when driven is forced against the adjacent pile. If necessary the piling may be caulked, hoop iron and yarn being frequently employed for this purpose. Interlocking steel sheet piling is now used more frequently than timber piling.

Removal of Timbers or Parts of Timbers.

Should it be necessary for any purpose to remove one or more struts, this is done by means of 'soldiering,' which consists of placing near each end of the struts to be removed vertical timbers, called soldiers, extending over three or more walings and bearing against the walings from which the struts are to be removed. See figs. 39 and 40. The soldiers are held against the walings by means of soldier struts, and wedges and packings are employed to ensure that the walings are securely held. In the case of shafts the operation just described is necessary when the driving of tunnels is commenced from them.

Refilling Trenches and Shafts.

In refilling excavations only as much timbering is removed as can be done with safety and, unless the work is so situated that settlement is of no importance, it is almost as essential that the ground should be secured during refilling as during excavation. Thorough punning of the refilled material is very important. Sometimes water is used to assist in consolidating the material.

In some cases all timber is left in; in others the frames are removed, boards or runners being allowed to remain. Frequently, however, all timber can be taken out. Frames are removed just in advance of the refilling or construction of the permanent work.

If boards only are being left in, the securing of a setting of piling or tucking boards by filled-in material or permanent work holds the toe of the setting above on account of the overlapping of the settings. Middling boards, being used only in good ground, do not have to be left in. In removing middling boards or tucking boards the ground must remain unsupported between the removal of a setting of boards and refilling, but piling boards and runners can be gradually withdrawn as the filling proceeds. The top one or two frames and settings of poling boards are sometimes left in as a precautionary measure when deep excavations are refilled, even when the lower frames can be removed.

Pressure of Water.

The moment of pressure of water on a retaining wall per each foot of length of wall is $d^3 \times 10{\cdot}4$, where d is the depth of water in feet. This is the moment at 1 foot. The total pressure is $31{\cdot}2\,d^2$, assumed to be concentrated at one-third the depth from the bottom of the water. Hence the moment $10{\cdot}4\,d^3$. The weight of the wall may be assumed concentrated at its centre of gravity, and the effect of the pressure of the water is to turn the wall upon the point O (fig. 41). Calling H the height of the wall in feet, and t its thickness in inches, and assuming one cubic foot to weigh 120 pounds, the moment of stability is $\frac{Ht^2}{2{\cdot}4}$ for rectangular walls, per foot of length; or $d^3 \times 10{\cdot}4$ must not exceed $\frac{Ht^2}{2{\cdot}4}$; or $t^2 = \frac{25\,d^3}{H}$. This enables the thickness of a wall to be determined, that will exactly balance the pressure. Safety would be just secured by adding 50 per cent. to the thickness at the base, and subtracting the same amount from the top thickness, thus giving the wall a sloping back as per dotted line, increasing the acting leverage of the C.G. (centre of gravity) of the section, so that the resultant pressure will now fall within the middle third of the wall thickness. This method is approximate and useful for small construction. Large masonry dams require more special consideration, and may be designed by calculations at each few feet of depth, designing the wall in a series of steps and drawing a final shape to enclose the whole in one harmonious section, which must also fulfil the conditions of strength proper to the material and crushing stress. Special care is necessary that water does not get in between bed joints, as it would greatly assist to turn a wall over.

It is usually considered desirable that the resultant of pressure on a wall should fall within the middle third of its thickness. Thus in fig. 42, if $a\,b$ to any scale represents the total pressure $31{\cdot}2\,d^2$ concentrated at the centre of pressure upon the face of a wall, and $b\,c$ to the same scale is the weight of the wall, the line $b\,c$ being drawn through the C.G. of the cross section, then if the diagonal of the rectangle $a\,b\,c\,d$ cuts the base of the wall within its middle third of thickness, the wall may be assumed fully safe. If the diagonal fall outside the middle third, the thickness of the wall must be increased. It may be made safe by building the wall higher, and thus loading it; but the danger of this method is that a greater area is exposed to wind pressure, and if margins of safety are narrow the addition may be worse than useless in small work. Where a tank wall forms a continuation of an earth retaining wall, for example, special care is necessary.

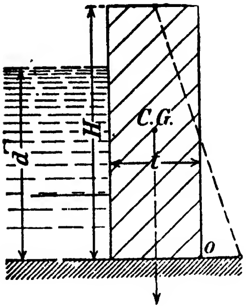

FIG. 41.

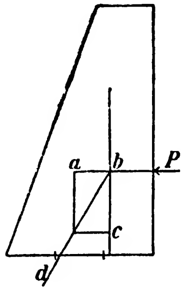

FIG. 42.

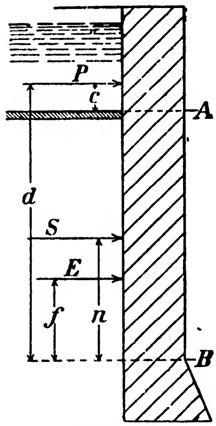

FIG. 43.

The upper part of the wall must be safe at the bed joint level with the bottom of the tank and the wall, taken as a vertical cantilever subject to a lateral thrust at a distance two-thirds of the water depth from the water surface; it must be safe against overturning at any joint lower down. It must also be safe against the added thrust of the earth behind the lower portion plus the further pressure due to the tank full of water above, which must be treated as per the rule on page 459, fig. 45. Thus in fig. 43 the wall must be safe on the line A against the moment of the water pressure P c. It must be safe at the line B against the moment $(P \times d)$ + the moment $(E \times f)$ + the moment $(S \times n)$. Here E is the horizontal component of the earth pressure, and f is one-third A B; S is the horizontal component of the surcharged load, and n is one-half of A B. The safety must be proved at sufficient other depths between B and A and below B. Economy is promoted by sloping the wall against the earth between the points A and B. The wall in the figure is palpably erroneous, being far too thin for its height; it might be made safe by a sufficiency of cross-ties buried in the concrete bottom of the tank, in which case the wall from A to B must be made safe by treating it as a beam exposed to a virtual load at S and E.

Equilibrium of Retaining-Walls.

By Rankine's theory the pressure of earth on a vertical plane, AB (fig. 44), may be considered as acting at a point, P, one-third AB from base A, and in a direction parallel to the surface. Let w = weight of earth in pounds per cubic ft., ϕ = angle of repose of earth, P = total lateral earth pressure per ft. of length, and h = vertical height of wall in feet.

For a bank with horizontal top $$P = \frac{wh^2}{2} \cdot \frac{1 - \sin\phi}{1 + \sin\phi}$$

For bank with any surface slope, θ, of indefinite length

$$P = \frac{wh^2}{2}\cos\theta \frac{\cos\theta - \sqrt{\cos^2\theta - \cos^2\phi}}{\cos\theta + \sqrt{\cos^2\theta - \cos^2\phi}}.$$

For bank with maximum surface slope, ϕ, of indefinite length

$$P = \frac{wh^2}{2}\cos\phi.$$

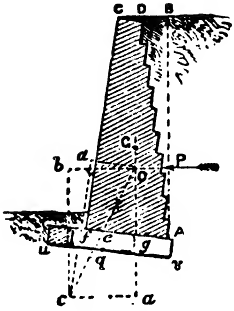

FIG. 44.

For bank with surface slope of definite length an intermediate value is taken.

To resist the pressure there is weight of wall and of earth, ABD, resting on its back, which call W; this acts vertically from centre of gravity, G. The revetment may fail by overturning round f, by crushing at f, by sliding on Af.

Overturning round f.—On any scale make oa = W, ob = P; then oc is resultant (R), acting in direction oe at e. If e falls within base, the revetment will not overturn without crushing the toe at f; but e should fall within the centre third of Af.

Crushing at f.—The resultant, R, must be resolved into two forces, cd (N), perpendicular to, and do parallel to, Af, acting at point e; the former is the crushing force.

Pressure per square inch at f on 1′ length of wall $= \frac{2N}{fg \times 12''}$, where $fg = 3fe$.

The pressure at f should not exceed power of material to resist crushing, divided by factor of safety, 4 to 8 (in practice seldom as high as 8).

Sliding on Af.—Force tending to produce sliding is od; force tending to resist it is N × coefficient of friction at the joint Af od should not exceed N × $\frac{4}{5}$ coefficient of friction.

Surcharged Wall.

If n = height of wall in feet, c = height of surcharge in feet, t = mean thickness of wall, in feet, to sustain horizontal bank; t' = mean thickness of wall, in feet, to sustain bank with indefinitely long natural slope, the factor of safety being about the same as for t; t'' = mean thickness in feet of surcharged wall; then

$$t'' = \frac{nt + 2ct'}{n + 2c}.$$

Effect of Weight of Buildings on Retaining-Walls.

Let w_1 = weight of building per unit of surface; the rest of the notation as at commencement. The total horizontal pressure, P, on revetment, due to the weight of building

$$= w_1(h - x)\frac{1 - \sin\phi}{1 + \sin\phi},$$

acting at $\frac{1}{2}$OB from O; and the total horizontal pressure, P_1, on revetment caused by the earth

$$= \frac{w(h - x)^2}{2} \cdot \frac{1 - \sin\phi}{1 + \sin\phi},$$

acting at $\frac{1}{3}$OB from O.

If the front of the building were farther back from AO the effect would be less, but cannot be determined.

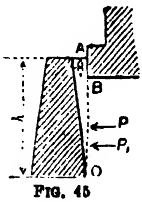

FIG. 45

Rankine's theory assumes the earth a homogeneous, incompressible granular mass with no cohesion. These assumptions are by no means true for some materials, and although giving results erring on the side of safety, more accurate results are obtained by use of Coulomb's theory. This theory assumes that the wall has to support a wedge which has the back of the

wall for one side and a plane termed the 'Plane of Rupture' for the other. By this assumption, where :—

Δ = angle of inclination of the back of the wall to the horizontal.

ε = angle of friction between the base of the wall and the foundation.

θ = the angle of surcharge.

$$P = \frac{wh^2}{2} \cdot \frac{\sin^2(\Delta - \phi)}{\sin^2\Delta \, . \sin(\Delta + \varepsilon)\left\{1 + \sqrt{\dfrac{\sin(+\phi\varepsilon) \, . \sin(\phi - \theta)}{\sin(\Delta + \varepsilon) \, . \sin(\Delta - \theta)}}\right\}^2}$$

Values of ε between concrete and—

Wet clay, 6° to 11°	Dry clay, 17° to 22°
Sand, 22°	Gravel, 22°

For supporting waterlogged ground the pressure due to water and the pressure due to backing are taken separately and then added, but the weight of the backing is reduced by the ratio

$$\frac{\text{Unit weight of backing under water}}{\text{Unit weight of backing in air}} = \frac{w - \left(\dfrac{100 - v}{100}\right) \times 62 \cdot 4}{w}$$

where v = the percentage voids in the backing.

The plane of rupture and total pressure by Coulomb's Wedge Theory can be found graphically by Rebhann's Method.

GRAPHIC DETERMINATION OF EARTH PRESSURE.

(Rebhann's Construction.)

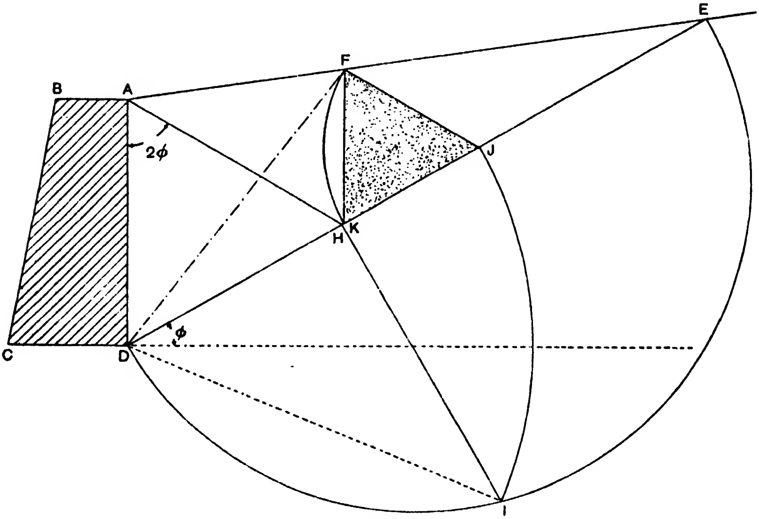

FIG. 46.

(a) *Wall with no surcharge.*—See fig. 46. AE represents the upper surface of the earth, AD the back of the wall, and DE the natural slope of the ground (*i.e.* the angle of repose = ϕ). Set off AH making an angle of 2ϕ with AD and intersecting DE in H. Upon DE as diameter describe a semicircle, and at H draw HI at right angles to DE. From D as centre and with radius DI describe an arc cutting DE in J. Draw JF parallel to AH, then DF is the required plane of rupture. From J as centre and with radius JF describe an arc to cut DE in K and join FK.

Then the area of the triangle FJK in square feet, multiplied by the weight of earth in pounds per cubic foot gives the magnitude of the earth pressure against the back of the wall per foot of its length. This pressure acts at a point two-thirds of the total depth from the surface down the back of the wall AD, and may, in the general case, be taken as acting parallel to DE.

(b) *Wall surcharged.*—See fig. 47. AGE represents the upper surface of the earth. First join DG and then draw A*g* parallel to DG to intersect EG produced in *g*. From *g* draw *gh* making

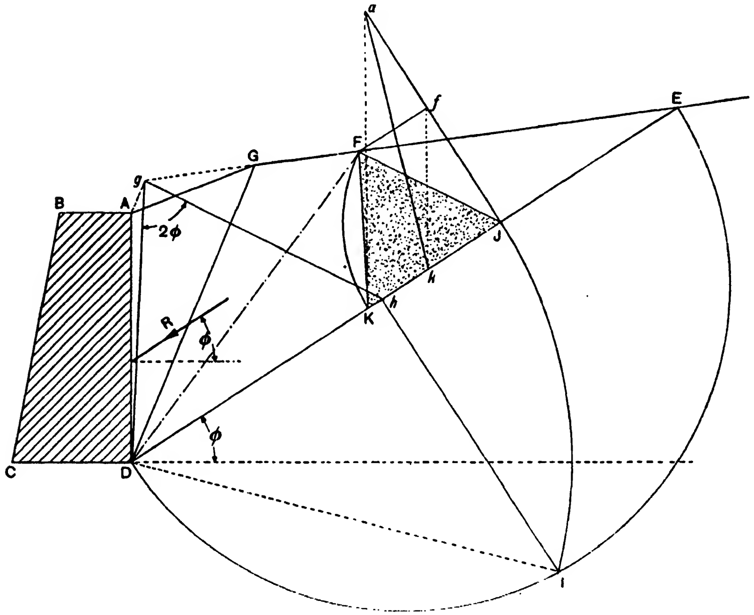

Fig. 47.

an angle of 2φ with D*g*. On DE as diameter describe a semicircle and at *h* draw *h*I at right-angles to DE. From D as centre and with radius DI describe an arc cutting DE at J. Draw JF parallel to *gh*; then DF is the required plane of rupture. The earth pressure triangle FJK is constructed as before. It is most convenient to reduce this triangle to a triangle *a*J*k* having the same area and of a height *a*J equal to the height of the wall. Project F to *f* parallel to DE, and join *a*K. From *f* draw *fk* parallel to *a*K, and join *ak*. Then *a*J*k* is the true earth pressure figure, and by projecting the centre of gravity of this figure on to the back of the wall the 'Centre of Pressure' through which the resultant R must act is obtained.

Foundations of Retaining-Walls.

Find the pressure perpendicular to *uv* (fig. 44). the weights and pressures being taken from point *v* instead of from A. If *q* is centre of pressure, *qu* should nearly equal *qv*, in order that the pressure may be uniformly distributed (this is unnecessary if the pressure at *u* is within what the earth can bear without yielding), and greatest pressure at *u* should not be greater than earth will bear, usually 1 to 1½ ton, or say 2,500 to 3,500 lbs. per square foot. Foundations to be carried deep enough to avoid effects of heat and frost.

Prof. Rankine advises that the distance, fe, of centre of pressure from outside edge in buttresses, chimneys, walls, &c., should be as follows:—In a

Rectangle (solid).

$fe = \text{or} > \frac{1}{3} fA.$

Square (solid).

$fe = \text{or} > \frac{1}{3} fA.$

Ellipse (solid).

$fe = \text{or} > \frac{3}{8} fA.$

Circle (solid).

$fe = \text{or} > \frac{3}{8} fA.$

Hollow square (factory chimneys).

$fe = \text{or} > \frac{1}{6} fA.$

Circular ring (factory chimney).

$fe = \text{or} > \frac{1}{4} fA.$

It is advisable to check the distribution of pressure over the foundation to see that the pressure nowhere exceeds the permitted maximum. This can be done graphically by means of the method given on page 471 (Graphic determination of distribution of pressure due to eccentric loading).

Example of Brick Retaining-Wall.

Brickwork in mortar 100 lbs. per cubic ft., with a resistance to crushing of 500 lbs. per sq. in. and factor of safety of 8. Coefficient of friction for damp mortar, ·7. Weight of earth (w), 110 lbs. per cubic ft.; angle of repose (ϕ), 37°. Pressure on foundation of sandy gravel not to exceed $1\frac{1}{4}$ ton per sq. ft. Height of wall (h) above footings, 18 ft. Wall sustains horizontal bank level with top. Top of wall two bricks thick, to allow of solid coping. Batter, $\frac{1}{12}$.

Assume for trial fA (fig. 44) $= \frac{1}{3}h = 6$ ft. The back of wall being built with offsets of $4\frac{1}{2}''$ at every 18″ in height, DB will = 3′. Foundations to be 3 ft. below ground.

Weight of wall above bed joint, fA	= 6,750 lbs.	per foot run of wall.	
„ earth in front of AB	= 3,025	„ „	„
Total weight on fA	= 9,775 lbs. = W	„	„

The wall is more likely to overturn at f than at any other point; it will be sufficient, therefore, to inquire into the stability of that joint.

$$P = \frac{wh^2}{2} \cdot \frac{1 - \sin\phi}{1 + \sin\phi} = 4{,}594 \text{ lbs., which acts at P; AP being one-third AB.}$$

Drawing the parallelogram of forces, oc cuts Af at e, making $fe = 9\frac{1}{2}''$.

Resolving oc perpendicular and parallel to Af gives cd = 10,100 lbs.

$$\text{Pressure per sq. in. at } f = \frac{2 \times 10100}{3 \times 9\frac{1}{2}'' \times 12''} = 59 \text{ lbs.}$$

This gives a factor of safety of 10, which is more than sufficient.

Angle ocd will be found to be 20°, tan 20° = ·36, which gives a factor of safety of 2, the coefficient of friction being ·7. The wall is therefore stable.

The pressure on foundations perpendicular to uv will be found to be 14,000 lbs., or $6\frac{1}{4}$ tons, acting at q. To equalise the pressure on the earth, let $qu = qv$, which will make $uv = 12\frac{1}{2}$ ft., giving a pressure of about $\frac{1}{2}$ ton per sq. foot; but as the earth will bear $1\frac{1}{4}$ ton without yielding, a much less width will suffice.

Practical Rules for Retaining-Walls.

A mean thickness of one-fourth height with counterslope of one-fifth, built in steps, will not be far wrong for light soils. This gives a bottom thickness of about one-third height, a centre thickness of one-fourth height, and a top thickness of one-seventh height. A mean thickness one-third height will generally do for stiff clay.

The following rule has been extensively used for brick retaining-walls:—

Top thickness, 1 ft. $10\frac{1}{2}$ in.; face batter of 1 in 6, and after every five courses from top increase thickness by half a brick; front batter should not be more than one-sixth, or it will let in moisture and encourage vegetable growth in the joints. Long walls should have counterforts at back. Walls retaining soils through which water freely passes, such as clean gravel and sand, should have a French drain of loosely packed rubble, &c., running along the back footings, from which good-sized weepholes, from 6 to 10 ft. apart, should lead through the base. With more retentive soils a French drain at least 9 or 12 inches wide should run nearly the whole way up the back of the wall. In some cases extra weepholes at higher levels may be advisable. The mouths of the weepholes should always be carefully protected by loose packing.

Trautwine's Rule for Retaining-Walls.

The horizontal thickness (*ab*, fig. 48) at the base of a vertical or nearly vertical retaining-wall *cdba*, which sustains a backing of either sand, gravel, or earth, level with its top, *cd*, as in the figure should not be less than the following in railroad practice, when the foundations are not more than about 3 feet deep.

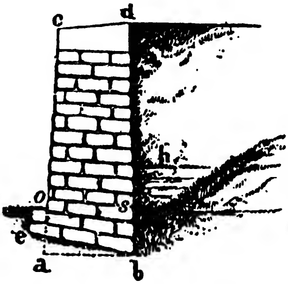

FIG. 48.

When the backing is deposited loosely, as usual, as when dumped from carts, cars, &c.—

Wall of cut stone or of first-class large-ranged rubble in mortar, *ab*.	·35 of its entire vertical height, *db*.
Wall of good common scabbled mortar-rubble or brick	·4 of its entire vertical height, *db*.
Wall of well-scabbled dry rubble	·5 of its entire vertical height, *db*.

With good masonry, however, we may take the height *ds* instead of *db*, and then the above proportions of *ds* will give a sufficient thickness at the ground-line, *os*.

When the backing is somewhat consolidated in horizontal layers, each of these thicknesses may be reduced, but no rule can be given for this.

The offset, *oe*, in front of the wall is not included in these thicknesses.

When, however, the backing is a pure clean sand or gravel, we should use only the full dimensions, inasmuch as the tremor caused by passing trains would neutralise any supposed advantage from ramming materials so devoid of cohesion. Such sand may be rammed with much advantage for the purpose of compacting it in foundations; but a different principle is involved in that case. When it is done, even with cohesive earths, with a view of saving masonry in retaining-walls, it is probable that the expense will generally be found quite equal to that of the masonry saved.

The base, *ab*, in fig. 48, is four-tenths of the height, *bd*. In the foregoing thicknesses at base, the back, *db*, of the wall is supposed to be vertical; and the face, *ca*, either vertical or battered (sloped or inclined backward) to an extent not exceeding about 1½ inch to a foot; which limit it is rarely advisable to exceed in practice, owing to the bad effect of rain, &c., upon the mortar when the batter is great. The base of a vertical wall need not, in fact, be as thick as one with a battered face; but when the batter does not exceed 1·5 inch to a foot the difference is very small.

A mixture of sand or earth with a large proportion of round boulders, paving pebbles, &c., will weigh considerably more than the materials ordinarily used for backing, and will exert a greater pressure against the wall, the thickness of which should be increased, say, about one-eighth to one-sixth part, when such backing has to be used.

The wall will be stronger if all the courses of masonry be laid with an inclination inwards, as at *oeb*; especially if of dry masonry, or if time cannot be allowed (as it always should be when practicable) for the mortar to set properly before the backing is deposited behind it. In retaining-walls, as in the abutments of important arches, the engineer should place as little dependence as possible upon mortar, but should rely more upon the position of the joints for stability.

An objection to inclining the joints in dry (without mortar) walls is that rain-water, falling on the battered face is thereby carried inward to the earth backing, which thus becomes soft, and settles. This may be in a great measure obviated by laying the outer or face courses horizontal; or by using mortar for a depth of only about a foot from the face. The top of the wall should be protected by a coping, *cd*, which had better project a few inches in front. After the masonry has been built up to the surface of the ground, the foundation pit should be filled up; and it is well to consolidate the filling by ramming, especially in front of the wall.

The back, *db*, of the wall should be left rough. In brickwork it would be well to let every third or fourth course project an inch or two. This increases the friction of the earth against the back, and thus causes the resultant of the forces acting behind the wall to become more nearly vertical, and to fall farther within the base, giving increased stability. It also conduces to strength not to make each course of uniform height throughout the thickness of the wall, but to have some of the stones (especially near the back) sufficiently high to reach up through two or three courses. By this means the whole masonry becomes more effectually interlocked or bonded together as one mass, and therefore less liable to bulge. Very thick walls may consist of a facing of masonry and a backing of concrete.

Where deep freezing occurs the back of the wall should be sloped forwards for 3 or 4 feet below its top, as at *co*, fig. 49. which should be quite smooth, so as to lessen the hold of the frost and prevent displacement.

FIG. 49.

A slight bulging in a new wall does not necessarily prove it to be actually unsafe. It is generally due to the newness of the mortar and to the greater pressure exerted by the fresh backing, and will often cease to increase after a few months. It need not excite apprehension if it does not exceed ¼ inch for each foot in thickness at *a*.

After a wall, *abco*, fig. 50, with a vertical back has been proportioned by Trautwine's rule, it may be converted into one with an offsetted back, as *aino*. This will present greater resistance to overturning, and yet contain no more material. Thus, through the centre, *t*, of the back, draw any line, *in*; from *n* draw *ns* vertical; divide *is* into any even number of equal parts (in the figure

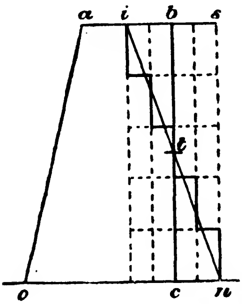

FIG. 50.

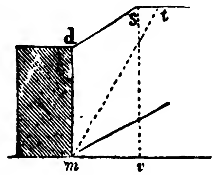

FIG. 51.

there are 4), and divide *sn* into one more equal part (in the figure there are 5). From the points of division draw horizontal and vertical lines for forming the offsets, as in the figure.

When, as in fig. 51, the backing is higher than the wall, and slopes away from its inner edge, *d*, at the natural slope, *ds*, of 1½ to 1, the following thicknesses at base will at least be found sufficient for vertical walls with sand. They are deduced from experiments.

In Table VI., the first column contains the vertical height, *sv*, of the earth, as compared with the vertical height of the wall, which latter is assumed to be 1; so that the table begins with backing of the same height as the wall, as in fig. 48. Without increasing the base these vertical walls may be changed to others with battered faces to any extent not exceeding 1½ inch to a foot, or 1 in 8, without sensibly affecting their stability.

TABLE VI.

Total Height of the Earth, compared with the Height of the Wall above Ground.	Wall of Cut Stone in Mortar.	Good Mortar Rubble or Brick.	Wall of Good Dry Rubble. 1·9	·690	·903			
2	·707	·930			

When the earth reaches above the top of the wall, as in figs. **51** and **52**, the wall is surcharged, and the earth that is above the top is called the surcharge. When the surcharge is carefully deposited above the wall, so as to slope back at a steeper angle than 1½ to 1, as, say, at 1 to 1, theory does not require the wall to be as thick.

WHARF WALLS

are an instance where the thickness should be increased, notwithstanding that the pressure of the water in front helps to sustain them. The earth behind such walls is not only liable to be very heavily loaded when vessels are discharging, but is apt to become saturated with water, especially below low-water level, and thus to exert a very great pressure against the walls. Moreover, the water gets under the wall, and by its upward pressure virtually reduces its weight, and consequently its stability. The same cause, of course, diminishes the friction of the wall upon its base. Such walls are, therefore, very liable to slide if the foundation is smooth and horizontal, and have done so even when the foundation had a considerable inclination backward.

If the back is stepped according to the rule on p **462** the proportionate thickness at base will, of course, be increased. Face batter, 1½ inches to a foot, or one-eighth of the height. Back either vertical, or stepped according to Fig. **50**. The strength is very nearly equal to that of a vertical wall with a base of ·4 its height. Experience has proved that such walls, when composed of well-scabbled mortar rubble, are safe under all ordinary circumstances for earth level with the top.

A retaining-wall is usually in greater danger for a few months after its completion than after time has been allowed for the mortar to harden perfectly and for the backing to settle. When there are suspicions of the safety of a new wall, it would be well to place strong temporary shores against it, at about one-third to one-half of its height above ground. In some cases permanent buttresses of masonry may be built for the purpose. They should be well bonded into the wall.

The pressure of the earth backing will be much reduced if the first few feet of its height be made up in thin horizontal layers, to be consolidated by being used by the masons instead of scaffolding, as shown at *h*, fig. 48, p. 461. Frequently this can be done without inconvenience, and at very trifling cost.

Reinforced Concrete Retaining Walls.

These are of two main types, viz. :—

(1) Simple cantilever walls, figs. 53A and B.
(2) Counterfort walls, fig. 54.

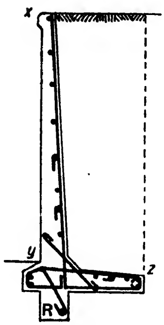

Fig. 53A.

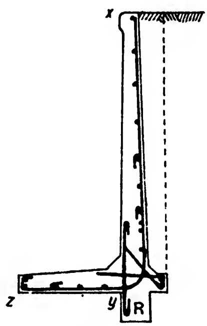

Fig. 53B.

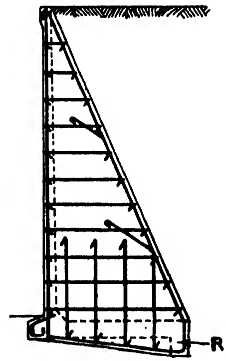

Fig. 54.

Type (1) are suitable for heights up to 15 ft. The portions *xy* are designed as cantilevers loaded with the earth pressure of the bank. In fig. 53A the portion *yz* is a cantilever loaded with the dead weight of the earth above it, and in fig. 53B the loading on *yz* is the upward reaction of the earth.

Type (2) are employed for greater heights and loading. The counterforts and toe are designed as cantilevers, but the wall and heel are designed as continuous slabs spanning the counterforts.

The rib R in all cases serves to resist forward sliding and is designed to take shear.

CHIMNEYS.

Stability of Brick and Masonry Chimney Shafts.

The limit of stability to be observed for chimney shafts is that the wind must never bring tension on any joint. For this to be the case the 'weight moment,' that is, the weight of the length of shaft above any joint, multiplied by the diameter (or 'width' in the case of a square shaft) of the shaft at that joint, must not be less than the 'pressure moment,' *i.e.* the total wind pressure against the length of shaft above the joint, multiplied by the height of the shaft above the joint.

The wind pressure is assumed to act horizontally on the projected area of the shaft. Since in the case of octagonal and circular chimneys this pressure is not normal over the whole surface, but varies from a maximum to zero, the pressure on the projected area is reduced accordingly, thus :—

Square chimneys 56 lbs per square foot (maximum generally assumed in British Isles).
Octagonal ,, 35 lbs. ,, ,, ,, (*i.e.*, $\frac{5}{8}$ of above).
Circular ,, 28 lbs. ,, ,, ,, (*i.e.*, $\frac{1}{2}$ of above).

Direct compression in the section due to weight of brickwork $= c = \frac{W}{A}$ tons per sq. ft.

Stress due to wind pressure $= s = \pm \frac{P \times h \times y}{I}$ tons per sq. ft.

Where W = the weight of brickwork (excluding lining) above any horizontal section (tons).
A = the area of the section (sq. ft.).
I = the moment of inertia of the section in foot units.
y = the width of the section along the line of the direction of the wind (feet).
P = the total wind pressure above the section (tons).
h = the height in feet of the centre of the wind pressure above the section.

For safe design $c - s$ should be not less than 200 lbs. per sq. ft. and $c + s$ should be not greater than the working pressure of the bricks or masonry employed. (For safe loads on materials, see p. 436.)

Dimensions of Chimneys. General Rules and Formulæ.

The Ministry of Health's Byelaws, Series IV, Buildings, Clauses 57–76 are compulsory in many localities (H.M. Stationery Office, London, price 1*s*. 6*d*. net).

Outside diameter at ground should not be less than $\frac{1}{10}$th the height, unless it is supported by some other structure.

Batter varies from 1 in 60 to 1 in 10; 1 in 24 is very common. Or the batter should be from $\frac{1}{16}$th to $\frac{1}{4}$ inch to foot on each side.

Thickness of brickwork: One brick (8 or 9 in.) for 25 ft. from the top, increasing $\frac{1}{2}$ brick (4 to $4\frac{1}{2}$ ins.) for each 25 ft. from the top downwards. If the inside diameter exceeds 5 ft., the top length should be $1\frac{1}{2}$ brick, and if under 3 ft. it may be $\frac{1}{2}$ brick for 10 ft.

Generally a much less height than 100 ft. cannot be recommended for boiler chimneys, as the lower grades of fuel cannot be burned as they should be with a shorter chimney.

Tall Chimneys should always stand alone: if connected with the rest of the buildings, the increased settlement due to their weight on so small a foundation area causes rupture in the masonry. The distance from furnace to shaft should not exceed $\frac{3}{4}$ height of shaft. They should be built and allowed to settle before the connecting flue is made.

Circular form is best; with the same quantity of material it covers a great area, is therefore more stable, and the effect of wind upon it is much less.

In any case the flue should be circular: it can hardly be too large, as it can always be reduced by dampers. It should be lined with a detached skin of firebrick for a certain distance up, increasing in proportion to the heat of the vapours carried off, and separated from the main shaft by an air-space.

Chimneys to receive Vapours of a very high temperature are built altogether of fire-bricks.

Caps tie head of chimney together, but projecting caps catch the wind, and cause oscillation. A dangerous chimney has been saved by removing the cap.

The *Scaffolding* used for building a chimney should be so arranged that it does not prevent the chimney from settling.

The *Intensity of Draught* required varies with the kind and condition of the fuel and the thickness of the fires. Wood requires the least, and fine coal or slack the most. To burn anthracite slack to advantage a draught of $1\frac{1}{2}$ inch of water is necessary, which can be obtained by a well-proportioned chimney 175 feet high.

Design of Tall Chimneys.

45 feet is an ordinary height to serve two steam boilers, but in some towns, as Manchester and Leeds, 90 ft. is the minimum allowed. They are sometimes proportioned for height according to the coal burnt per week of 56 hours, thus:—

4 tons per week	= 75 ft. high.	50 tons per week	= 150 ft. high.
13 „ „	= 100 „	100 „ „	= 188 „
26 „ „	= 120 „	150 „ „	= 200 „

Another rule is to make the height of the chimney three times length of boiler plus twice distance of furthest boiler to chimney; this allows 1 ft. of height for every foot the gases travel round the boiler, and 2 ft. of height for every foot of external flue.

A round chimney should not exceed twenty-five times its internal diameter in height.

A formula relating the internal area of cross section A (sq. ft.), the height H of the chimney (ft.) and the H.P. of the boilers served is:—

$$\text{H.P.} = 3\cdot33(A - 0\cdot6\sqrt{A})H.$$

This is based on 5 lbs. of coal for boiler H.P. and errs on the generous side.

London County Council By-Laws. (*Abstract.*)

London Building Act (Amendment) Act, 1935.

A chimney shaft forming part of a building shall be constructed in a manner approved by the district surveyor subject to (*a*) the standard of stability not being lower than stated below and (*b*) proper precautions are taken to prevent damage to the building through heat or through corrosion of structural steel.

Prior to erection, the site shall be properly cleared of unsuitable material and all cavities filled in an approved manner; if concrete is used it must conform to the by-laws.

The intensity of the calculated pressure on earth shall not exceed that allowed by the district surveyor. It shall comply with the by-law as required for a building (p. 322).

The shaft and footings shall be of suitable brickwork jointed with suitable mortar; the brickwork shall have a batter of at least 1½ ins. in every 10 ft. of height. The thickness of the brickwork at the top and for 20 ft. below shall be at least 8½ ins. and shall be increased at least 4 ins. for every additional 20 ft. or part thereof, measured downwards. Any cap, cornice, pedestal, plinth, string course or other variation shall not be included in the thickness. Footings shall be provided immediately below the base of the shaft and shall spread all round by regular offsets to a projection not less than the thickness of the enclosing brickwork at the base.

Any metal used in connection with a chimney shaft or the footings shall be properly protected.

The height of a chimney shaft shall be measured from the base to the top. It shall not exceed ten times the least width at the base if such base be square or twelve times the external diameter or the least width, respectively, if such base be circular or of any regular polygonal shape.

Any internal lining in a chimney shaft shall be provided as additional to and independent of the thickness of the brickwork and shall not be bonded to the latter.

Flues are ducts not exceeding 80 sq. ins. in area. They shall be surrounded by not less than 4 ins. in thickness of solid bricks or blocks properly bonded and jointed or of concrete cast in position or (except in party walls) of such materials in combination with metal. No flue shall be less than 7½ ins. across in every direction.

Every chimney or stack formed by the combination of two or more chimneys shall, in the case of a flue to a gas-fired appliance, be carried to a height of not less than 18 ins. and in all other cases to not less than 36 ins. above the roof-flat or gutter adjoining but shall not be carried up to a greater height than six times the least width of the chimney at the level of the highest point in such line of junction unless the chimney is adequately secured against overturning. Every chimney which projects from a wall shall be properly bonded to or otherwise properly attached to the wall.

The highest six courses of every chimney or stack constructed of bricks or blocks shall be jointed with cement mortar.

Chimneys having proper soot-doors of an area of not less than 40 sq. ins., fitted in proper frames, may be constructed at any angle; but all other chimneys shall not be inclined at less than 45° to the horizontal. All angles shall be properly rounded. (This requirement does not apply to flues from gas-heated appliances.)

The thickness of the upper side of every chimney where the course of the flue makes an angle of less than 45° with the horizon, shall be at least 8½ ins. except in flues provided solely for gas-fired appliances. Unless required solely for a gas-heated appliance the inside of every chimney shall be properly rendered or pargeted or lined with fireclay or stoneware at least ¾ in. thick or other like incombustible material of sufficient thickness. The spandril angles are to be filled in solid with incombustible material.

Where a chimney passes through a floor or roof within 9 ins. of combustible material or below or against any woodwork, the outside of such chimney must be properly rendered or pargeted.

Proper precautions must be taken to prevent the heat from any chimney or flue injuriously affecting concrete or structural steel.

A flue shall not be used for more than one fire or other heating apparatus except with the approval of the district surveyor.

ARCHES.

Setting-out Arches.

Semi-elliptical Arch (fig. 55).—To set out a *semi-elliptical arch*, draw a line, AB, equal to the span or transverse axis of the ellipse. At the centre of AB draw the semi-conjugate, CD, at right angles, equal to the rise. Then, from the vertex, C, with radius AD or DB equal to half the span, describe an arc intersecting AB in E and F.

The points E, F, will be the foci of the ellipse. If two nails or pegs be fixed in the foci, and a line attached to them equal in length to AB, then the curve traced by a nail, keeping this line stretched, will be the ellipse required the lines EGF, EHF, ECF, EIF, &c., being all equal to span AB, and to each other.

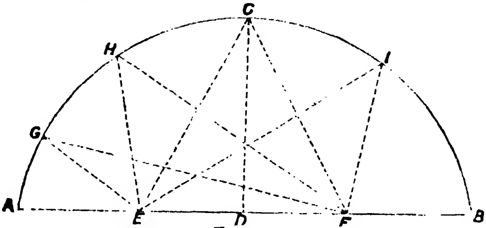

Fig. 55.

Many-centred Circular Arch.—Curves formed of arcs of circles of unequal radii, and similar in appearance to the ellipse, are sometimes adopted for the arches of bridges; with the same rise and span, they may be constructed to give a greater waterway, and in stone bridges they have been preferred by practical stonecutters, but in brick bridges they have no advantage in simplicity over elliptical arches. They may be described with three or a greater odd number of centres. The number of centres will depend on the relation between the span and rise; when the latter is one-third, or a greater fractional part of the former three centres may be used, but if the rise is less than one-third of the span, then five, or a greater odd number, must be taken. In practice it will be found troublesome to describe arcs from a large number of centres, nor, indeed, will occasion be found for using curves of this description. The following is a method of describing a curve composed of three arcs each of 60°.

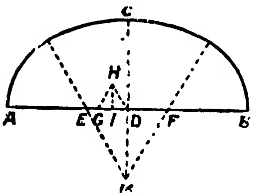

Fig. 56.

Let AB (fig. 56) represent the span, and CD the rise. Take DG = AD – DC, and on it describe an equilateral triangle, DGH; let fall the perpendicular HI, and take IK = HI. Lay off DF = DE. On EF describe the equilateral triangle EFK; then E, F, and K will be the centres required.

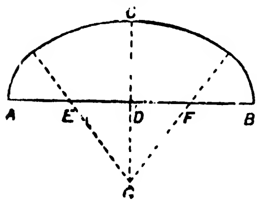

Fig. 57.

For an oval arch, rise one-third, bisect the half-spans AD and DB (fig. 57) in the points E and F, and produce versed sine CD to G, making DG = DC; then E, F, and G will be the three centres with which the curve may be described. In setting out arches, the practical difficulty arises from the elasticity of string. Instead of a string, soft wire about a tenth of an inch in diameter should be used. When the radius does not exceed 12 or 15 feet, a slip of wood may be used, with a nail at each end.

The Design of Brick and Masonry Arches.

A preliminary design is prepared by using the formulæ and tables given below, which is plotted. From this drawing the dead load on the arch can be calculated. The live load to which the arch will be subjected is then determined. For arches in buildings the loading given on p. 437 is suggested; and for bridges, either the Ministry of Transport or British Standard loading are recommended.

The lines of resultant pressure are then drawn for the following conditions:—

(*a*) Dead load over the whole span + live load over half the span.
(*b*) ,, ,, ,, ,, + live load over the whole span.

In the case of a three-hinged arch, the lines of resultant pressure must pass through the hinges; and to draw these lines adopt the same procedure whereby the polygon KRS is drawn in Fuller's Method given on p. 469. If the two pressure lines so produced do not lie wholly within the middle third of the arch thickness, the arch would be subject to tension, and should therefore be thickened until the lines do lie within the middle third.

In the case of a rigid arch the line considered is that which emerges from the arch ring at the haunches with the greatest inclination to the horizontal, and is known as the curve of least resistance, possessing as it does the least horizontal thrust at the abutments. The most expeditious method of plotting this curve is by Fuller's Method given on p. 469.

To find the Depth of Keystone for first-class Cut-stone Arches, whether Circular or Elliptic.

$$\text{Depth of key in feet} = \frac{\sqrt{\text{Rad.} + \text{half span}}}{4} + {\cdot}2 \text{ foot.}$$

For second-class work this depth may be increased about one-eighth part; or for brick or fair rubble, about one-third.

Depths of Keystones for Arches

Of first-class cut stone. For second-class add about one-eighth part. For brick or fair rubble add about one-third part.

Span.	Rise, in Parts of the Span.						
	½	⅓	¼	⅕	⅙	⅛	1/10
Feet.	Key. Feet.	Key Feet.	Key. Feet.	Key. Feet.	Key. Feet.	Key. Feet.	Key. Feet.

260	4·23	4·31	4·47	4·66			
280	4·38	4·46	4·63				
300	4·53	4·62	4·80				

In large arches it is advisable to increase the depth of the archstones toward the springs; but when the span is as small as about 60 to 80 or 100 feet, this is not at all necessary if the stone is good, although the arch will be stronger if it is done. In practice this increase, even in the largest spans. does not exceed from ¼ to ½ the depth of the key, although theory would require much more in arches of great rise.

Thickness of Arches.

Centre of pressure at every joint of arch and abutment should fall within centre third.

Thickness of arch at crown $= \sqrt{r} \times B$, where r is the longest radius of curvature at intrados B, as deduced from practice, is as follows:—

		Feet.
Arch above ground standing solitary between abutments	B =	0·12
Arch forming one of series of arches with piers between	=	0·17
Underground archway in hard materials, such as rock or conglomerate	=	0·12
Underground archway in gravel or firm earth	=	0·27
Underground archway in wet clay or quicksand	=	0·48

Fuller's Method of drawing the Curve of Least Resistance for a Rigid Masonry or Brick Arch. (See fig. 58.)

Draw the outline of the suggested arch and mark off by dotted lines the middle third.

Draw a loading diagram showing the dead load ABCD over the whole arch, and the live load EFGB over half the arch.

Divide the diagram into an even number of parts having approximately equal horizontal length. Assume the load represented by the area of each part to act at its centre of gravity as a concentrated load, *i.e.* (1), (2), (3), etc.

Draw a polar diagram for these loads P*xy* with any pole P and from it plot the funicular polygon KLM.

It is now necessary to draw a polygon for this loading to pass through the centres of the haunches K and R and a point S selected at random on the maximum vertical, *i.e.* (4).

PH is drawn on the polar diagram parallel to the closing line of the polygon KM, and intersecting the load line at H. From H, the horizontal line P_1H is drawn so that the polar distance h_1 of $P_1 = \frac{LT}{SV} \times h$ where $h =$ the polar distance of P.

A polar diagram P_1xy is then drawn, and from it the polygon KSR is plotted.

The load lines (1), (2), (3), etc. will cut this polygon in points 1, 2, 3, etc. Select at random two points X and W in KR produced and join XS and SW. Project points K, R, 1, 2, 3, etc. horizontally on to these lines to intersect them in X, W, I, II, III, etc., and drop verticals at each point. On to these verticals project horizontally the intersection of the middle third of the arch with the load lines from which they are derived, obtaining the figure *a*, *b*, *c*, *d*, *e*, *f*. This figure is a distorted outline of the middle third having the same degree of distortion as was given to the line of resistance K, R, 1, 2, 3, etc., by projecting it on to the straight lines XS and SW. The Curve of Least Resistance similarly distorted will be represented by the two straight lines $\alpha\beta$ and $\beta\Delta$ which have the greatest inclination to the horizontal and lie wholly within the figure *a*, *b*, *c* *d*, *e*, *f*. If two straight lines cannot be drawn to lie wholly within the figure, the arch thickness must be increased. It will be noted that in the present case α, β and Δ coincide with *f*, *b* and W, but this is accidental and not essential.

The intersections of $\alpha\beta$ and $\beta\Delta$ on the verticals *f*, *a*, I, II, III, etc., are now projected horizontally back to the verticals K, R, 1, 2, 3, etc., thus giving the required curve $Q\beta R$.

For the reactions due to the curve, join QR intersecting ST in *t*. The rise of the original line

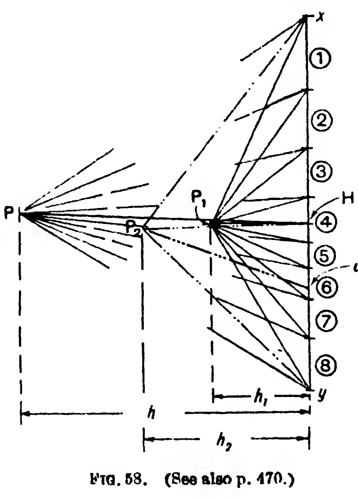

Fig. 58. (See also p. 470.)

FULLER'S METHOD OF DRAWING THE CURVE OF LEAST RESISTANCE FOR A RIGID MASONRY OR BRICK ARCH.

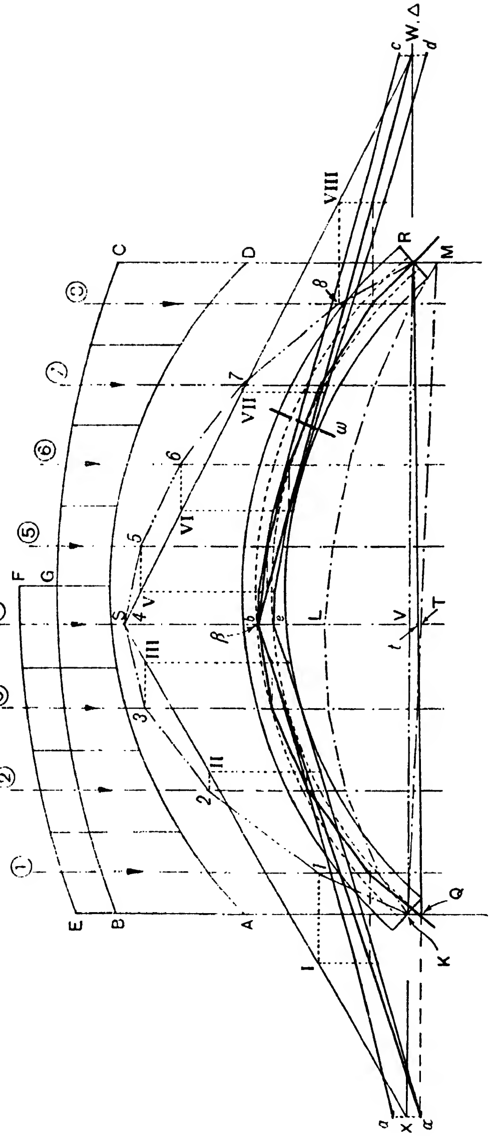

FIG. 58.

of resistance $= SV$ and the rise of $\alpha\beta\Delta = bt$. The horizontal thrust being inversely proportional to the rise, the horizontal thrust for $\alpha\beta\Delta = h_2 = h_1 \times \frac{SV}{bt}$ where h_1 is the horizontal thrust for the linear arch KSR, as scaled from the polar diagram.

From H draw P_2H parallel to QB, making the perpendicular distance of P_2 from $xy = h_2$, Then P_2 is the correct pole for the curve of least resistance and P_2x and P_2y are the reactions at the haunches, and are parallel to the direction of these reactions.

The intersection of the curve on any section ω gives the centre of pressure on that section and the corresponding ray $P_1\omega$ on the polar diagram gives the magnitude and direction of the pressure.

Where the centre of pressure does not coincide with the centre of gravity of the section, the pressure over the section will vary uniformly from a maximum at the side nearest to the centre of pressure to a minimum on the far side.

The variation of pressure over the section can be determined graphically as shown below, which method can be equally applied to loading on retaining wall foundations, bridge piers or any other form of eccentric loading.

Graphic Determination of Distribution of Pressure due to Eccentric Loading.
(See fig. 59.)

Assume a load P to be acting on unit length of a surface of width AB, and the centre of pressure to be at the point E. This load can be resolved into a normal load R, and a tangential load T. T should not exceed the resistance to sliding or cause greater than the permitted shear stress, as the case may be. Let C and D be the limits of the middle third of AB.

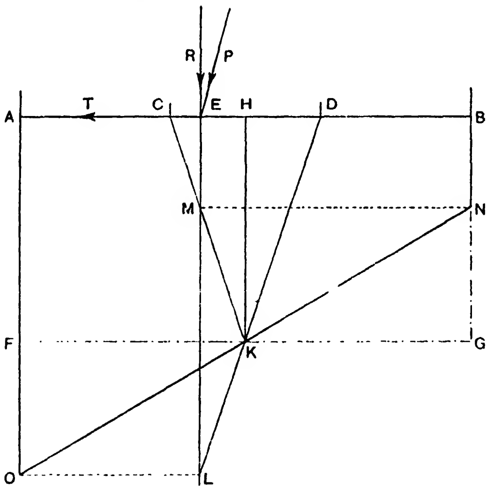

Fig. 59.

Draw the rectangle ABGF making $AF = \frac{R}{AB}$ to some convenient scale. This rectangle represents the pressure distribution on AB for a load R applied at the centre H.

From H and E draw HK and EL perpendicular to AB. Let HK cut FG in K. Join OK cutting EL in M, and draw DK produced to cut EL in L.

Project M horizontally to cut BG in N, and L to cut AF produced in O. Then AO equals the maximum and BN the minimum unit pressures on AB to the same scale as AF.

The figure ABNO is the pressure diagram for the surface. It is readily perceived that where E coincides with O, the figure would be a triangle as B and N would coincide indicating no pressure at B; and should E lie within the length AO, the perpendicular at E would cut KO produced above the line AB and therefore NB would be negative indicating tension.

Piers.

Thickness of piers, generally from ⅛ to ⅙ span. Short piers have vertical sides; high piers may have side batter of $\frac{1}{16}$.

In viaducts and long bridges, 1 pier in every 5 or 6 may be thickened as an abutment pier, so that an accident to a part may not cause the destruction of the whole.

In examining the stability of piers the live load is taken over the whole span on one side of the pier, and the dead load only, over the arch on the other side. The Resultant Pressure lines are then continued down to the foundations modified by the dead load of the pier and by each other giving a common resultant. For stability this resultant must remain in the middle third of the pier, and also it must not enter the ground at an angle to the horizontal less than the angle of friction. In addition the maximum pressure on the foundation must not exceed the maximum permitted bearing pressure for the particular ground.

For abutments the procedure and requirements for stability are the same except that in this case the earth pressure behind the abutments must be considered in place of the thrust from the adjacent arch.

Centering for Arches.

Centering is made of such stuff as is available. Fig. 60 shows what would be suitable for a 20 ft. arch of brick 2 ft. 3 ins. thick. The king post and struts might be of 2-in. stuff. The lagging is of 1½-in. plank, with centres 3 ft. apart; if 4 ft. to 5 ft. apart it should be of 2-in. plank. The struts are often placed at right angles to the arch, as shown in dotted lines.

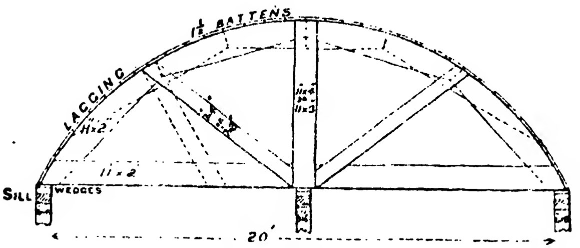

FIG. 60.

In centering for *concrete arches* the lagging should be of narrow battens, 3 ins. to 4½ ins., laid close, the joints being run in with whiting and plaster of Paris. The following dimensions have been followed:—25 ft. 6 ins. span: centres were 2 ft. apart, of 9-in × 1½-in stuff; lagging 4½ ins. × 1½ in., a 9-in. × 3-in. plank cutting into four for lagging, into two for ribs. There were two lines of intermediate supports. For flat or prismoidal roof of concrete 2-in. or 3-in. sheeting was used, on centres of 3-in. stuff, 4 ft. to 6 ft. apart.

The centres rest by the ends of their chords upon wooden *striking* or *lowering wedges*, for striking or lowering the centre after the completion of the arch. These consist of pairs of wedge-shaped blocks, as W, W, fig. 61, of hard wood from 1 ft. to 2 ft. long, about half as wide, and a quarter or more as thick (sufficient to lower the centre from, say, 2 ins. to 6 ins. or more, according to span and other circumstances).

It is of the utmost importance, especially in large arches, that the *centres should be lowered very slowly*, otherwise the momentum acquired by so heavy a body as an arch descending suddenly, even but 2 ins. or 3 ins., might possibly affect its shape, or even its safety. For this reason the wedges should not have a taper steeper than about 1 in 6 or 8 for arches of less than about 50 ft. span, or than 1 in 8 or 10 for larger spans. Vertical lines at equal distances apart should be drawn on the long sides of the wedges, as a guide for lowering them all to the same extent at a time; and this should not exceed in all about half an inch a day in intervals of about an eighth of an inch for 50 ft. spans, or about ·1 to ·25 of an inch per day in all for spans over 100 ft. Slowness is especially to be recommended in *brick arches*, not only because their greater number of joints exposes them to greater derangement of shape, but because even good brick has much less than the average crushing-strength of good granite, limestone, or sandstone, and therefore is far more liable than they to crack, or even to crush, when the strains are thrown almost entirely upon their edges.

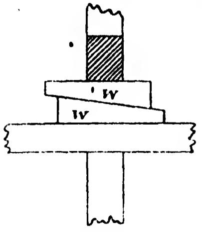

FIG. 61.

Easing and Striking Centres.—Much depends on temperature, mass of masonry or brickwork, composition of mortar, etc. With ordinary lime, centres should be eased while mortar is quite green, as soon as the arch is loaded to stability, and struck on an average after five to eight days. With small arches, one or two and a half bricks thick, 6 ft. to 8 ft. span, built in dry weather, the centres may be struck in three or four days. With slow-setting cement, if the arch be small and slight, so that it can be loaded to stability before the mortar of portion first commenced has set, the centres may be eased, as with lime, but they may be struck sooner, and the limit may be taken as the time at which the joints would become too hard set to admit of being raked out for pointing without seriously injuring the brickwork. If, in consequence of the cement being strong and quick-setting, or of the span or thickness of the arch being considerable, the arch cannot be completed before the portion first commenced has set, it is doubtful whether the centering should be eased at all, for fear of disturbing the setting of the cement. Centering for concrete should not be disturbed for at least fourteen days from the time of laying the concrete.

The main points to attend to are—to complete the arch to stability rapidly, and to prevent disturbance of the work while setting, by traffic over it, or vibrations from adjoining work, otherwise the setting power, of cement specially, is destroyed.

SECTION XIV

PART I

STEEL BRIDGEWORK

TYPES — ECONOMICAL SPAN — PROPORTIONS — STANDARD CLEARANCES — LIVE LOADS — BRIDGE FOUNDATIONS — PERMISSIBLE STRESSES — WIND PRESSURE — CENTRIFUGAL FORCE—MOMENTUM — IMPACT—TEMPERATURE—BEARINGS—FLOORING—CAMBER, RIVETING, ETC.

(Revised by J. D. W. Ball, A.M.I.C.E.)

TYPES.

Bridges consist of two parts:

(*a*) The substructure, comprising abutments, piers, caissons, and other forms of foundations.

(*b*) The superstructure, which comprises the bridge structure itself.

There are three known methods of carrying weight over space—*i.e.* by means of:

(1) The beam; (2) the arch; (3) the rope.

All bridges can be reduced to one, or a combination, of these types.

(1) THE BEAM.—The strength of the beam depends on transverse bending. The theoretic stress in the extreme fibres is inconsistent with experiments but the so-called discrepancy diminishes with the thickness of the web and the ratio of depth to span of the beam.

The principal groups of girder bridges are:

(A) Girders of uniform depth; (B) girders of uniform horizontal stress.

Group A: Parallel Girders.—In this case the shearing force is resisted by the web, and the diagram of moments forms the stress diagram.

Group B: Parabolic Girders—In this case, for uniform loading the shearing force is resisted by the flanges and the diagram of moments forms a diagram of depth.

All these types can be used in their inverted form, and it is from these forms that the Arch and Rope are evolved.

(2) The Arch.—For any given system of loading a theoretical arch can be designed so as to be in compression only, the neutral axis of the arch coinciding with the line of pressure: but unless it can resist bending, the arch will be in a state of unstable equilibrium. The horizontal stress varies with the rise.

(3) The Rope.—The shape which the loaded cable takes up is the same as the link polygon for the given load system drawn from one support to the other with a polar distance equal to the horizontal component of the pull in the cable. Stable equilibrium is obtained under changes of load. The horizontal stress varies with the dip.

Economical Span.

In bridging a large opening by a number of small spans, the economical span may be approximated in the following manner:—

Let

P = cost of one pier; G = cost of main girders for one span erected; n = number of small spans; l = length of small spans; L = total span

then,

$$n = \frac{L}{l}.$$

$$\text{Cost of piers} = (n-1)\,P.$$

Cost of main girders $= nG$, and G may be taken as proportional to the square of the span, so that,

$$G = al^2,$$

therefore

$$\text{Total cost} = C = (n-1)\,P + nal^2,$$

where a is a constant.

To get the minimum value of C, differentiate with respect to l and put it equal to zero. Therefore

$$\frac{dC}{dl} = 0.$$

But

$$C = \left(\frac{L-l}{l}\right) P + \frac{Lal^2}{l}.$$

$$= \frac{LP}{l} - P + Lal,$$

therefore

$$\frac{dC}{dl} = \frac{-LP}{l^2} + La = 0$$

therefore

$$\frac{P}{l^2} = a,$$

or

$$P = al^2 = G.$$

From this it follows that the most economical condition is when the cost of one pier equals the cost of one main girder for one span.

If G equals cost of 100 ft. span, the result may be expressed:

$$\text{Economical span} = \frac{100\sqrt{P}}{\sqrt{G}}.$$

(Ency. Brit.)

Economical Proportions of Girders.

Plate Girders.

Let

x = depth of girder in ins.; W = weight of girder in lbs.; f = allowable working stress (pounds per sq. in.) on gross area; t = thickness of web in ins.; L = extreme length of girder in feet; M = total bending moment at centre (inch-pounds).

Then the weight of the web is $\frac{10}{3}Ltx$, and that of the flanges, assuming the flange plates are the required theoretical lengths, $= \frac{10}{3}\left(1 \cdot 6 \frac{ML}{fx}\right)$,

therefore

$$W = \frac{10}{3} Ltx + \frac{10}{3}\left(1 \cdot 6 \frac{ML}{fx}\right),$$

$$\text{and W is a minimum when } x = 1 \cdot 27 \sqrt{\frac{M}{ft}}.$$

This formula is based upon the assumption that no portion of the web is included in flange area.

If the resistance of web is considered, then

$$x = 1 \cdot 46 \sqrt{\frac{M}{ft}}.$$

If the flanges are of constant section throughout, the foregoing formulæ become

$$x = 1 \cdot 41 \sqrt{\frac{M}{ft}} \text{ (web neglected); } x = 1 \cdot 63 \sqrt{\frac{M}{ft}} \text{ (web considered).}$$

Lattice Girders.

In trusses of the N type the maximum stiffness or minimum deflection is obtained when

$$x = \frac{d}{2}\sqrt{\frac{y+2}{y-2}} \times y,$$

where

d = length in feet between verticals; y = number of bays.

(*Sir Wm. Arrol & Co., Ltd.*)

For plate girders, the economic depth may be taken roughly as from $\frac{1}{10}$ to $\frac{1}{15}$ of the span, $\frac{1}{12}$ often being adopted; and for lattice girders should be not less than $\frac{1}{10}$ of the span, preferably $\frac{1}{8}$.

If shallower girders are necessary, the sections must be increased, so that the maximum deflection will not be greater than if the limiting ratio had not been exceeded.

Breadth of Flanges.

For plate girders this may be taken as about $\frac{1}{3}$ of the depth, or $\frac{1}{30}$ to $\frac{1}{40}$ of the span.

The width of booms in lattice girders should not be less than $\frac{1}{12}$ of the unsupported distance.

Cross Girders.—Depth should not be less than $\frac{1}{10}$ of the span, preferably $\frac{1}{8}$.

Rail Bearers should have a depth of not less than $\frac{1}{15}$ of the span.

Spans, Standard Clearances, etc.

Over-bridges carrying roads over railways are usually of the following spans (see fig. 1):

Over single line, 16 to 18 ft. Over double line, 28 to 30 ft.

Widths of over-bridges, between inside of parapets, are regulated by Act of Parliament, as follows, the roads being of the widths given for 50 yards each way:

Turnpike roads, 35 ft. Other public carriage roads, 25 ft. Private roads, 12 ft.

Under-bridges carrying roads under railway, span and headroom fixed by Act of Parliament.

Turnpike road, clear headroom, 12 ft. at springing, 16 ft. for centre 12 ft. of arch. Where tramways cross the bridge a minimum headroom of 18 ft. should be provided.

Other public and carriage roads, clear headroom 12 ft. at springing, 15 ft. for centre 10 ft. of arch.

Private roads, clear headroom 14 ft. for centre breadth of 9 ft. of arch.

In all cases, under-bridges must have a parapet at least 4 ft. 6 ins. above rail level.

STANDARD CLEARANCES FOR BRIDGES.

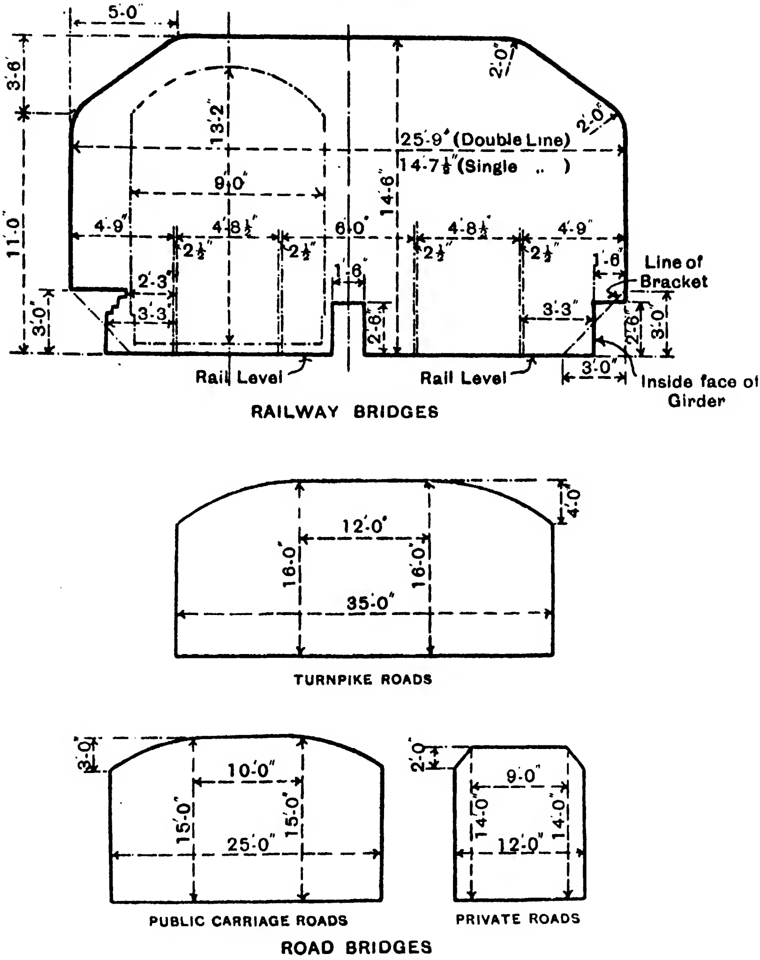

FIG. 1.

Live Loads on Bridges.

Rolling Load on Railway Bridges.

(1)

The effective weight of the rolling load, per foot lineal of each line of way, will depend upon the width of span. The heaviest train would consist of locomotives coupled closely together, but while a bridge of short span might frequently be covered by such a train, or by the two engines that often head the train, a bridge of very long span would never be subjected to such a load per foot lineal over its entire length. But for spans shorter than the length of one engine, the load may be very much greater than the weight of the engine per foot of its extreme length. Taking the worst position of the wheel-loads, and the heaviest class of engines now in use upon English lines of railway, the equivalent distributed load per foot lineal may be estimated as follows:—

For spans of	10	feet, a load of	4·40	tons per foot.	For spans of	100	feet, a load of	2·07	tons per foot.
„	20	„ „	3·25	„ „	„	150	„ „	2·00	„ „
„	30	„ „	2·88	„ „	„	200	„ „	1·90	„ „
„	60	„ „	2·30	„ „	„	300	„ „	1·75	„ „

In designing cross girders the maximum axle load is taken at 22 tons.

These loads are exclusive of any allowance for impact which may be allowed for by varying the unit stress per sq. in. to suit the application of the load:—From 4·5 tons per sq. in. for cross girders to 6·5 tons per sq. in. for main girders 100 feet span and over. The better plan, however, is to calculate the impact allowance from one of the impact formulæ given on p. 500.

The loads given above are considered to be the **greatest** that can be obtained **with** the present loading gauge of British railways.

(2)

Bridge to be designed for a moving load of two engines coupled and a uniformly loaded train or each track. Greatest stresses in any possible circumstances to be taken.

Where not specified take the following:—

***For Main Girders.*—Distributed rolling load per track = 1·5 tons per foot run, and an excess rolling load to occupy any position on the bridge at the same time equal to $15 \text{ tons} + \left(\frac{\text{span in feet} - 10}{10}\right)$ but not greater than 25 tons.**

***For Cross Girders.*—The load on each cross girder from each track:**

For all girders up to 7 ft. centres = 19 tons,
„ „ beyond 7 ft. „ = 1·5 tons per ft. run of track plus an excess load of

$$10 \text{ tons} - \left(\frac{10 - \text{centres of cross girders in ft.}}{5}\right),$$

but not greater than 10 tons. ***(Sir Wm. Arrol & Co., Ltd.)***

Locomotive Weight Distribution on Bridges.

In the case of the three-cylinder tank engines—London and North Eastern Railway—these engines are of the 0-8-4 type, 31 ft. 2 ins. total wheel base, 45 ft. 2¼ ins. long over buffers. The total weight in working order is 194 tons 9 cwt., the weight on the coupled wheels being 75 tons 14 cwt.

The general weight distribution is

	T.	C.
Weight per ft. on coupled wheels	4	9
„ „ „ engine wheel base	3	7
„ „ „ over buffers	2	6

For further details of locomotives refer to 'Weights of Locomotives and Rolling Stock,' Section XXXII, Part II.

British Standard Unit Loadings for Railway Girder Bridges and Highway Girder Bridges.

TABLE I.

British Standard Unit Loading for Railway Bridges for a Single Line of Way.

For Gauges of 4 ft. 8½ ins. and over.

FIG. 2.

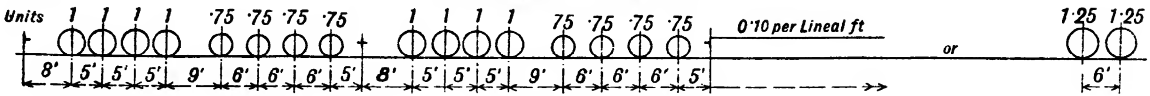

Diagram of Unit Loading.

In this table the unit of axle load is taken as 1 ton (2,240 lbs.).

For convenience of calculation the train load has been taken as equivalent to a train of vehicles with axles spaced 10 ft. apart, each axle carrying a load of one unit, the first axle being spaced 5 ft. from the end.

For British railways the loading recommended in the Requirements for Passenger Lines and Recommendations for Goods Lines of the Minister of Transport in regard to Railway Construction and Operation (1925) is 20 units for heavy main lines, with lower multiples for lines constructed for lighter loading.

BRITISH STANDARD UNIT LOADING FOR HIGHWAY BRIDGES.

FIG. 3. (Each 10 ft. width of carriageway of the bridge is to be assumed as completely occupied by a succession of Standard trains.)

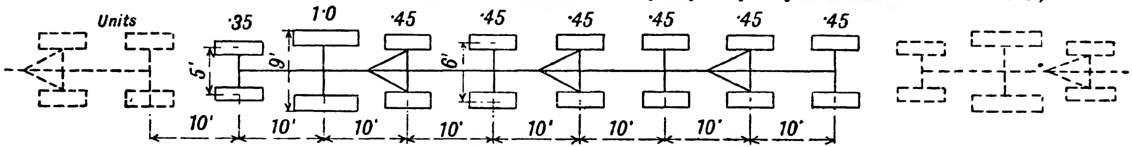

Diagram of Unit Loading.

In this table the unit of axle load is taken as 1 ton (2,240 lbs.).

When the passage of exceptional loads over a bridge is to be anticipated, a special multiple of the unit loading should be specified as applicable to road bearers, cross girders, and short panel lengths.

The multiple recommended by the Minister of Transport as a minimum for all road bridges in Great Britain is 15 units.

Ministry of Transport. Roads Department.

Standard Load for Highway Bridges.

The British Standards Institution's Loading (15 units) is accepted by the Ministry of Transport for the conditions to which it applies, but the Ministry of Transport's Standard Load, or the equivalent uniformly distributed load, tabulated below, is more commonly adopted.

The live load to be used consists of two items: (1) The uniformly distributed load which varies with the loaded length, and which represents the ordinary axle loads of the Ministry of Transport's standard train, perfectly distributed. (2) An invariable knife-edge load of 2,700 lb. per ft. of width applied at the section where it will, when combined with the uniformly distributed load, be most effective, *i.e.* in a freely supported span:—(*a*) for bending moment at midspan: at midspan point; (*b*) for shear at the support: at the support; (*c*) for shear at any section: at the section.

This knife-edge load represents the excess in the M.T. Standard train of the heavy axle over the other axles, this excess being undistributed (except laterally as already assumed).

In spans of less than 10 ft. (*i.e.* less than the axle spacing) the concentration serves to counteract the over-dispersion of the distributed load.

The uniformly distributed load, applicable to the 'loaded length' on the bridge or member in question, is selected from the table.

The 'loaded length' is the length of member loaded in order to produce the most severe stresses. In a freely supported span the 'loaded length' would thus be (*a*) for bending moment: the full span: (*b*) for shear at the support: the full span; (*c*) for shear at intermediate points: from this point to the farther support.

In arches and continuous spans, the 'loaded length' can be taken from the influence line curves.

In slabs the knife-edge load of 2,700 lb. per ft. of width is taken as acting parallel to the supporting members, irrespective of the direction in which the slab spans.

In longitudinal girders, stringers, etc., this concentrated loading is taken as acting transversely to them (*i.e.* parallel with their supports).

In transverse beams the concentrated loading is taken as acting in line with them (*i.e.* 2,700 lb. per ft. run of beam).

If longitudinal or transverse members are spaced more closely than at 5 ft. centres, the live load allocated to them shall be that calculated on a 5 ft. wide strip. With wider spacing this strip will be equal to the girder spacing.

In all cases, irrespective of span length, one knife-edge load of 2,700 lb. per ft. of width is taken as acting in conjunction with the uniform distributed load appropriate to the span or 'loaded length.'

Ministry of Transport. Standard Load for Highway Bridges.

Tabulated Values of Equivalent Distributed Loads.

Loaded Length.	Lbs. per Sq. Ft.	Loaded Length.	Lbs. per Sq. Ft.	Loaded Length.	Lbs. per Sq. Ft.

Bridge Foundations.

LOADS ON BRIDGE FOUNDATIONS.

CYLINDER BRIDGE PIERS. APPROXIMATE SAFE LOADS PER SQUARE FOOT (*J. Newman*).

	Tons per Sq. Ft.
Firm sand in estuaries and bays	5·0 to 5·6
Considered safe on firm sand (in Holland)	6·0
Very firm, compact sand, foundations at depths not less than 20 ft.	6·7 to 7·8
Firm shale and clean gravel	6·7 to 8·9
Compact gravel	7·8 to 10·0

Calculated loadings (neglecting friction), tons per square foot: Benares bridge, 11·19; Jubilee bridge, 9; Gorai bridge, 8·5 (all deep foundations); Blackfriars bridge, 4·75: Rupnarayan bridge, 6·7 (or, assuming skin friction as 5 cwts. per square foot, the loading on the base of the pier is about 4·5 tons per square foot).

CLYDE BRIDGE, CALEDONIAN RAILWAY.

Caissons 48 to 89 ft. long and 20 to 23 ft. wide:

Land Piers.—Distances from river-bed about 50 and 60 ft.: depths below level of river-bed about 20 and 30 ft. Depths below quay level and loadings, 50 ft., 4·12 tons per sq. ft.; 61 ft., 4·73 tons; 57 ft., 4·75 tons.

River Piers.—Depths below river bed and loadings: 44 ft., 5·66 tons per sq. ft.; 44 ft., 5·96 tons; 48 ft., 6·04 tons; 44 ft., 6·12 tons.

SKIN FRICTION ON BRIDGE FOUNDATIONS.

(Caissons and 'Wells' or 'Cylinders.')

Foundations of the Empress Bridge over the Sutlej.

Brick Cylinders, 19 Ft. in diameter, sunk on an average 110 Ft.	Skin Friction. Cwts. per Sq. Ft. Mean.	Max.	Min.
Average of 36 cylinders sunk to depths varying from 10 to 27 ft., average 19 ft., under their own weight only, 25½ to 33 tons, average 31 tons.	0·85	1·33	0·63
Average of 100 observations in sinking 36 cylinders, at depths from 17 to 64 ft., loads 31 to 249 tons, average 132 tons besides the weight of the cylinders.	2·13	4·08	1·29
Average of 9 observations in sinking 3 cylinders by pneumatic process at depths varying from 44 ft. to 63 ft.	2·71	3·52	2·32

Papaghni Bridge.—Cast-iron cylinders 12 ft. in diameter and brick cylinders of the same diameter. The following frictional resistances were noted when sinking the piers; cwts. per sq. ft. In the upper sand 2·08 to 2·20; in black clay, 3·50 to 5·60; in silt below the clay, 2·72 to 4·28; in the lower sand, 2·58 to 3·16.

Chitravati Bridge.—Friction through 33 ft. of sand, 10 ft. of clay, and 7 ft. of clay, sand, and boulders—2·32 to 3·77 cwts. per sq. ft. Friction through 33 ft. of sand, 10 ft. of clay, and 3 ft. of sand and clay—2·93 to 3·62 cwts. per sq. ft.

Tavy and Laira Bridges, Devonshire.—2·0 to 2·8 cwts. in mud.

Concrete Cylinders at Haulbowline Dockyard (H. E. Oakley).—Twenty-three cylinders, 8 ft. in diameter, were sunk through silt. The average skin friction for a cylinder varied from 4·2 to 8·6, the mean being 5·9. In only three cases was the average for a cylinder less than 5·2 cwt per sq. ft. In seven cases the maximum resistance recorded exceeded 9 cwts. per sq. ft.

Caissons of Barnes Railway Bridge.—The caissons are 28 ft. by 18 ft. The skin friction in London clay was 2·03 cwts. for one, and 2·95 cwts. for the other, per sq. ft.

A Shaft sunk at Oxford Circus, London.—Skin friction only 1·0 cwt. per sq. ft. The low value being attributed to (1) the cylinder keeping its shape very well; (2) being kept very upright; and (3) a pocket being formed below the cutting edge and pugged clay inserted.

A Shaft sunk at Greenwich.—In sand and ballast, skin friction 4 to 4½ cwts.; in shelley clay, 6 cwts. per sq. ft.

Waterway of Bridges.

The simplest cases of waterway calculation are those in which the conditions are such that the amount of heading up is not restricted. In these cases the limiting velocities which may be allowed decide the area of waterway which is necessary. Above the bridge the mean velocity of the stream will be reduced by the heading up.

It may be assumed that the water surface will fall to the original water level before it passes the piers, unless the channel of the river below the bridge has been altered. Taking the water level as the same, the new depth will be the same as the original depth, *plus* any lowering of the bed of the stream at the bridge site. The new width may be taken as the length of waterway. These two dimensions give the new area from which the new velocity can be calculated directly from the discharge, or by

$$V_2 = V_1 \times \frac{d_1 l_1}{d_2 l_2}$$

where

d_1 = original depth; d_2 = new depth; l_1 = mean width of stream cross-section; l_2 = length of waterway.

The new mean velocity is that to which the piers of the bridge are subjected, as well as the bed of the stream for a short distance below the bridge. This distance depends on the velocity and depth of the current. The limiting velocities can best be decided by a study of records of the behaviour of local strata and local masonry under similar conditions.

The following figures provide a rough guide to the velocities usually allowed.

Limiting Velocities in Feet per Second.

On clay, 0·70 to 1·0; on sand which must not be disturbed (shallow foundations) 1·2 to 1·5; on firm, pebbly beds, 3·0 to 3·5; on stony or shingly beds, 4·0; on stratified rock, 6·0; on hard rock, 10·0.

For inferior brickwork, with better masonry in the cutwaters, and on the floor of the waterway at the feet of the cutwaters, about 5·0; better masonry, up to about 8 ft. per second. For ordinary pitching (floor) about 5·0. For very well-shaped bridge openings with thick piers allowing of easy curves, higher values may be allowed, and very high values may be permitted when the masonry is exceptionally strong, such as ashlar of hard stone with fine joints.

Waterway Calculations.

In the case of a bridge or culvert intended for the passage of flood waters which pool up on the upstream side, the discharge may usually be calculated without velocity of approach, especially when the water level on the downstream side is not much lower. This is an ordinary case where a railway embankment crosses land liable to flooding. The head is the difference between the water level below the opening and that above it, when the latter has reached its maximum. This may be a natural maximum, or one fixed by the discharge capacities of the bridges and culverts through the embankment. The amount of headway above this level, under the bridge floor, will depend upon what flotsam is carried by the water in floods.

The formula for discharge is :—

$$D = c\,A\,\sqrt{2gh},$$

where

D = discharge in cubic feet per second (cusecs); A = area of opening in square feet up to the lower water level; h = head, or difference of water levels (in ft.); g = 32·2 approx.; c is a coefficient depending partly upon the size of the opening, and partly upon its form, especially the curves of the cutwaters and wing walls.

Ordinary values for c are in many cases 0·90; for large and well-designed openings, 0·92 to 0·95; for smaller openings, 0·85 to 0·90.

In the case of culverts through an embankment, or for bridges, for the maximum discharge before the embankment is overtopped, it may be necessary to know the discharge when the opening is drowned. If it is drowned on both sides the discharge is :—

$$D = c\,A\,\sqrt{2gh},$$

where

h = difference of water levels, and c = about 0·75 to 0·85, according to the form and size of the opening.

Where the floor of the bridge presents a sharp edge a fairly low value of c should be taken and a fairly high value for well-shaped culverts.

In British measure, $\sqrt{2g} = 8 \cdot 02$; in metric measure, $\sqrt{2g} = 4 \cdot 419$.

When the upstream end is drowned and the downstream end is not drowned, the discharge is found by :—

$$D = cl \sqrt{2g} \left[\frac{2}{3}\left(h^{\frac{3}{2}} - h_2^{\frac{3}{2}}\right) + \left(h_1 - h\right)h^{\frac{1}{2}}\right],$$

where

l = the width of the opening ; h = the difference in water levels ; h_1 = the head above the bottom of the opening ; h_2 = the head above the top of the opening ; c may be taken as 0·75 to 0·85.

When the span is a long one and the waterway deep, a fairly high value may be given to c, but for a culvert the value may be taken as lower than that for the same culvert when wholly drowned.

In a considerable number of cases the waterway of the bridge is nearly as great as that of the stream, or quite as great when a single span clears the flood channel. Even with a considerable number of spans the bridge may obstruct the waterway very little if the piers are thin and are provided with good cutwaters and joinwaters. The velocity of approach may then be taken as v, the mean velocity of the stream, and the following relation will serve for preliminary calculations :

$$D = c\,A \sqrt{2g\,(h + h_a)}\,;$$

where

$ha = \frac{v^2}{2g}$; $A = dl$, l being the waterway of the bridge, and d the depth to the floor under the bridge.

For sluggish streams h may be neglected, and for a stream with a sharp fall it may be taken as the fall in a length measured about ¾ that of the piers. The equation, so used, may be useful in preliminary calculations ; where, for instance, the mean velocity of the stream is measured, but not its cross-sectional area, or where the discharge has been separately found. In the case of a sluggish stream it may be possible to fix the value of d, approximately.

Calculations involving Afflux.

Where the actual fall is small, as in most large rivers, and where the bridge considerably impedes the river, the total head driving the water through the opening is usually calculated as : $(x + h_a)$, where x = the afflux and h_a = head equivalent to the velocity of approach. The discharge is then :

$$D = c\,A \sqrt{2g\,(x + h_a)},$$

where

A = the smallest cross-sectional area of the waterway under the bridge, usually taken as that given by a water surface at the original water level.

$$x = \frac{v^2}{2g}\left(\frac{l^2}{c^2 l_1^2} - \frac{d^2}{(d + x)^2}\right),$$

where

l = the mean width of the stream ; d = mean depth of the stream below the bridge ; l_1 = the total width of waterway in the bridge openings ; c = coefficient of contraction, say 0·9 to 0·95 for large bridge openings and about 0·85 for small openings with only moderately good cutwaters and wing walls.

First insert the following provisional value of x in the right-hand side of the above equation.

$$x \text{ (provisional)} = \frac{v^2}{2g}\left(\frac{1{\cdot}1\, l^2}{l_1^2} - 1\right).$$

This gives a new value of x.

Repeat the solution of the longer equation with the new value of x on the right-hand side.

Next, to find h_a.

The head is calculated as that at one place, due to afflux and velocity of approach, and the velocity of approach is, therefore, the new reduced velocity of the deepened stream above the bridges, thus :

$$va = \frac{d}{d + x}\,v, \text{ and } h_a = \frac{v_a^2}{2g}\,;$$

we can then use the equation:

$$D = c A \sqrt{2 g (x + h_a)}.$$

If the length of the waterway is only estimated at first, within limits, take a probable value, and having found x, find l_1 by the equation:

$$l_1 = c \frac{vl (d + x)}{\sqrt{[2gx (d + x)^2 + v^2 d^2]}}.$$

In some cases x will be decided by the maximum water level which may be allowed, and the value so found will be used in the equations.

Discharge through Long Culverts.

The foregoing formulæ for discharge are suitable for short culverts, and for fairly long culverts when the velocities are low. For long culverts and for high velocities the head necessary to carry the water through the barrel regarded as a pipe must be added. The heads may be found by a pipe discharge formula, or, for small diameter culverts, may be taken from the tables (see 'Water Supply,' Section XVIII., Part VI.).

(Reginald Ryves, M.Cons.E.)

Weights of Bridgework.

Dead Loads.—The following are weights of various types of bridge floors, etc.:—

Jack arch flooring	140 lbs. per cu. ft.
Steel trough flooring	13–56 per sq. ft.
Roadway setts in cement	120 ,,
Timber sleepers	125 lbs. each.
Ballast (average depth 12 ins.)	100 lbs. per sq. ft. of floor.
Sleepers and ballast	100 lbs. per cu. ft.
5-lb. rails, chairs and all fastenings	$1\frac{1}{4}$ cwt. per lin. ft. of single track.
Jarrah wood-block paving $2\frac{1}{2}$ ins. thick, including mastic, pegs, and screws	$13\frac{1}{2}$ lbs. per sq. ft.
Tar macadam	120 lbs. per cu. ft.
Concrete filling over buckled plates	140 lbs. per cu. ft.
Fish plates	40 lbs. per pair.
,, bolts	$5\frac{1}{2}$ lbs. per set (4).
Oak keys	$2\frac{1}{4}$ lbs. per pair.
Chairs	45 lbs. each.

Approximate Weights of Girders, etc.

Unwin's Formula.

W_1 = weight of girder per ft. run, exclusive of cross-girders or flooring

$$= \frac{Wr}{cs - lr},$$

where

W = load to be carried in tons; l = span in ft.; r = ratio of span to depth; s = working stress in tons, sq. ins.; c = a constant, which may be taken from 1,200 to 1,400 for small plate girders and 1,700 to 1,900 for truss bridges.

Johnson, Bryan & Turneaure Formula.

Deck plate girders	$w = 9l + 120$
,, lattice girders	$w = 7l + 200$
Through pin bridge	$w = 5l + 350$

(These figures are for single tracks)

where

l = span in ft.; w = weight of each girder in lbs. per ft. run.

American Formulæ.

(1)

The following empirical formulæ, although roughly approximate, are useful as guides in assuming dead loads of ordinary truss road bridges (exclusive of flooring, cross-girders, and joints:—

For a capacity of 100 lbs. per sq. ft.,

$$W = s + 5b + \frac{(b-6)}{8} + \frac{l^2}{300} \quad . \quad . \quad . \quad . \quad . \quad (1).$$

For a capacity of 80 lbs. per sq. ft.

$$N = s + 5b + \frac{bl}{16} + \frac{l^2}{300} \quad . \quad . \quad . \quad . \quad . \quad . \quad (2).$$

For any other capacity of live load s_1, find W by formula (1), remembering $s = 100$; call required dead load W_1, then $W_1 = W - \left[1 + \frac{(b-12)l}{320}\right](100 - s_1)$,

where

W = dead load per lin. ft. exclusive of floor and joists (lbs.); s = live load per sq. ft. (lbs.); b = clear width of roadway (ft.); l = length of span (ft.).

(2)

For weight of small plate and angle girders,

$$P = \frac{Wl}{20d}$$

where

P = weight of beam (lbs.); W = total live load supported (lbs.); l = distance in feet between supports; d = total depth of beam in inches.

Skeleton Weights.

These formulæ are useful for obtaining the first approximation to the weight of main girders or trusses, but a more reliable approximation is obtained by calculating the skeleton weight and adding a percentage for details.

For trusses or systems of lateral bracing $P = \frac{3 \cdot 4k}{2240} \Sigma lA$;

where P is the total weight of the truss in tons, l is the length in feet of each member between intersection points, A the corresponding cross sectional area in square inches, and 3·4 lbs. the weight of a 1 inch square bar, one foot in length. Average values for the constant k are as follows:—

If A = area provided, including lacing bars, $k = 1 \cdot 2$.
If A = area provided, excluding lacing bars, $k = 1 \cdot 3$.
If A = area required, excluding lacing bars, $k = 1 \cdot 4$.

The method of skeleton weights is also extremely useful for determining economic outlines for trusses with regard to type, depth, number of bays, etc.

Working Stresses.

The following figures are those of a leading structural engineering company, in which a reduced working stress is used.

Permissible Maximum Stresses.

(A) *Railway Bridges.*

The working stresses shown below have been proportioned to allow for dynamic action of the live load on lightly loaded girders or members of girders.

(B) *Road Bridges.*

To provide for the effects of the dynamic action of the live load on lightly loaded girders or members of girders, the live load stresses to be increased by 25 per cent. in the case of main girders and 33⅓ per cent. in the case of floor girders.

(C) *Railway and Road Bridges.*

(1) The combined stresses resulting from the rolling load, dead load, wind, momentum, and centrifugal force, shall not produce a greater tensile stress than half of the elastic limit, or equal to $\frac{3}{10}$ of the minimum ultimate tensile strength of the material, nor more than the corresponding compressive shearing, bearing, and bending stresses as hereinafter set forth, but

(2) The combined stresses resulting from the rolling load and dead load alone, exclusive

of wind, momentum, and centrifugal force, shall not produce greater tensile stresses than those given below.

TENSILE STRESSES.

Railway Bridges.

For main girders, cross-girders, and rail bearers of plate construction:

Under 20ft. span	4½ tons per sq. in.
20 ft. to 25 ft.	4¾ ,, ,,
25 ft. to 30 ft.	5 ,, ,,
30 ft. to 50 ft.	5¼ ,, ,,
50 ft. to 80 ft.	5½ ,, ,,

For trusses and lattice girders:

80 ft. and under 160 ft. span—	
Bottom chords	5½ tons per sq. in.
Diagonals	4½ to 5½ tons per sq. in.
160 ft. and under 200 ft. span—	
Bottom chords	5¾ tons per sq. in.
Diagonals	4½ to 5¾ tons per sq. in.
200 ft. to 400 ft. span—	
Bottom chords	6 to 7 tons per sq. in.
Diagonals	4½ to 7 tons per sq. in.
All spans—for wind bracing	8½ tons per sq. in.
Floor suspenders	2½ ,, ,,

Road Bridges.

For main girders, cross-girders, and stringers:

Bottom chords	7 tons per sq. in.
Diagonals	5–7 tons per. sq. in.
Wind bracing	8½ ,, ,,
Floor suspenders	3½ ,, ,,

Note.—The 4½ tons stress on diagonals of railway bridges, and the 5 tons stress on road bridges, will apply to those at the centre portion of the span and to the counterbracing at the same point. The higher stresses will apply at the end portions where variations of stress are not so great. Intermediate diagonals will be subject to stresses lying between these limits.

COMPRESSION STRESSES.

Railway and Road Bridges.

For plate girders, the gross area of the compression flange shall not be less than that of the tensile flange, nor shall the compression stresses per sq. in. be more than 85 per cent. of the corresponding tensile stresses.

For truss and lattice girders the compression stress per sq. in. shall, in the case of riveted members, not exceed the fraction '$0{\cdot}95-0{\cdot}003R$' of the corresponding specified tensile stress nor in the case of pin joints the fraction '$0{\cdot}95-0{\cdot}0045R$,' where $R =$ the ratio of the length of the unbraced portion of the member to its least radius of gyration; nor in any case shall it exceed 85 per cent. of the said tensile stress.

No compression member in railway bridges shall have a greater length than 100 times its least radius of gyration, or 45 times its least width, except for wind bracing, which may have a length not exceeding 120 times its least radius of gyration.

In the case of road bridges no compression member shall have a length exceeding 120 times its least radius of gyration, except wind bracing, which may have a length not exceeding 140 times its least radius of gyration.

ALTERNATING STRESSES.

Railway and Road Bridges.

Members subject to alternate tension and compression stresses shall be proportioned as struts to resist the greater stress plus half the lesser, except for wind bracing, which shall be proportioned for the greater stress only. The sum of the stresses to be used for connections.

PERMISSIBLE UNIT STRESSES IN SWING BRIDGES.

The unit working stresses in main girders shall be 10 per cent. less than those for simply supported spans. *(Sir W. Arrol & Co., Ltd.)*

PERMISSIBLE UNIT STRESSES, IN POUNDS PER SQUARE INCH.

Kind of Strain, and Loading.		Structural Steel.	Axle Steel.	Steel Castings.	Cast Iron.	Rolled Copper.	Brass.
Tension	(A)	16,000	18,000	12,000	3,000	6,000	3,000
	(B)	10,600	12,000	8,000	2,000	4,000	2,000
	(C)	5,300	6,000	4,000	1,000	2,000	1,000
Compression	(A)	16,000	18,000	16,000	12,000	6,000	3,000
	(B)	10,000	12,000	10,000	8,000	4,000	2,000
Bending	(A)	16,000	18,000	15,000	6,000	—	—
	(B)	10,600	12,000	10,000	4,000	—	—
	(C)	5,300	6,000	5,000	3,000	—	—
Shear	(A)	12,000	14,000	9,000	3,000	3,600	—
	(B)	8,000	9,600	6,000	2,000	2,400	—
	(C)	4,000	4,800	3,000	1,000	1,200	—
Torsion	(A)	10,000	12,000	7,500	3,000	—	—
	(B)	6,600	8,000	5,000	2,000	—	—
	(C)	3,300	4,000	2,500	1,000	—	—

A. For a static load; *B*. For a varying load producing stresses of tension or compression only; *C*. For a varying load producing equal maximum strains in opposite directions, accompanied by shocks and vibrations.

The permissible unit stresses for bending (given opposite *B*)—10,000 for cast steel and 4,000 for cast iron—should be used for determining the strength of toothed gearing. The teeth in cut gearing should conform to the following proportions :—

$$P = s\,p\,f\,y.$$

where,

P = pressure on tooth in pounds ; s = permissible unit stress ; p = pitch, in inches ; f = face of tooth, in inches ; y = a factor.

For wheels moving at slow speed (up to about 100 ft. per minute), where strength only is to be considered, y = 0·05.

The strength of uncut teeth should be computed for a face of one and one-half times the pitch, or

$$P = \frac{3\,s\,p^2\,y}{2};$$

which conforms approximately with the assumption that the pressure is carried on one corner of the tooth.

For higher velocities, which tend to increase the shock and wear, this value should not exceed :—

$$y = 0{\cdot}05\ \frac{10}{\sqrt{v}} = \frac{0{\cdot}5}{\sqrt{v}}$$

where

v = velocity in pitch circle, in feet per minute.

For bronze wheels, the same values should be used as for cast iron.

FIXED BEARINGS.

For the permissible unit pressure for fixed bearings of different metals, those for compression, in the table, should be used.

Working Stresses in Structural Steel.

(BRITISH STANDARD SPECIFICATION FOR GIRDER BRIDGES.)

Except as hereinbefore modified, structures shall be so designed that the calculated working stresses in structural steel of the 'A' quality specified in Clause 1, Part 1, of this Specification shall not exceed the following :—

For Parts in Tension.

On the net section for axial stress,

9 tons (20,160 lbs.) per sq. in. (14·17 kg. per mm.²).

For Parts in Compression.

On the gross section of the compression flanges of plate girders and I beams with outside edges stiffened with angles or channels,

$$9\left(1-0\cdot0075\,\frac{l}{b}\right) \text{ tons per sq. in.}$$

Ditto, with unstiffened edges,

$$9\left(1-0\cdot01\,\frac{l}{b}\right) \text{ tons per sq. in.}$$

where,

l = the greatest unsupported length as defined in Clause 11, Part 4, of this Specification, and

b = the breadth of the flange,

provided that the gross area of the compression flange shall be not less than the gross area of the tension flange.

On the gross section of compression members of truss and lattice girders with riveted connections for axial stress,

$$9\left(1-0\cdot0038\,\frac{l}{r}\right) \text{ tons per sq. in.}$$

On the gross section of compression members of truss and lattice girders with pin connections for axial stress,

$$9\left(1-0\cdot0054\,\frac{l}{r}\right) \text{ tons per sq. in.}$$

Where

l = the greatest length of the unbraced portion of the member

and

r = the least radius of gyration,

provided that, in truss and lattice girders, the working compressive stress on the gross section shall in no case exceed 7·65 tons (17,136 lbs.) per sq. in. (12·05 kg. per mm.^{2}).

For Parts in Shear.

On the gross section of web plates,

5·5 tons (12,320 lbs.) per sq. in. (8·66 kg. per mm.^{2}).

On shop rivets, turned tight-fitting bolts and pins,

6·5 tons (14,560 lbs.) per sq. in. (10·24 kg. per mm.^{2}).

For Bearing Areas.

On shop rivets, turned tight-fitting bolts and pins,

15 tons (33,600 lbs.) per sq. in. (23·62 kg. per mm.^{2}).

NOTE.—For connections which are to be made in the field or where black bolts are used instead of rivets, an excess of 15 per cent. in the case of field rivets and 20 per cent. in the case of black bolts over the number required according to the above working stresses, both for shear and bearing, shall be provided.

For Pins subjected to Bending.

On the extreme outer fibres,

13·5 tons (30,240 lbs.) per sq. in. (21·26 kg. per mm.^{2}).

Where structural steel of the milder quality specified in Clause 1, Part 1, of this Specification for material to be pressed cold is used, the foregoing working stresses where applicable shall be reduced by 10 per cent.

FOR PLATE GIRDERS AND BEAMS EMBEDDED IN CONCRETE.

On the tension and compression flanges of plate girders and I beams, the compression flanges and webs of which are solidly embedded in a continuous concrete matrix or jack arches, and with an effective cover of not less than 2 ins. concrete throughout over upper surfaces of the top flange, and where no account has been taken of the strength of the embedded matrix :—

10 tons (22,400 lb.) per sq. in. (15·75 kg. per mm.^{2}).

HIGH TENSILE STRUCTURAL STEEL.

In May 1934 the British Standards Institution published the British Standard Specification No. 548, for High Tensile Structural Steel for Bridges and General Building Construction, relating to steel having a range of tensile breaking strength from 37 to 43 tons per sq. in., and a yield point varying from 19 to 23 tons per sq. in., according to the thickness of the plate or section.

The working stresses usually allowed in steel of this quality are about 40 per cent. higher than the values specified for mild steel (structural steel, A quality) on p. 495.

High-tensile steel has been increasingly used of late years, especially in the construction of long-span bridges.

FIRST-CLASS BRITISH PRACTICE IN BRIDGEWORK.

Brief Specification.

1. Materials to conform to the British Standard Specifications.

2. All steel to be by open-hearth acid or basic process.

3. No material to be used until tested and passed.

4. Steel castings to be Grade 'C.'

5. Bolts and nuts, coach screws, clips, etc., to be Grade 'C' wrought iron.

6. All oak to be English or Scotch.

7. Edges of all flange, end, and web plates and ends of all bars to be planed, or where planing not possible, to be dressed fair and true by hand.

8. Wherever shearing is adopted a $\frac{1}{8}$ in. strip to be left for planing, plates and bars showing less than $\frac{1}{8}$ in. rejected.

9. All plates, bars, angles, tees, etc., carefully levelled, straightened, joggled, or upset by pressure and not by hammering, both before and after they are drilled.

10. Templates and gauges to be made to correspond exactly with each other in order that all holes may be straight through and through. Steel gauge $\frac{1}{16}$ in. less in diameter than hole shall pass through easily, irrespective of thickness of plates or bars.

11. Holes for turned bolts to be a driving fit.

12. All holes to be drilled and burrs carefully removed. Holes for rivets to be $\frac{1}{16}$ in. larger than nominal size of rivet.

13. Wherever practicable, all riveting to be done by machine. All loose rivets and such as may be cracked or have burnt or badly formed heads or with heads eccentric with the shaft or where the shaft does not fully fill the hole, cut out and replaced by others.

14. No edge of rivet or bolt hole to be nearer edge of plate or bar, etc., than a distance equal to one and a half times the diameter of rivet.

15. All work riveted or bolted together to be absolutely in contact over whole surface. Immediately before being assembled together whole of surfaces to be thoroughly cleaned and painted with a thick coat of genuine red lead paint.

16. All bolts to be forged and not welded. Screwed to Whitworth's thread. Those taking a shear stress to be so screwed that no part of the thread is in contact with bearing surface.

17. The barrel of all turned bolts to be $\frac{1}{16}$ in. larger in diameter than the screwed portion. Machined washers to be provided.

18. All bolts to be dipped in hot boiled linseed oil.

19. Cover plates connecting different thicknesses of plates to be planed off, the step to be sloped off.

20. All work to be temporarily erected and put together with service bolts.

21. All steelwork to be scraped and cleaned of all rust, mill-scale, and dirt and brushed with wire brushes.

22. All steelwork not to be galvanised to be given two coats of Dixon's Silica Graphite Paint No. 2, or natural colour, and a further two coats after erection, the last a finishing coat of approved colour. No oils or thinners to be used.

Girder Bridge Specification.

A specification issued by the British Standards Institution (No. 153—1933) deals with railway and highway bridges. The first part is concerned with materials of construction (structural and rivet steel, cast steel, steel for pins and rollers, wrought iron and cast iron); these are required to be in accordance with existing B.S. specifications, and the latter are printed as appendices, making the present document complete in itself. The second part gives requirements as regards workmanship, and includes clauses on straightening, planing and shearing, drilling, punching and reaming, rivets and riveting, smithed work, bolts and nuts, temporary erection at contractors' works, painting, measurement, and packing and marking for export. Parts 3, 4 and 5 (revised in 1937) deal with loads and stresses, details of construction, and erection.

WIND PRESSURE.

During a period of fourteen years, from 1890 to 1904, observations were made at fourteen different stations in the United Kingdom, and it was found that the maximum mean wind velocity only reached the following values:—

77–80	miles	per hour	on one occasion.
73–77	"	"	"
70–73	"	"	five occasions.
65–69	"	"	"

The records of many stations in the British Isles from 1906 to 1918 show that the maximum gusts recorded were :—

99 miles per hour, once.
90 ,, ,, twice.
85–90 ,, ,, nine times.

Velocities very much in excess of these values have been officially recorded by the Robinson anemometer, the velocity of the cups being multiplied by 3, to give the actual velocity of the wind. This figure is now recognised to be too high, and a value of 2·2 is substituted as a multiplier.

The velocity of wind, and therefore the pressure, increases with the height above ground.

The following observations are due to Mr. Adam Hunter, M.I.C.E., and were taken on the Forth Bridge by means of small gauges 1·5 sq. ft. in area placed at different heights.

Year.	Date.	Pressure in Pounds per sq. ft. at Various Heights.				
		50 ft.	163 ft.	214 ft.	214 ft.	378 ft.

The two readings at 214 ft. are at opposite ends of the bridge.

Relation between Velocity and Pressure.

(See Sec. XXXII, Part II.)

Notes on Wind Pressure on Bridges.

There is considerable shielding effect of the leeward members of a framed structure by those on the windward side, dependent mainly upon their distance apart.

The determination of effective wind pressure on bridges presents many difficulties, arising chiefly out of the irregular shape and construction of those other than plate girder spans.

Plate girders are not, strictly speaking, flat plates, and up to 10 per cent. increase in area is often allowed for the effect of their cup-shape form.

The following remarks are taken from the British Standard Specification :—

'Where wind pressure has to be taken into consideration, it shall be treated as a moving load not subject to any impact effect and shall be assumed to act horizontally at a slight angle to the transverse axis of the structure so as to take effect on the exposed area of the flooring and the leeward parts in the case of openwork structures, except where any portion may be temporarily screened by a moving load. Where the leeward girder is at a distance from the windward girder not exceeding twice its depth, the effective area of the former shall be taken at half the exposed surface, but where the distance apart exceeds twice the depth, the whole exposed surface shall be taken into account. When the structure is unoccupied by a moving load, the maximum pressure shall be assumed to be 50 lbs. per sq. ft. (244·12 kg. per m.^{2}), but when there is a moving load thereon a pressure of 30 lbs. per sq. ft. (146·47 kg. per m.^{2}) in the case of railway bridges, and 20 lbs. per sq. ft. (97·65 kg. per m.^{2}) in the case of road bridges, shall be assumed as acting on the exposed surfaces both of the structure and the moving load, the pressure on the latter being taken as acting through the centre of gravity of the exposed area. The maximum results from the wind blowing in either direction, and with the structure loaded or unloaded, shall be taken. Where, owing to the position of the bridge or local conditions, these pressures cannot be reached or may be exceeded, the engineer may, at his discretion, alter any of them, as required.'

In providing the necessary anchorage for the bridge a train of empty passenger carriages to be assumed to be on the bridge, weighing 10 cwt. per lin. ft., and in the case of a double track the leeward track only to be loaded.

It is customary to specify a reduced wind pressure for a loaded span for the following reasons :—

(*a*) Because the total area exposed to the wind is increased, and hence the allowance necessary for the rise in pressure due to gusts above that corresponding with the maximum mean wind velocity is not so great as is necessary with a smaller area.

(*b*) Because the resistance offered by a body like a train is not so high as that offered by a surface like a bridge.

During a storm of great intensity the speed of trains crossing bridges will probably be reduced, owing to a feeling of insecurity on the part of drivers, but it cannot be assumed that the impact of trains, except for spans less than 150 ft., will be reduced ; for this depends more upon critical speeds than upon their maximum velocities.

It is therefore necessary, in such cases, where a reduced wind pressure is assumed for calculation, to carefully consider the effects of wind in all its aspects, treating it particularly as a moving load on the train.

The shielding effect of double bars will be to a large extent eliminated if the wind is treated as acting at a slight angle as mentioned.

In bridges of large dimensions it is necessary to make a somewhat different and more exact computation of wind pressures, and where the spaces are large, separate calculations for each individual member based upon their size, shape, and form, may be essential.

Centrifugal Force.

South American Railway Practice.

Centrifugal force on bridges on curves taken at 0·02 of the live load for each degree of curvature up to 5°, and reduced by 0·001 for every degree of curvature above 5°—the force considered as acting at a height of 5 ft. above rail level. In short spans where impact is high, a percentage for impact is added.

British Practice.

Centrifugal force for each degree of curvature, assumed to be 1 per cent. of the maximum rolling load on all tracks for a speed of 30 miles and under, and 1 per cent. added for each increase in speed of 10 miles per hour. Considered as acting at 5 ft. above rail level.

The radius in feet (R) is reduced to degrees of curvature (D) by means of the following formula:—

$$D \times \frac{5730}{R}.$$

Theoretically, centrifugal force varies *directly* as the weight of the train, and as the square of the velocity at which it travels, and *inversely* as the radius of the curve, or

$$P = \frac{W}{g} \times \frac{V^2}{r},$$

where

W = weight of train in tons ; V = its velocity in ft. per sec. ; r = radius of curvature of rails in ft. ; g = 32, the force of gravity ; P = centrifugal force in tons.

The whole of the centrifugal force is not usually neutralised by the superelevation of the rails, hence the allowances are made as above.

British Standard Specification for Centrifugal Force.

Where a structure carrying a railway is situated on a curve, provision shall be made in designing the members for the stresses due to the centrifugal action of the moving loads, each track on the structure being considered as occupied. The allowance for the centrifugal effect shall be calculated from the following formula :—

$$C = \frac{WV^2}{15\ R}$$

where,

C = the centrifugal effect per lineal foot considered as a moving load, acting at a height of 6 ft. (1·83 m.) above the level of the rails, unless otherwise specified by the engineer ;

W = the equivalent distributed live load per lineal foot;

V = the allowable maximum speed of the train in miles per hour, as specified by the engineer; and

R = the radius of the curve in feet.

No increase for impact effect shall be made on the stresses due to the centrifugal action.

Momentum of Trains.

Tractive Force and Braking Stresses.

In bridges of large dimensions special attention should be given to the details of the structure, to provide for the longitudinal stresses resulting from sudden application of continuous brakes to the train while on the bridge. The horizontal force resulting from such action can be taken as one-fifth of the weight of the train.

The adhesion weight of locomotives is usually about 450 lbs. per ton of load on the coupled axles.

(Refer also to Power, Tractive Force, and Adhesion of Locomotives, Train Acceleration, etc., Section XXXII., Part II., 'Railways.')

Longitudinal Forces.

Where a structure carries a railway, provision shall be made for the stresses due to the tractive effort of the live load and the braking effect resulting from the application of the brakes to such load while passing thereover, these forces being considered as acting at rail level.

(*a*) For railways worked by steam or electric locomotives, the amount of the tractive effort on one track shall be ascertained by multiplying one and three-quarter times the maximum end shear due to the live load on that track by a factor equal to :—

$$\frac{20}{L + 75}$$

where,

L = the span in feet. The load on the track shall be calculated from the shear table for end shear as set out in Appendix I., or such other loading as may be specified by the engineer. The factor shall not exceed 0·15 as a maximum.

The braking effect shall be similarly determined by using a factor equal to :—

$$\frac{12}{L + 90} + 0{\cdot}075$$

also limited to a maximum of 0·15.

(*b*) In the case of lines worked solely on the electrical multiple unit system, the amount of the tractive effort on one track shall be ascertained by multiplying the sum of the actual wheel loads on the span by a factor equal to :—

$$\frac{3}{L - 10} + 0{\cdot}10$$

where,

L = the span in feet. The factor shall not exceed 0·20 as a maximum.

The braking effect shall be similarly determined by using a factor of 0·20 for all spans.

(*c*) Where the structure carries more than one track, all the tracks shall be considered as being occupied simultaneously by the live loads, tractive and braking forces being applied to alternate tracks. The maximum effect on any girder with two tracks so occupied shall be allowed for, but where there are more than two tracks, a suitable reduction may be made on these forces for the additional tracks at the discretion of the engineer.

No increase for impact effect shall be made on the stresses due to the longitudinal forces.

(*B.S.I.*)

Impact.

If a load is applied suddenly to a structure, vibration will ensue and the strain—and thus the stress—will reach twice the value which would occur if the load were gradually applied. There is a great similarity between the results of experiments on variation of stress and sudden loading. The French Government obtain working stresses by means of the Launhardt-Weyrauch formula, but in America and this country various impact formulæ have been devised, but which are by no means final.

Theory prescribes that the following circumstances at least should be taken into account in any impact formula:—

(1) The length of the bridge;
(2) The ratio of live to dead load;
(3) The natural frequency of the bridge;
(4) The fluctuation in rail pressure due to balance weights, hammering, etc.;
(5) The size of the driving wheels.

To supply the necessary information required under (3), a systematic research is required dealing with bridges of various sizes and types.

Waddell's Formula.

$$I = \frac{400}{L + 500},$$

where

L = length of that portion of the span which is covered by the live load when the maximum stress under consideration is produced, and I is the percentage by which the maximum static stress is to be increased.

Allowance for Impact in Bridges.

S = span in ft.; V = velocity in ft. per sec.; T = time in secs. required by a train travelling at velocity V to travel from the point where a given member commences to receive the stress to the point where the stress is a maximum (i.e. in a plain girder, T is the time taken to pass half the span); D = maximum allowable deflection; t = time taken for a free falling body to fall through a height D, then

$$t^2 = \frac{D}{16}, \text{ or } t = \tfrac{1}{4}\sqrt{D}$$

If

P = percentage allowance for impact, then

$$P = \frac{50V\sqrt{D}}{S}.$$

As the formula is correct for a single concentrated load only, it gives excessive allowances for long spans, and P may be reduced $\frac{1}{30}$th of its found value for each 25 ft. span in spans of over 25 ft.

In all cases where V is such that the load traverses the half span in less time than t, the percentage for impact must be 100, the maximum V being fixed at 100 ft. per sec.

For a deflection of $\frac{1}{2500}$ of the span, $P = \dfrac{V}{\sqrt{S}}$, less the allowance for spans above 25 ft.

These formulæ are based on the idea that impact must vary with the time of application of the load. On a long bridge even a high speed train only reaches its position of maximum bending moment after several seconds, so that the bridge deflects slowly to its maximum deflection and goes very little beyond what the train at rest would produce. This applies to main members. Floor beams and their attachment, however, receive maximum stress very rapidly, for the train advances to full effect in the brief space of one panel length. On floor stringer end-connections the first end is loaded absolutely instantaneously; the stringer itself takes its maximum load in about half a panel length, and so on; each member is to be allowed for impact according to the time required from its first feeling the load to the time of maximum moment. No simple load can produce an impactive stress more than double its static stress, but a swaying locomotive may have more than half its load on the wheels of one side, so that a wheel which may cause a maximum load on, say, the first end of a floor stringer, may happen to be loaded at the moment perhaps 30 per cent. more than its half share of the load on its axle, and at the same time it may happen that the balance weight is just delivering its downward hammer blow. Thus care is needed to give ample strength to details even of larger bridges, but the main members of a large bridge are but little affected by the trivial details of locomotive swaying, hammer blow, &c.

British Standard Specification for Impact Effect on Road Bridges.

In the case of road bridges the addition to the live load, which shall cover all impact effects due to the vehicle and its load or to irregularity of surface, shall be ascertained by multiplying the live load by a factor derived from the following formulæ:—

(1) For bridges carrying one line of traffic only:—

$$I = 0 \cdot 75 - 0 \cdot 002\,l \text{ with a maximum value of } 0 \cdot 60.$$

(2) For bridges carrying two or three lines of traffic:—

$$I = 0 \cdot 65 - 0 \cdot 002\,l \text{ with a maximum value of } 0 \cdot 50,$$

where I = the factor and l = the effective span in feet.

For a main girder the effective span shall be the distance between the centres of bearing plates or rocker pins.

For a cross girder, other than an end cross girder or intermediate cross girder at which the continuity of the flooring is interrupted, l shall be the distance between centres of the cross girders on either side thereof. In the case of an end cross girder or intermediate cross girder at which the flooring is interrupted l shall be the distance between the centres of the cross girder and the adjacent cross girder, or where the flooring is continued beyond the cross girder the distance between the centre of the adjacent cross girder on the one side and the termination of the floor members on the other, except that where the floor members terminate on an abutment or pier the centre of the bearing of the floor members thereon shall be taken as the limit of l on that side.

For a longitudinal bearer the effective span shall be the distance between the centres of the adjacent cross girders supporting the bearer or the centre of the cross girder supporting the bearer at one end and the centre of its bearing on the abutment or pier at the other.

When a member supports or assists in supporting more than three lines of traffic the engineer shall specify any required modification of formula (2).

In the case of all end cross girders on which the flooring is terminated and for bridges in which the deck does not form a rigid combination with the bridge structure, as in the case of timber decking bolted thereto, no maximum limit shall be imposed on the value of I.

The allowance for impact on road bridges is based upon the assumption that the carriage-way on and immediately adjacent to the bridge is properly constructed and maintained in good surface.

No addition for impact shall be made to the live load due to pedestrian or equivalent light traffic.

Bridge Stress Committee's Recommendations for Impact Effect.

The Bridge Stress Committee found all existing locomotives in this country to be covered by the British Standard Unit Loading multiplied by 18 units, and that three of the four main railways designed bridges for main lines and principal branches for 18 units.

The Committee consider that the effects of existing locomotives are covered by the following combinations :—

18 units of load with a total hammer blow of	5 tons at	5 revs. per sec.
16 ,, ,, ,, ,,	12·5 ,,	5 ,,
15 ,, ,, ,, ,,	15 ,,	5 ,,

For the design of new bridges the Committee recommends the following loadings which may be taken to cover any locomotives which are likely to be designed in the future :—

Loading A, 20 units of load with a total hammer blow of	$0 \cdot 2\ n^2$ tons
Loading B, 16 ,, ,, ,, ,,	$0 \cdot 5\ n^2$ tons
Loading C, 15 ,, ,, ,, ,,	$0 \cdot 6\ n^2$ tons

where n is the number of revolutions per second, generally taken to be 5, or at most 6.

For the A loading the total hammer blow is divided equally between the two central coupled axles, or alternatively for short spans, between the two axles loaded with 1·25 units (page 482, fig. 2).

For the B loading the total hammer blow of $0 \cdot 5n^2$ tons is distributed as follows : $0 \cdot 18\ n^2$ tons on each of the central coupled axles and $0 \cdot 07\ n^2$ tons on each of the outer coupled axles, or alternatively for short spans a hammer blow of $0 \cdot 278\ n^2$ tons is supposed to be concentrated on one of the two axles loaded with 1·25 units.

For the C loading the total hammer blow of $0 \cdot 6\ n^2$ tons is distributed as follows : $0 \cdot 217\ n^2$ tons on each of the central coupled axles, and $0 \cdot 083\ n^2$ tons on each of the outer coupled axles, or alternatively for short spans hammer blows of $0 \cdot 055\ n^2$ tons on one of the two axles loaded with 1·25 units, and $0 \cdot 278\ n^2$ tons on the other axle.

For rail bearers or small culvert superstructures, the hammer blow is by no means equally divided between the two wheels of an axle. For the A loading six-fifths of the hammer blow, and for the B and C loadings five-sixths of the hammer blow should be calculated as applied to one wheel.

To provide against lurching in the case of deck spans each girder should be calculated to carry five-eighths of the total load instead of one-half, equivalent to an increase of 25 per cent. In the case of through bridges the corresponding maximum proportion of the load carried by each girder should be calculated on the supposition that either rail load of any track may be subject to an increase of 25 per cent. and the remaining rail load to a decrease of 25 per cent.

To cover the effect of rail joints and other irregularities provision should be made for an additional concentrated load of $\frac{n^2}{6}$ tons on each track, equivalent to a distributed load of $\frac{n^2}{3}$ tons, where n as before is the number of revolutions per second.

These additions to the British Standard Unit Loading make up the total impact allowance in accordance with the recommendations of the Bridge Stress Committee, except that for long spans the effect of the synchronization of two locomotives is considered.

Temperature Variation and Stresses.

Variation of Temperature and Expansion.

Records which have been made at Greenwich show the average range for twenty years to be 11° below and 13° above the mean temperature. The maximum annual range of temperature in the shade may be 85°, and in the sun as much as 137°. The theoretical expansion which these temperatures would cause in steel would be $\frac{5}{8}$ in. and 1 in. respectively in a length of 100 ft.

The observed movement in the Forth Bridge is $\frac{7}{16}$ in. per 100 ft., while the rise in the crown of one of the cast-iron arched ribs of the Old Southwark Bridge was $1\frac{1}{4}$ ins., the length of the chord of the intrados of which was 246 ft. and the versed sine, 23 ft. 1 in.

In tropical and sub-tropical countries the variation between the highest day temperature and the lowest night temperature may be as much as 150° F. or more.

Provision for Expansion.

For spans less than 40 ft. it is not customary to provide bearings with means of expansion, but for spans in excess of this, provision for expansion to the extent of 1 in. in every 100 ft. should be allowed. No allowance is usually made for expansion and contraction in the direction of the width of the structure, but in large and wide bridges it will be necessary to consider this.

Temperature Stresses.

The forces due to unequal temperatures on different parts of a lattice girder bridge act very slowly and, due to the slow yielding property of ductile metals such as steel, cause the parts of the frame to adjust themselves to the gradual stresses to which they are subjected. Nevertheless temperature stresses in large bridges must be carefully considered.

If the ends of a bar or portion of a bridge are rigidly fixed, a difference of temperature of 100° F. will cause a stress of 8·51 tons per sq. in.

Let

l = length of a bar at 0° F. (in feet); l_1 = its length at t° F. (in ft.); ϕ = coefficient of linear expansion for 1° F.; E = Young's modulus,

then

$$\text{Elongation for } t^\circ = \phi . t . l; \quad l_1 = l(1 + \phi t);$$

$$\text{Stress per }^\circ\text{ F.} = \phi \times E \text{ tons per sq. in.}$$

Bedplates and Bearings.

Types of Bearings.

Bridges of spans below 100 ft. are not usually fitted with any special means for allowing free expansion, but are simply fitted with a sole plate resting on a bearing block, the holes in the sole plate at one end of the bridge being slotted to allow of movement. The bearing block may rest upon hair-felt or sheet lead.

Bridges over 100 ft. span should rest at one end on roller bearings of not less than 4 ins. diameter, or some other form of expansion bearing.

The average type of roller bearing is usually very liable to rust up and become filled with dirt, etc., that falls from the bridge, and so becomes practically useless, unless very carefully designed with a view to eliminating this source of trouble.

For bearings of large span bridges to be really satisfactory, they should have some means of providing for the deflection of the bridge under load. This is now arranged for by having some sort of knuckle at both ends of the bridge; a bearing of this type is shown in fig. 4, which, however, is not to be regarded as satisfactory as regards the roller portion, which should be protected from rust and dirt.

The pressure in pounds per lineal in. on rollers of mild steel **should not exceed 560*d*, where *d* equals the diameter of the roller in ins.**

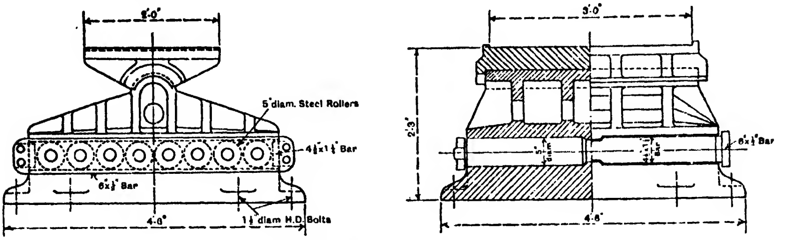

Fig. 4.—Combined Knuckle and Roller Bearing.

The bedplates should be of sufficient area to distribute the load over the masonry abutments, the limiting or working pressures being

Granite	**25 tons per sq. ft.**
Hard stone	**20 ,, ,,**
P.C. concrete (1-2-4)	**18 ,, ,,**

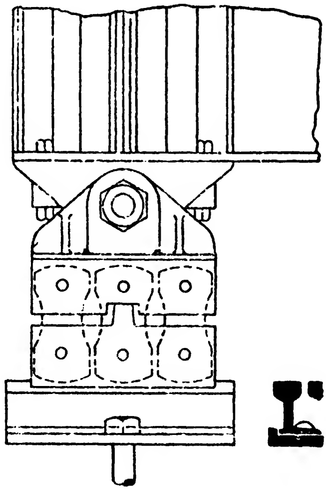

Fig. 5.—Combined Rocker and Roller Bearing.

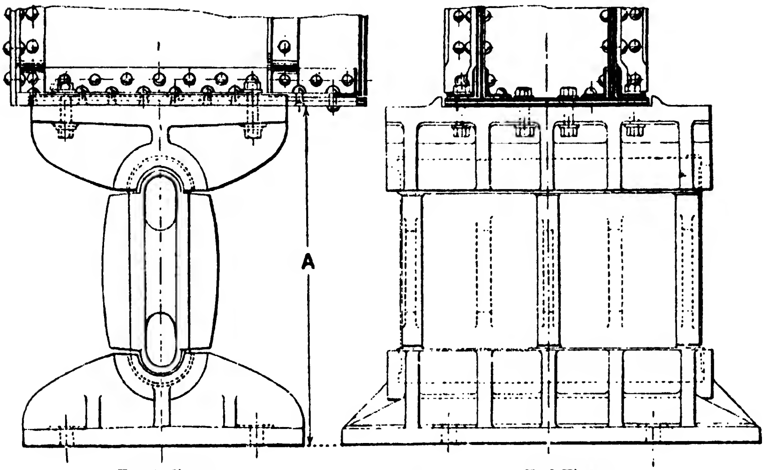
A form of end bearing is shown in fig. 5, which is a combined rocker and expansion bearing for the free end of the bridge. The pin in this case takes the place of the knuckle in providing for deflection.

Rigby's Patent Expansion Rocker Bearing.

A very excellent bridge bearing for spans of 100 ft. and over, is the one designed and patented by the late Mr. H. Rigby, M.I.C.E.

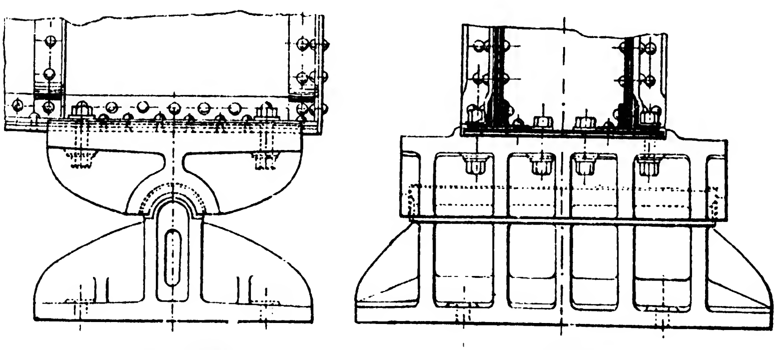
The bearing for both fixed and free ends is shown in figs. 6 and 7.

In this type the knuckles provide for deflection and the rocker for expansion. These bearings are considerably cheaper than most other forms, much simpler in construction, and are quite immune from the effects of rust and dirt in operation.



Front View. End View.

Fig. 6.—Rigby's Patent Expansion Rocker Bearing.



Front View. End View.

Fig. 7.—Rigby's Patent Bearing for Fixed End.

Flooring.

Buckled Plate Flooring.

The resistance of square buckled plates, bolted or riveted down all round, is double the resistance of the same plate merely supported all round, and if the two opposite sides be wholly unsupported, its resistance is reduced in the proportion of 8 to 5.

The stiffness of buckled plates is as the square of the thickness, and inversely as the curvature.

Two inches curvature suffices for 4 ft. square and ¼ in. thick.

Ordinary plates are made 3 ft. and 4 ft. square.

Weight and Safe Load of Buckled Plates, 3 ft. square.

8	⅜ in. . .	135·0	9·0	1·0	1·8	0·755

The safe loads may be doubled for buckled plates of puddled steel.

Buckled plates are usually made 3 ft. to 6 ft. square and ¼ in. to ⅜ in. thick. They can also be obtained in long lengths having several buckles to the plate.

To calculate the load uniformly distributed over a buckled plate, which will crush it—the plate being square and fastened all round the edges—multiply the depth to which the plate is buckled by the square of the thickness, both in inches, and by 165; the product will be the crushing load in tons (nearly). Central load which will crush a buckled plate, about one-third of uniformly distributed load. *(Rankine.)*

Corrugated Plates and Troughs.

These plates and troughs are made of ordinary steel plate and can be obtained in sizes from 2½ ins. deep to 16 ins. deep, and in lengths up to 30 ft., without joint in the smaller sizes and up to 40 ft. in the larger sizes and thicknesses. The advantages claimed are:—

(1) Ordinary plate is used and pressed in moulds in such manner that no deformation of the plate occurs.

(2) The sections can be made of any thickness to suit requirements and are therefore very economical from the point of view of weight.

The smaller sizes are manufactured with several corrugations in one plate and the larger sizes with only one trough or corrugation.

Distribution of Load.

It may be assumed that the wheel loads are distributed over 5 ft. run of the floor if the sleepers are parallel with the troughs and 10 ft. if at right angles to the troughs.

The strength and stiffness of trough or corrugated flooring, when riveted up, is considerable. Each trough may be treated as a girder, but then each girder is connected to its fellow; thus when the load is applied to, say, one trough it cannot deflect without dragging down its adjoining troughs for some distance on each side.

Floor Troughing.

Troughs, fig. 8, are composed of special rolled sections of the form of splayed channels and can be obtained in many sizes. The advantages claimed are that the webs are thin and the bottoms and tops thick, and so approach what is required from the girder point of view, also that the riveting is situated at the neutral axis, where the bending stresses are a minimum.

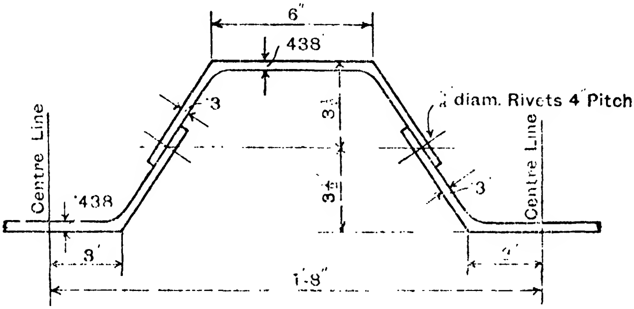

Fig. 8.—Steel Trough.

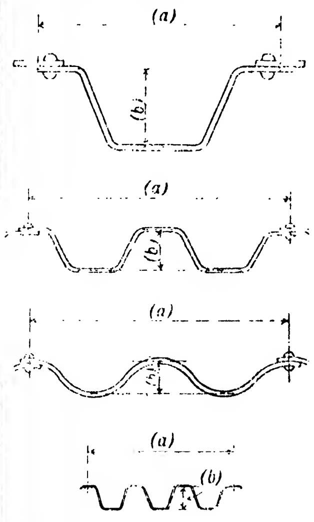
Weight over sq. ft. of area covered = 24·52 lbs Section Modulus = 21·62.

Steel Troughing.



Section.	Depth Centres. (b)	Normal Width Centres. (a)		Thicknesses.	Max. Length Pressed.	
	Ins.	Ft.	Ins.	Ins.	Ft.	Ins.
A	15	2	8	$\frac{3}{8}$–$\frac{1}{2}$	40	0
B	12	2	8	$\frac{3}{8}$–$\frac{3}{4}$	40	0
C	10	2	6	$\frac{3}{8}$–$\frac{3}{4}$	40	0

O	4	2	8	$\frac{3}{16}$–$\frac{7}{16}$	20	0
P	3	2	0	$\frac{3}{16}$–$\frac{7}{16}$	20	0
M	3	1	6	$\frac{1}{8}$–$\frac{3}{16}$	10	0
N	2½	1	0	$\frac{1}{8}$–$\frac{3}{16}$	10	0

CAMBER.

The provision of an upward camber in bridge girders gives a better appearance to the bridge, and, moreover, obviates the additional stress, due to the centrifugal force of the train running round the curve, which would otherwise occur due to deflection.

Bridges of 100 ft. span and upwards are usually given a camber of 1 in. for every 40 ft. in length. Plate girders of small dimensions are not usually cambered.

For parallel or bow-topped lattice girders the increase in the length of the top boom and bays therein can be found as follows:—

If

c = camber in ins.; N = number of bays; D = depth between centres of flanges: l = length of one bay in ft.; L = horizontal length of bottom boom in feet; x = increase in length of one bay in top boom in inches; y = total increase in length of top boom,

then $$x = \frac{8cD}{N^2 l},\quad y = \frac{8cD}{Nl}\quad \text{when } c = 1 \text{ in. in } 40 \text{ ft.};\quad x = \frac{LD}{5N^2 l},\quad y = \frac{LD}{Nl}.$$

RIVETING.

Rivet Pitches.

The pitch of rivets in the direction of the stress should not exceed 6 ins., or 16 times the thickness of the thinnest outside plate or bar, nor less than 3 times the diameter of the rivet.

At the ends of compression members the pitch should not exceed 4 times the diameter of the rivets for a distance equal to twice the width of the member.

In the flanges of girders the pitch should not exceed 4 ins. In webs composed of two or more plates, the rivets, used solely for causing the several thicknesses to act as one plate, should not be spaced more than 12 ins. apart in any direction.

The distance from the centre of the rivet (or bolt hole) to the edge of a plate or bar should not be less than 1½ times the diameter of the rivets in the case of planed or rolled edges. When practicable, the distance should be at least 2 diameters of the rivet, but not to exceed 8 times the thickness of the plate.

In chain riveting the distance between centre lines of adjacent rows should preferably not be less than 3 diameters of rivet, and in no case less than 2½ diameters.

In zigzag or staggered riveting the distance between centre lines of adjacent rows should preferably be not less than 2½ diameters, and never less than 2 diameters.

Diameters of Rivets.

There are various rules for obtaining the most suitable diameter of rivets, but they are not often used in structural steelwork.

In practice, a ¾ in. or ⅞ in. diameter rivet is adopted whenever possible, and it is best not to use any formula to obtain the diameter in terms of the thickness of the plate.

The following is an exceedingly good rule and is almost universally followed:—

¾ in. rivets for ⅜ in. plates.
⅞ in. ,, ,, ½ in. ,,
1 in. ,, ,, ⅝ in. ,, and over.

It is difficult to get rivets of larger diameter than 1 in. closed by hand.

PART II

PLATE GIRDER BRIDGES.

LIVE LOAD — WEBS AND STIFFENERS — JOINTS — CROSS GIRDERS—RAIL AND ROAD BEARERS—CURTAILMENT OF FLANGE PLATES — DEFLECTION — CANTILEVER PLATE GIRDER BRIDGES.

(Revised by J. D. W. Ball, A.M.I.C.E.)

LIVE LOAD.

Criterion for Maximum Bending Moment.

For a maximum bending moment under any load in a system of wheel loads on a girder, the load considered must be as far from one end of the girder as is the centre of gravity of all the wheel loads from the other end of the girder. Or, in other words, the load considered and the centre of gravity of all the loads in the girder must be equidistant from the ends of the girder. It is often possible to determine by inspection which load will produce the absolute maximum bending moment due to the passage of the live load.

Criterion for Maximum Shear.

The maximum end shear for a system of concentrated moving loads will occur when the reaction is a maximum.

The maximum positive shear in any section of a girder occurs when the foremost load is at the section, provided W is not greater than $\frac{P_1 L}{a}$. If W is greater than $\frac{P_1 L}{a}$, the greatest shear will occur when some succeeding load is at the point.

In this case—

W = the sum of the loads; P_1 = the foremost load; L = the length of the span; a = the distance apart of the foremost and next load in succession.

In plate girders with cross girders, to determine the position of wheels to give maximum shear in panel to left of any cross girder, one of the large wheels is always placed over the cross girder; the wheel so placed should satisfy the following conditions:—

(1) The load to left of the cross girder, and including the load over the cross girder, must be equal to or greater than the total load on bridge divided by number of panels.

(2) The load to left of the cross girder, and not including the load over the cross girder, must be less than the total load on bridge divided by number of panels.

It will sometimes be found that more than one arrangement of the loads will satisfy the above conditions. In such cases it is necessary to figure the shear for the different loadings and use the greater. (*American Bridge Co.*)

WEBS AND STIFFENERS.

Distance apart of Stiffeners.

The distance apart which stiffeners should be placed can be found by the following formula:—

$$L = \sqrt{\left(\frac{5}{K} - 1\right) 1500 t^2},$$

where

L = distance apart in ins.; t = thickness of web in ins.; K = stress per sq. in. to be provided for—*i.e.* $\frac{\text{total shear at a section}}{\text{net area of web}}$.

The position of stiffeners should be so arranged as to cause no irregularity in rivet pitches, *i.e.* the pitch should alter if it is necessary at a stiffener. All stiffeners should bear tightly at the top and bottom against the flange angles, and wherever possible, stiffeners should be placed at all web joints.

In British practice, stiffeners are seldom placed at distances wider apart than the depth of the girder, with 6 ft. as a maximum when the thickness of the web is less than $\frac{1}{60}$ of the unsupported distance between the flange angles.

Stiffener angles over the bearings should be designed to carry the entire shear at that point without exceeding the safe stress (packings should not be included in the area); they should be proportioned as struts with fixed ends, having a length equal to ¾ of the depth of the girder.

Compound Web Plates.

Web plates composed of two or more plates should not be used where the total thickness is less than 1 in. (For Riveting, see p. 230.)

Reduction of Web Thickness.

The following is a graphical method of obtaining the necessary lengths of web plate of given thickness or the thickness of web plates of given length. The thickness of web plate required at the abutments must first be calculated in each case.

Distances such as 'a' measured to ¾ in. scale in fig. 1, give the reduction in thickness permissible.

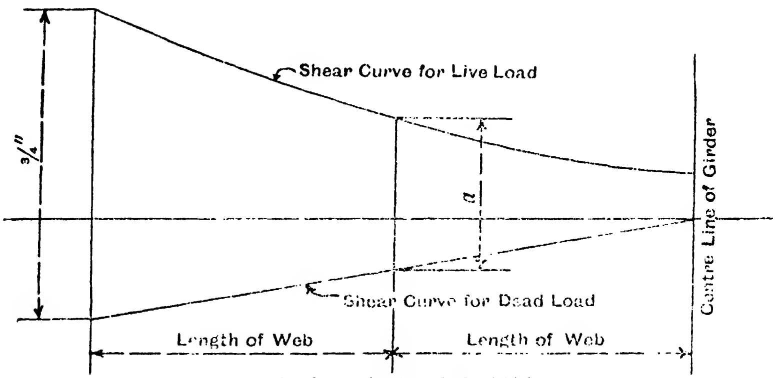

FIG. 1.—Reduction of Web Thickness.

JOINTS.

Thickness of Cover Plates.

The thickness of cover plates may be determined as follows:—

$$\text{Single covers} = t + \frac{t}{8}$$

$$\text{Sum of thickness of double covers} = t + \frac{t}{4}$$

where

t = thickness of plates joined.

Flange Angle Splices.

If a girder is so long that the angles cannot be obtained in one length, or if for any other reason it is necessary to splice the angles and the girder is to be shipped in one length, the splices in the angles should be as far apart as possible and on opposite sides of the web plate. Where the area of the flange angle is too great to be conveniently spliced by one angle, a splice angle with area equal to about ¾ of the area of the flange angle should be placed on each side of the girder.

Web Splices.

When part of the web is counted as flange area and the bending moment at the web joint actually requires this area of web to bring the flange stress down to the maximum allowed, there should be, in addition to the number of rivets required to take shear, sufficient rivets as near each flange angle as practicable to take the proportional part of the flange stress taken by the piece of web.

The net area of these splice plates must be made equal to area of web used as flange area multiplied by the depth of girder divided by the distance centre to centre of splice plates.

The number of rivets required to equal the net area of two splice plates, multiplied by the unit stress in flanges and divided by least value of one unit (shear or bearing) in web plates.

It is desirable to arrange the rivets so as not to cut out more than two rivet holes in the line next the joint, or at the ends of the plates; see fig. 2.

The vertical splice plates should have rivets enough on each side of splice to take the vertical shear at the position of the splice.

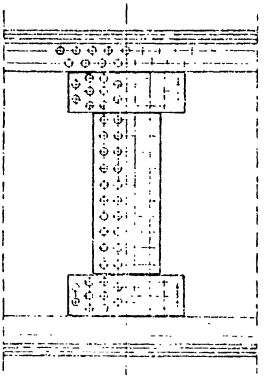

FIG. 2.—Web Joint.

Flange Splices.

If for any reason the flange plates have to be joined, a cover must be provided at each splice; the rivets connecting the cover must be such that their strength is equal to the plate spliced.

It is often possible to arrange the splices in a stepped manner with only one cover plate; such a joint is shown in fig. 3, and is suitable for a shipping joint.

The final cover must be at least equal in thickness to the thickest plate spliced, and, in the example, serves as a cover for the four plates.

The distance apart of the 'steps' must be such that the strength of the rivets between each is not less than will suffice to develop the full strength of each plate.

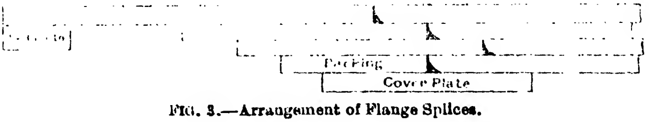

FIG. 3.—Arrangement of Flange Splices.

Rivets in Connection Plates.

When a single system of lateral bracing is used, the number of rivets connecting the plates to the girder should be sufficient to take the sum of components (in direction of girder) of both laterals connecting on the plate. (See fig. 4.) If AB requires 5 rivets and BC requires 4 rivets lay off in the direction of *ab* to any convenient scale a distance *by* of 5 and in the direction *bc* a distance *bw* of 4. Drop perpendiculars *wv* and *yx* and scale the distances *vb* and *bx*. The sum of these two distances represents the number of rivets required to connect the plate to the girder.

If a double system of bracing is used, they are proportioned for tension only, and the number of rivets required to connect the plate to the girder will be the number required to take the component of one lateral in the direction of the centre line of the girder.

There should be rivets enough connecting the plate to the cross girder or strut (if any) to take the component of one lateral in the direction of the cross girder or strut.

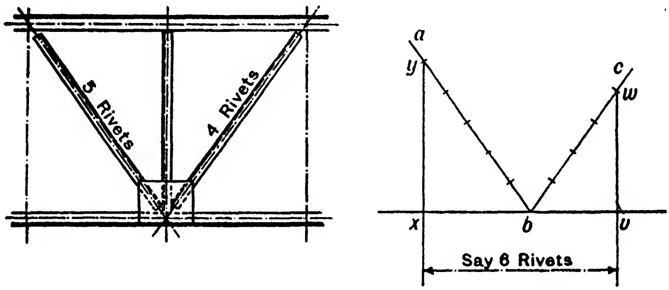

FIG. 4.—Rivets in Connection Plates.

CROSS GIRDERS.

Distance apart of Cross Girders.

. Generally speaking, it is not economical to place the cross girders in railway bridges closer together than 5 ft.; at intervals shorter than 5 ft. the load will usually consist of the heaviest axle load of the live load, while for intervals of 5 ft. and upwards it is necessary to consider the several positions that may be occupied by the axles in the heaviest portion of the live load.

The distance apart should be considered in relation to the centres of the heaviest wheel loads which will come upon them.

It is often found that increasing the spacing of the cross girders adds but little to the load which they will have to sustain, and it is usually economical to adopt a wide spacing, say from 6–10 ft.

In lattice girders the spacing of cross girders, depth of truss, and panel length must all be considered in relation to each other, for the cross girders will usually be placed at panel points to avoid secondary stresses in the booms.

The economy of placing cross girders far apart only applies in a modified degree to highway bridges, as in such cases the dead weight of the roadway forms a considerable part of the total load.

PROPORTIONS.

The depth span ratio of cross girders should be not less than 1 : 10, preferably 1 : 8, otherwise in bridges with buckled plate flooring considerable trouble is likely to occur with the rivets holding the plates down, working loose, or the plates fracturing at the seatings.

CONNECTIONS.

The connections of the main girders should be rigid, and 50 per cent. should be added to the number of rivets required to take the shear to resist the bending action.

In plate girders the web stiffeners may be made to considerably strengthen the end connections of cross girders, and in lattice girders a bracket plate of ample proportions should be fitted.

RAIL AND ROAD BEARERS.

Rail Bearers.

These should be in general placed 5 ft. apart, and must be proportioned to take the greatest wheel loads imposed by one, two, or more axles, as the case may be. Although they act as continuous girders, much depends upon the rigidity of the end connections and the deflection of the cross girders. Where they rest upon the cross girders they have a greater chance of acting continuously; but usually for the purpose of designing their section they will be treated as separate spans.

Road Bearers.

The distance apart of road bearers will be decided in relation to the width of the bridge and the centres of the wheels composing the maximum live load, and will be greatly decided by the type of bridge floor adopted. They should be designed as supported at the ends.

Proportions of Rail and Road Bearers.

The depth should not be less than $\frac{1}{12}$ of their span.

Curtailment of Flange Plates.

Unless this is done the girders will be stronger at the abutments than they need be. This can be remedied by either of the following methods:—

(1) Keeping the depth constant and varying the thickness of the flanges along the length.
(2) Varying the depth of the girder and keeping the flange thickness constant. By this method the girder theoretically becomes parabolic.

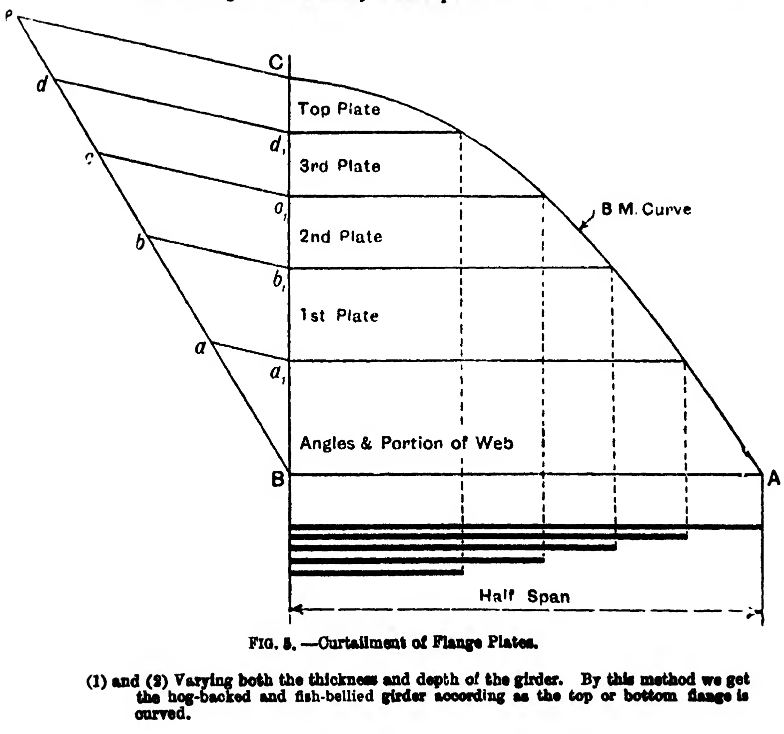

FIG. 5.—Curtailment of Flange Plates.

(1) and (2) Varying both the thickness and depth of the girder. By this method we get the hog-backed and fish-bellied girder according as the top or bottom flange is curved.

There are variations of this, for both top and bottom flanges are sometimes curved.

In most cases (1) is the most economical on account of there being less workmanship required in the manufacture.

The curtailment of flange plates in method (1) is carried out as follows :—

Referring to fig. 5, ABO is the bending moment curve on half the girder AB.

On any inclined line Be set out points a, b, c, d, as follows —

Be = Modulus of section of total flange at centre of girder (including portion of web if allowed for in calculations).
de = Modulus of section of top plate (net).
cd = " " 3rd " "
bc = " " 2nd " "
ab = " " 1st " "
Ba = " " bottom plate and angles (including portion of web if allowed for in calculations).

Join eO and draw parallels dividing the vertical Bc into similar spaces.

Lines drawn horizontally to meet the bending moment curve will now give the theoretical necessary lengths of the flange plates.

In practice the plates are continued for from two to four pitches of the rivets and the first plate over the main angles is always continued to the ends of the girder.

A close approximation is obtained by substituting the net area of each plate, and of the bottom plate and angles for the modulus of section referred to above.

Deflection.

Elastic Deformation.

Is one which disappears entirely on the removal of the external forces causing the stress.

The amount of deflection in girders depends mainly upon the following :—

(1) The length of the girder;

(2) The unit stress in the flanges.

The deflection arises from the top flange being compressed and the bottom flange being extended, and the amount of deflection is not materially affected by the kind of web in deep girders.

Mohr's Theorem.

A loaded beam takes up the same form as an imaginary cable of the same span, which is loaded with the bending moment curve on the beam and subjected to a horizontal pull equal to the flexural rigidity (EI). The deflected form of the beam is called the *elastic line* of the beam.

Graphical Construction for any Loading.

(Flanges of beam of uniform section.)

(1) Draw the bending moment diagram for the given loading of the beam.

(2) Treat the bending moment diagram as a load diagram and divide it up into narrow vertical strips; set down the mid-ordinates on a vector line.

(3) Draw the vector diagram with a polar distance equal to the flexural rigidity (EI).

(4) Draw the funicular polygon for this vector diagram and reduce it to a horizontal base, then the link polygon gives the elastic line.

The scale to which the deflections can be scaled is determined as follows :—

1 in. on the length of the bending moment diagram = x ft.
1 in. on the height of the bending moment diagram = y ft. tons.

Therefore in fig. 6 1 in. in height of any mid-ordinate of the bending moment diagram 1, 2, represents $d \times x \times y$ sq. ft. tons. Calculate the length of EI in sq. ft. tons to this scale $= \dfrac{EI}{144 \times d \times x \times y}$ inches), where E = modulus of elasticity in tons per sq. in., and I = moment of inertia in inch units); then the deflections will be to the scale of 1 in. = x ft.

It will be found convenient to reduce the length of EI for practical use, so the polar distance can be taken as $\frac{EI}{n}$, where n is some convenient divisor. The deflection scale will then be 1 in. = $\frac{x}{n}$ ft.

(*E. S. Andrews, B.Sc., M.I.C.E.*)

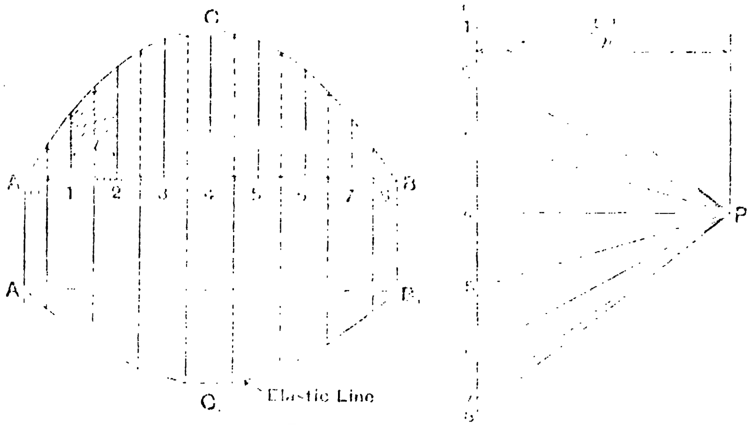

FIG. 6.—Graphical Determination of Deflection.

ACTUAL AND THEORETICAL DEFLECTION.

The difference between the actual and calculated deflection is due to various causes; in riveted girders the stiffness of riveted joints and covers, and the position and form of the floor, all tend to reduce the actual deflection, while poor quality of workmanship in the riveting and fitting together of parts tend to cause the actual deflection to exceed that calculated.

CANTILEVER PLATE GIRDER BRIDGES.

Cantilever plate girders, alternating with suspended spans, are being much used at the present time.

Kincardine-on-Forth Bridge.—On either side of the swing span there are seven 100 ft. spans with 50 ft. suspended girders in the second, fourth and sixth openings. The lower flanges are all arched to a radius of 290 ft. The web plates are 9 ft. deep at the supports and 5 ft. deep at the centre of each span. Across the 30 ft. width of roadway there are six of these girders, spaced at 6 ft. centres, the footpaths being carried on cantilever brackets in continuation of the diagonal bracing fitted between the girders at 10 ft centres. The bearings of the cantilever spans are alternately fixed and sliding. The projecting upper half of the ends of the suspended spans rest on socket and knuckle bearings on the projecting lower half of the cantilever ends, and these bearings at one end of each suspended span rest on a slide plate.

Storstrom Bridge.—Anchor spans are 189 ft. 7 ins. between bearings with 29 ft. 2 ins. cantilever arms. Suspended spans in alternate openings are 145 ft. 10 ins. Each span is carried on two main girders, 24 ft apart, with parallel flanges and 12 ft. built-up web plates. The anchor spans are supported on fixed and expansion cast steel bearings on alternate piers.

SECTION XIV

PART III

LATTICE GIRDER BRIDGES.

LIVE AND DEAD LOAD STRESSES—PROPORTIONS OF BOOMS AND STRUTS—PIN-JOINTED MEMBERS—VARIATION OF STRESSES—PORTAL BRACING—DEFORMATION AND DEFLECTION.

LIVE AND DEAD LOAD STRESSES.

Criterion for Maximum Bending Moment and Maximum Shear.

The maximum bending moment at any joint in a bridge loaded with wheel loads will occur when the average load on the left of the section is the same as the average load on the whole span.

The maximum shear in any panel in a bridge loaded with wheel loads will occur when the load on the panel is equal to the load on the bridge divided by the number of panels.

(*Ketchum.*)

Maximum Loads on Inclined Braces.

The maximum tension in any inclined brace occurs when the leading axle is at the foot of the brace, the live load covering the larger segment of the bridge from the foot of the brace to the farthest support.

The maximum compression in any brace occurs when the leading axle is under the head of the brace; the live load covering the shorter segment of the girder to the nearest support.

(*R. J. Woods.*)

Shears and Counterbracing.

(*a*) The maximum live load shear (positive) in any panel of a truss is equal to the left reaction when all the joints at the right of the panel are loaded and all joints at the left of it are unloaded.

(*b*) The dead load negative shear in any panel at the right of the centre is equal to the amount of dead load between the panel and the centre of the span (including a half panel load at the centre if the truss has an even number of panels).

(*c*) No counter is required in any panel beyond the centre of the truss in which the dead load negative shear exceeds the maximum live load positive shear; but in each panel beyond the centre in which the live load positive shear can exceed the dead load negative shear, a counter is required.

Stresses in Parallel-Flanged Girders with Uniform Rolling Load.

Divide span into a number of equal parts, one less than the number of bays (see fig. 1), obtaining points such as a, a_1. On the base A_1B_1 set up length $A_1O = \frac{PL}{2}\left(\frac{b-1}{b}\right)$, where P = intensity of load, L = span of girder, b = the number of bays.

Through O draw a parabola with vertex at B, and project points such as a, a_1, down to meet the parabola in points such as e, e_1, and project horizontally across bays as shown.

Then the maximum stresses in the diagonals for passage of the live load from right to left are obtained from this curve. Negative shears in a similar manner.

The position of the load to give maximum stresses in diagonals is obtained from

$$x = \left(\frac{n.y}{b-1}\right),$$

where

x = distance travelled by the load beyond end of nth bay, y = length of bay, and b = number of panels.

(*E. S. Andrews, B.Sc., M.I.C.E.*)

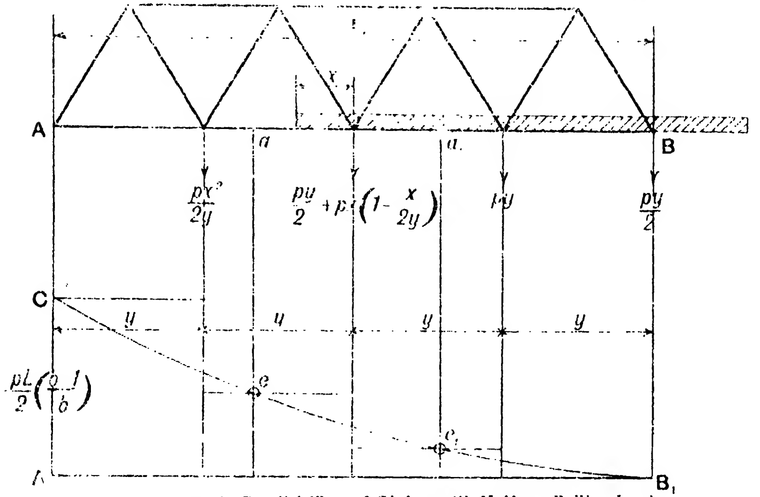

FIG. 1.—Stresses in Parallel-Flanged Girders with Uniform Rolling Load.

Distribution of Dead Load.

For spans under 200 ft. the total dead load shall be assumed to act at the loaded chord. For 200 ft. and over the total dead load will be distributed at top and bottom chords as follows:—

On Loaded Chords.

(*a*) Half the load resulting from trusses;
(*b*) Weight of horizontal wind bracing in plane of chords;
(*c*) Weight of floor system, permanent way, etc.;
(*d*) Half load resulting from weight of cross bracing in the case of deck bridges.

On Unloaded Chords.

(*a*) Half load resulting from trusses;
(*b*) Weight of horizontal wind bracing in plane of chords;
(*c*) Half the load resulting from weight of cross bracing in the case of deck bridges and the whole of it in the case of a through bridge. (*Sir Wm. Arrol & Co., Ltd.*)

Stress in Members.

In parallel flanged lattice girders the stresses in the diagonals

$$= \frac{\text{load on diagonal} \times \text{length of diagonal}}{\text{depth of girder}}$$

i.e. load $\times$ sec. ϕ. ϕ being the angle which the diagonal makes with a vertical line.

Force Diagram.

A very convenient and rapid method of determining the stresses in the members of a truss is by means of a force diagram as described on page 31.

If the truss contains relatively few bays, three or four diagrams will determine all the maximum stresses, having previously determined the total panel point loads which will produce the maximum stresses in the various members.

If the truss contains a fair number of bays it is more convenient to proceed by the method of influence lines or unit loads. A table is first prepared giving the stresses in each member, due to a unit load, applied in turn at each panel point. These stresses can be determined in one or two cases by drawing the corresponding force diagram, but when one or two have been done in this way, formulæ can be written down for determining the remainder and errors, if made, will be self-evident as the figures run in series. The headings for such a table are given below.

Member.	Stress due to a Unit Load at Panel Point.									Sum of Compression Stresses.	Sum of Tension Stresses.	Algebraic Sum of Stresses.
	4	3	2	1	0	1′	2′	3′	4′			

Generally speaking, the only variable panel point load will be that due to the weight of the truss and lateral bracing. The floor load will be constant for each panel, and it is also usual to consider the live load as constant at each of the loaded panel points, although the value of this constant panel point live load will generally depend on the length of the portion of the bridge assumed to be covered with live load.

The total dead load stress in each member in turn is determined by multiplying the variable panel point truss load by the corresponding unit load stress and summing these, by multiplying the panel point floor load by the algebraic sum of the unit load stresses, and adding the two results.

Live load chord stresses will be obtained in a similar way, but for web members, the live load stress may be tension or compression, according to which portion of the bridge is loaded, and these total tension or compression stresses will be obtained by multiplying the sum of the unit load tension stresses by the appropriate panel point live load, or the sum of the unit load compression stresses by the appropriate panel point live load.

Ritter's 'Method of Sections.'

This consists of drawing 'lines of section' cutting the bridge truss in not more than three of its members. These lines divide the truss into two parts, one of which is supposed to be removed, the external forces acting on the other portion alone being considered.

The stress in any one of the three members cut by the 'line of section' can be found by taking moments round the point of intersection of the other two.

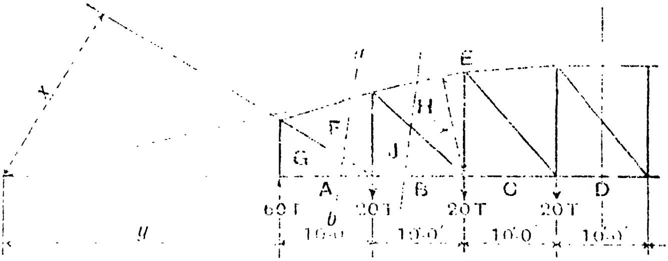

Fig. 2.—Ritter's Method of Sections.

This method is not applicable to finding the stresses in the flanges of parallel-flanged girders; for the flanges if produced would not meet.

In fig. 2 draw the sectional line ab, cutting FE, FG, GA; then,

Stress in FG $\times x = 60 \times y$, y being measured to the point of intersection of FE and AG.

It will be seen that the moments of the stresses on the members which meet at the point indicated become zero; and it is only necessary to equate the moment of the stress on the third member to the algebraic sum of the moments of all the external forces acting on the portion of the truss considered.

If it is required to find the stress in the member HE, with the live load in the position shown, then,

$$\text{Stress in HE} \times x' = (60 \times 20) - (20 \times 10).$$

Stresses in the vertical struts can be found in a similar manner.

Braced or Lattice Struts.

The least number of panels

$$= \frac{\text{Least radius of gyration of whole strut}}{\text{Least radius of gyration of unbraced portion}}$$

In the case of a strut composed of an angle at each corner, the least radius of gyration of unbraced portion must be taken as one of the angles.

Batten plates should be spaced from 2–3 times the overall width of the side braced, while the inclination of diagonals to the axis of the member should not be less than 45°.

The thickness of bars with single lacing should not be less than $\frac{1}{40}$ of their length; with double bars, not less than $\frac{1}{60}$ of their length.

Ties.

Ties should usually be designed to be of rigid construction, but may be of rolled flat bars except near the centre of the span, where they must be composed of rigid sections.

Counter bracing must be of similar construction to the centre ties.

Rolled bars forming long ties should be provided with distance pieces to reduce vibration.

Pin-jointed Members.

Pin Connections.

The tearing, shearing, and bearing strengths of the joint should be made as nearly as possible equal to each other, and to the tensile or compressive strength of the bar in which the joint occurs.

Usually the bearing stress on the pin is taken at somewhat less than for rivets, to allow for imperfect fitting of the pin.

The bending strength of pins is very important, for if the pin becomes distorted the distribution of the loads and the calculation of the stresses is very uncertain.

Secondary bending in the top booms and strut members of a bridge merit greater attention when they are connected with pin joints. In this country pin joints will not often occur anywhere other than in suspension bridges, but in America pin-jointed bridges are very common.

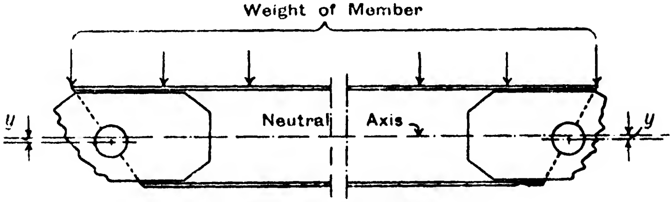

FIG. 3.—Pin-jointed Member with Eccentric Pins.

The position of pins may be so fixed that when the maximum stress (direct compression) comes upon the chord through the pins, it will produce an amount of bending moment equal to that produced by the weight of the member, but in the opposite direction.

In the ordinary type of top boom or end post section, this condition will be effected when the position of the pins is fixed at a distance y (see fig. 3), perpendicularly below the centre of gravity of the section, given by the formula

$$y = \frac{M}{Sc},$$

where M is the bending moment in inch pounds due to the weight of the member, and Sc is the total maximum direct compressive stress in the member in pounds.

Variation of Stresses.

Wöhler's Experiments.

When the elastic limit is not overpassed it is possible, under certain conditions, to fracture steel by repeating the stress a sufficient number of times. Wöhler showed that it was the range of stress, and not the maximum stress, that determined the number of applications before rupture.

The general conclusions are that:

(*a*) The greatest tensile stress a bar will bear for an indefinite number of times is for iron and steel about half its ultimate static breaking stress.

(*b*) The number of repetitions required to produce fracture is increased if the range through which the stress is varied is reduced.

(*c*) A bar will be strongest when exposed to varying stresses of the same kind, and weakest when exposed to stresses of opposite kinds, *i.e.* tension and compression.

The stress caused by a load suddenly reversed is three times the static stress, and a load suddenly applied causes a stress of twice the static stress. (Refer to 'Impact,' p. 500.)

Relation between Sudden Loading and Repetition of Stress.

The similarity between the results of experiments on variation of stress and sudden loading has given rise to many assumptions that Wöhler's results were really due to the effects of sudden loading, and that the two are really aspects of the same question.

Although there are many points which require to be decided in the consideration of these experiments, for practical reasons it seems best to allow for either one or the other, and not for both simultaneously in one member.

In the case of cross girders and vertical suspenders, allowance should be made for the full value of the elastic vibrations due to sudden loading; while rail bearers and main girders, both plated and latticed, of spans up to 100 ft., should be designed with an allowance for sudden loading or impact, using one of the impact formulæ evolved for the purpose.

In the flanges of girders and the principal members of arched and suspension bridges of large dimensions the stress variation takes place more gradually, and allowance for variation of stress can be made by adopting a reduced stress, based on the amount of variation of stress.

Launhardt-Weyrauch Method.

The working stress is varied according to the relative amounts of live and dead loads.

Members Subjected to Tension Only.

$$\text{Working stress} = \frac{f}{1\cdot 5}\left(1 + \frac{\text{minimum load}}{2 \times \text{maximum load}}\right) \text{ tons per sq. in.,}$$

being the static or dead load working stress.

Dynamic Method.

$$\text{Working stress} = \frac{f}{1 + \dfrac{\text{live load.}}{\text{total load}}};$$

$$\text{The sectional area of a bar in tension} = \frac{\text{maximum load}}{\text{working stress}}.$$

Members Subjected to Alternate Stresses.

Members of bridges subjected to alternate tension and compression should be proportioned as struts, to resist the greater stress added to ½ of the lesser stress, except in the case of wind bracing, where the members should be proportioned to resist the greater stress. The sum of the stresses should be used in designing the connections.

Portal Bracing.

Design.

There are many types of portal bracing which may be used; A to F, fig. 4, show some common forms.

The fixing of the lower ends may be assumed as either hinged or fixed.

They may be considered as fixed by virtue of the direct stress due to vertical loading, when $V \times \frac{1}{2}s$ is $>$ M max. at A or B with fixed ends; $M \text{ max.} = \frac{Rd}{4}$, where V = total stress in the column.

The following treatment for the calculation of the stresses is due to Mr. Milo S. Ketchum in 'Steel Mill Buildings,' in which book he deals with the stresses in many types, with both hinged and fixed ends.

Stresses in Portal (a). Columns Hinged.

The deflections in the columns are assumed to be equal, then,

$$H = H_1 = \frac{R}{2}.$$

Taking moments about the foot of the windward column,

$$V_1 = -V = \frac{Rh}{s},$$

Having found the external forces, the stresses in the members may be found either by algebraic or graphical methods.

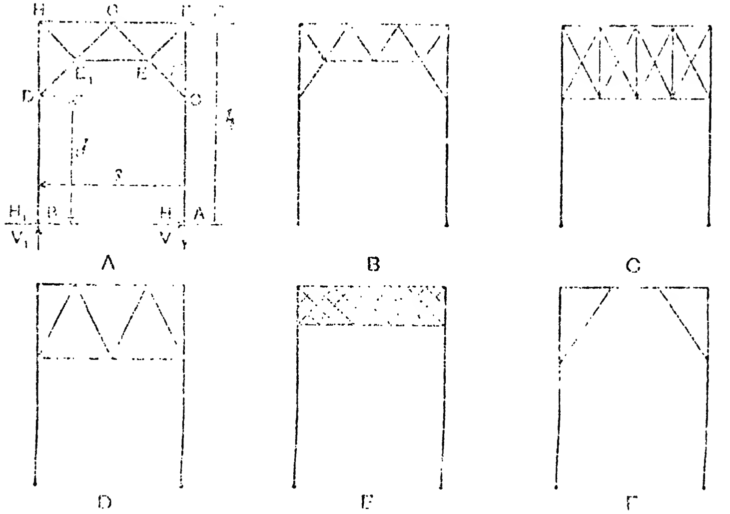

FIG. 4.—Types of Portal Bracing.

To obtain the stress in member GC, pass a section (Ritter's method of sections), cutting GF, EF, and GC, and take moments of the external forces to the right of the section about point F as centre.

$$GC = -\frac{Hh}{(h-d)\sin\phi}.$$

But $$H = \frac{R}{2}, \text{ and } (h-d)\sin\phi = \frac{s}{2} \times \cos\phi.$$

Substituting these values in the above expressions,

$$GC = -\frac{Rh}{s\cos\phi} = -V\sec\phi.$$

Resolving at C and F we have: stress in EF = 0, and also stresses in EE_1 and HE_1 = 0.

To obtain stress in GD, pass a section cutting HG, HE, and GD, and take moments of the external forces to the left of the section about point H as centre.

$$GD = \frac{Hh}{(h-d)\sin\phi} = +V\sec\phi;$$

To obtain stress in GF, pass a section cutting GF, EF and GC, and take moments of the external forces to the right of the section about point C as centre.

$$GF = + \frac{R(h - d) + Hd}{h - d}.$$

To obtain stress in HG, pass a section cutting HG, HE, and GD, and take moments of the external forces to the left of the section about point D as centre.

$$HG = - \frac{Hd}{h - d}.$$

The stress in the windward post AF is zero above and V below the foot of the knee brace C the stress in the leeward post is zero above and V_1 below the foot of the knee brace D.

The shear in the posts is H below the foot of the knee brace, and above the foot of the knee brace is given by the formula—

$$S = \frac{Hd}{h - d} = \text{stress in HG}.$$

The maximum moment in the posts occurs at the foot of the knee braces C and D, and is

$$M = Hd.$$

The stresses in portal (*b*) are found in a similar manner, but it will be found that all members are stressed in portals (*b*) and (*d*).

Deformation and Deflection.

Actual and Theoretical Deflection.

There is usually a difference between the actual and calculated deflection of framed structures. This is due to various causes, principally the rigidity and stiffness of the joints or otherwise, and the actual deflection is usually in excess of that calculated.

Contrary to statements that the amount of deflection is independent of any change of form which may take place in the web, and is not affected by the form of web, it is found that the deformation of the web members contributes largely to the total deflection.

Deflection of a Lattice Girder.

The theoretical deflection of a framed structure can be found both analytically and graphically when the elastic deformation of each member caused by the stress in it is known.

The following method is that developed by Maxwell and Mohr, and is taken from Sir W. Arrol & Co.'s Handbook :—

Example.—Find the deflection at the centre of a lattice girder 100 ft. span, 10 ft. deep, and loaded with a distributed load of 1 ton per ft. run (see fig. 5).

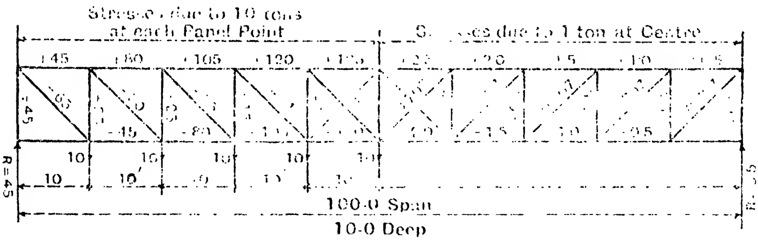

FIG. 5.—Deflection of Lattice Girders.

Let

L = length of any member in ft. ; l = length of any member in ins. ; S = total stress in any member due to 100 tons distributed load ; P = stress per sq. in. in any member due to 100 tons distributed load ; ϕ = total stress in any member due to 1 ton placed at the point at which it is required to find the deflection ; A = gross area of any member in sq. ins. plus 5 to 10 per cent. to allow for the effect of covers, joints, etc. ; E = modulus of elasticity of steel which may be taken as 12,000 tons per sq. in.

First calculate the stresses in each member due to the distributed load of 100 tons and obtain the sectional areas of the members; then ascertain the stress (U), in each member due to the load of 1 ton at the point where the deflection is required.

The elastic deformation of any member is $\frac{S}{EA}$ (or $\frac{LS}{1000\,A}$, if L is in ft.).

The results are then placed in tabular form as follows :—

Member.	L. Length	S. Total Stress	A. Area.	P. Stress per Square Inch.	$\frac{Pl}{E}$.	U.	Contribution to Deflection $\frac{PlU}{E}$	Summation.
Top Boom	Ft.	Tons.	Sq. Ins.	Tons.	In.	Tons	In.	In.

The required deflection of the girder is thus found to be 2·05 in., the flanges contributing 1·35 in. and the web 0·70 in.

SECTION XIV

PART IV

SWING AND BASCULE BRIDGES.

PARTICULARS OF BRIDGES—WORKING STRESSES—FRICTION AND LUBRICATION—HYDRAULIC LIFTING AND SLEWING MACHINERY—CIRCULAR GIRDERS.

SWING BRIDGES.

The most usual types are either of the 'centre bearing' or 'rim bearing' type, and may be either 'single leaf' or 'double.'

The depth of a single leaf swing bridge is four times greater than that required for a double-leaf bridge of the same span, when the bridge is treated while in motion as a cantilever.

On the other hand, the length of a single-leaf swing bridge is less than the combined lengths of the two leaves for the same opening, but the double leaf type requires two sets of operating machinery.

The full advantages of swing bridges are only to be obtained when they span two openings; in such cases the necessity for counterpoises or kentledge does not exist and the effects of wind pressure are to a great extent neutralised.

A further classification of types is as follows:—

(a) Those which turn entirely upon rollers, *i.e.* the rim bearing type.

(b) Those where the weight is proportioned to be borne partly by rollers and in part by a centre pivot.

(c) Those swung entirely upon a pivot.

(d) Those which are lifted on a water centre by hydraulic power.

(e) Those which are lifted on a water centre by hydraulic power, but not sufficient to lift the whole weight.

In the latter type the tail is heavier than the toe, and the excess weight is borne by rollers running on a roller path, and adds stability to the bridge when swinging.

In type (e) of the above classification should also be included those swing bridges which are carried on a circular pontoon, the effect of which is practically a low-pressure hydraulic ram.

The general principle of these water-borne swing bridges is as follows:—A sealed circular pontoon or buoy is placed under the centre of gravity of the superstructure, and suitably and rigidly connected thereto in such manner as to be always submerged with a constant buoyancy and capable of being turned with the superstructure.

The upward pressure due to the buoyancy of the pontoon is less than the total weight of the bridge, the remainder of the weight resting upon roller paths which are carried on a gridiron or circular girder supported upon piles in the bed of the river as in several bridges over the river Weaver, Cheshire, designed by Mr. John A. Saner, M.I.C.E.

One of these bridges consists of two braced girders 112 ft. long, 17 ft. high over the centre of gravity, with a 19 ft. 6 ins. roadway, and weighs 303 tons, of which 255 tons is water borne.

In this case the consumption of electric power to turn the bridge is 0·24 of a unit for each swing, a swing including the withdrawal of the wedges, opening and closing of bridge and replacement of wedges.

It is stated that this type of swing bridge is more economical in operating expenses than any other swing bridge of equal size.

A swing bridge at the Spencer Dock, Dublin, has the pontoon working in an outer caisson, the 5 per cent. excess weight of the bridge being carried upon a centre pivot placed at the bottom of the pontoon. Lateral rollers with the roller path fixed to the underside of the bridge are provided in this design.

Lattice girders are preferable for all spans in excess of 100 ft. on account of their much less resistance to wind pressure.

In all cases where rollers at the tail end are provided, an excess of counter weight should be provided, so that the rollers are loaded when the bridge is swinging with not less than 10 tons when the bridge is covered with snow and allowance has been made for the increase in weight of the roadway and footpaths due to wet.

Hydraulic presses or wedges should be provided at heel and toe to relieve the rollers and pivot of weight when the bridge is in the fixed position for sustaining road traffic.

BASCULE BRIDGES.

Bascule bridges may be either single leaf or double, but are usually double-leafed.

The most modern types are as follows :—

(*a*) Those in which the pivot is overhead and the balance weight either overhead or below the level of the bridge floor.

(*b*) Those where the pivot is situated below the level of the bridge floor and the counterweight likewise.

(*c*) Those in which there is no fixed axis, but the tail of the bridge is in the form of a circular segment, upon which the bridge rolls backward and forward.

PARTICULARS OF BRIDGES.

TRANSPORTER BRIDGES.

Another type of bridge which avoids high approaches is the Transporter Bridge. The first bridge of this type to be erected in this country was completed in 1905 and provides access between Widnes and Runcorn. The central span is 1,000 ft. between centres of towers and the height from high-water level to the underside of the stiffening girders of the cable suspension bridge, which also carry the trolley from which the car is hung, is 82 ft. The car is 55 ft. long by 24 ft. 6 ins. wide.

Working Stresses,

PERMISSIBLE WORKING STRESSES.

The maximum permissible unit stresses per sq. in. should be less for the main girders, cross girders, and rail bearers than those allowed for simply supported spans; about 10 per cent. is a usual figure. (Refer to ' Working Stresses, p. 493.)

ROLLERS.

Rollers supporting swing bridges should generally be of solid forged steel or cast steel, with suitable gun-metal liners and collars and provision for adjustment at the ends of the rollers.

The rollers and surfaces of both upper and lower paths should form parts of conical surfaces with a common vertex at the centre.

The size of the rollers should bear some relation to the diameter of the roller circle, and in general will not exceed 2 to 3 ft. diameter.

BEARING PRESSURE ON ROLLERS.

The following safe bearing pressures in pounds per lineal inch on rollers are taken from the *Transactions of the American Society of Civil Engineers*, vol. xxxiii.

Description.	Rollers at rest.	Rollers in Motion.
Cast Iron	400 d	200 d
Rolled or Cast Steel (28–32 tons)	800 d	400 d
Axle Steel (35–38 tons)	—	500 d
Tool Steel (60 tons)	—	800 d
Tool Steel hardened	—	1900 d

where d is the diameter in inches.

The values given are for rollers and bearing surfaces of the same material; if they are of different materials, lower values should be used.

Sir W. Arrol & Co., in their Handbook, give the safe load in pounds per lineal inch on rollers, as 560 d, where d = the diameter of the roller, the mean diameter being taken for conical rollers, the rollers and plates being of cast iron, wrought iron, or steel; for rollers in motion one-half the above value to be taken. It is stated that the working stress is one-fifth the elastic limit for cast iron, and one-third the limit for wrought iron or steel, the elastic limit being reached in steel plates and steel rollers of 1 in. to 16 ins. diameter at 880 d.

Bearing Pressures on Rotating and Sliding Surfaces.

MAXIMUM BEARING VALUES FOR ROTATING AND SLIDING SURFACES IN POUNDS PER SQUARE INCH.

Bearings on which the Speed is slow and intermittent.	
Pivots for swing bridges, hardened tool steel on special phosphor-bronze	3,500
Trunnion bearings for bascule bridges, axle steel on phosphor-bronze	2,000
Wedges, cast-iron on bronze	600
Wedges, cast-iron on cast-iron or structural steel	500
Screws which transmit motion on projected area of thread	200
Ordinary Cases, Parts moving at Moderate Speeds.	
Hardened steel on hardened steel	2,000
Hardened steel on bronze	1,500
Tool steel (not hardened) on bronze	900
Structural steel on bronze	600
Cast-iron on structural steel	400
Cast-iron on cast-iron	400
On crosshead slides, speed not exceeding 600 ft. per minute	50

In order to prevent heating and seizing at higher speeds, the pressure on pivots or foot-step bearings for vertical shafts and journals should not exceed :—

$$\text{On pivots, } p = \frac{160000}{n\,d}\text{ ; on journals, } p = \frac{300000}{n\,d},$$

where

n = number of revolutions per minute; d = diameter of journal or pivot in inches.

For crank pins and similar joints with alternating motion, the limit bearing values given in the above formula may be doubled.

Ball and Roller Bearings.

(See Section XX., Part I.)

Centre Pivots.

The construction of centre pivots for swing bridges requires careful consideration. They should be of ample proportions, and the pressure per square inch should not exceed 2 to 3 tons per square inch, or excessive friction will ensue.

The pivots should preferably consist of four parts; the lower casting and upper castings of steel, with an upper revolving pin of tool steel with a convex surface, and the lower fixed cup of phosphor bronze with a concave surface of slightly larger radius than the upper revolving pin, to assist lubrication.

Pivots have been designed in which a 'Tabloid' was placed between the upper revolving pin and the lower stationary cup. The 'Tabloid' was of phosphor bronze with spherical upper and lower surfaces, the upper pin on the bridge and the lower cup also having spherical surfaces. This type of pivot is, however, only suitable for bridges in which the slewing power is applied at two or more diametrically opposite points, for where the slewing force is applied at only one point, a slight displacement of the bridge on the seating has been found to occur, resulting in considerable eccentricity.

Pressures on Quadrants and Tracks of Rolling Lift Bascule Bridges.

The following data refer to four bridges constructed during recent years :—

Clear Span.		Radius of Quadrant.		Rolling Load.	Width of Bearing.	Pressure on Track.	Materials in Quadrants and Tracks
Ft.	Ins.	Ft.	Ins.	Tons.	Inches.	Tons per Lineal Inch.	
58	3	18	3	414	26·0	15·92	Mild steel 28–32 tons.
100	0	21	0	631	38·0	16·61	Quad. plate mild steel.
100	0	21	0	516	22·0	23·45	Track plate cast steel.
150	0	28	0	2,922	50·25	58·15 average.	Track plate cast steel 35 tons. Quad. plate mild steel 36-40 tons.

(*Selected Paper No.* 8, *Inst.C.E.*)

Friction and Lubrication.

Rolling Friction.

Let

P = force required to propel roller (lbs.) ; W = load on roller (lbs.) ; R = radius of roller (ins.) ; h = depth of depression caused in track (ins.) ; K = a constant ; then,

$$P = \frac{WK}{R - h},$$

or, as h is usually very small compared with R,

$$P = \frac{WK}{R} \text{ (nearly)}.$$

The value of K varies from 0·007 to 0·015.

Some Experiments on Friction.

The following experiment, undertaken by Sir Wm. Arrol & Co., Ltd., is particularly applicable to the friction of roller rings in turntable swing bridges :—

Two beams, each 175½ ins. long by 5¾ ins. broad, each weighing 1570 lbs., were planed to a smooth surface and accurately levelled. One beam was laid dry upon the other and afterwards two rollers, 2½ in. diameter, were placed 7 ft. apart between them. The force required to start motion was obtained for different loads.

In experiments with eleven American turntable swing bridges, the friction showed a maximum of 7·94 lbs. per 1,000 lbs. weight of moving structure ; but one bridge showed as low as 3·53 lbs.

Further experiments in America on new swing bridges, before the gearing, etc., had had an opportunity to wear smooth, were as follows ; for bridges which have been in operation for some time, the coefficients given will be less :—

Load.	Force to Start Motion.		Coefficient of Friction.	Percentage of Load.	Remarks.
	Total.	Pounds Per Ton.			
lbs.	lbs.	lbs.			
1570	450–500	650–716	0·29–0·32	29–32	Sliding Friction.
2130	475–560	500–590	0·224–0·263	22–26	,,
1570	2·73	3·9	0·00174	0·17	Rolling Friction.
2240	5·44	5·44	0·00243	0·24	,,

For rim-bearing swing bridges, the late C. Shaler Smith found the total frictional resistance in the livering to vary from 0·004 to 0·008 of the load on the rollers. Messrs. Boller & Schumacher found the coefficient to be 0·0035 for the Thames River Bridge, and Theodore Cooper found this to be 0·0038 for the Second Avenue Bridge.

For centre bearing bridges, Mr. C. Shaler Smith found the frictional resistance at the circumference of the pivot to be 0·09 of the weight turned. Mr. Schneider found the coefficient of frictional resistance at the circumference of the pivot, on hardened steel and phosphor bronze discs, with the usual working pressure of about 3,000 lbs. per sq. in., to be 0·067 at the start and 0·015 to keep the bridge moving at uniform speed. For the total frictional resistance, including that of the shafts and gearing required for hand operations, the highest coefficients observed were 0·115 for starting and 0·08 for keeping the bridge in motion.

(*Proceedings American Society of Civil Engineers.*)

Experiments by Beauchamp Tower show that a steel shaft in a lubricated gun-metal bearing seizes at about 600 lbs. per sq. in. as for steady running, while in a dry bearing they seized at about 80 lbs. per sq. in.

Professor Goodman found that the seizing pressure increases as the viscosity of the oil increases.

Horse-Power Absorbed in Revolving Bearings.

Let

W = total load on bearing in lbs.; D = diameter of bearing in ins.; N = number of revolutions per minute; ϕ = coefficient of friction.

For Cylindrical Bearings:

$$\text{Work done per minute in ft.-lbs.} = \frac{\phi W \pi D N}{12};$$

$$\text{Horse-power absorbed} = \frac{W \pi D N \phi}{12 \times 33{,}000} = \frac{\phi W D N}{126{,}000}.$$

For Flat Pivots:

$$\text{Horse-power absorbed} = \frac{\phi W D N}{189{,}000}.$$

Lubrication.

Oil should always be led to the point of least pressure in a bearing.

Oils for heavy pressure should be thick, that they may resist being forced out.

Lubricants for Various Cases.

Nature of Pressure, etc.	Type of Lubricant.
Heavy pressure with slow speed	Graphite, soapstone, tallow, and other greases.
Heavy pressure with high speed . .	Sperm oil, castor oil, and heavy mineral oils.
Light pressure and high speed . . .	Sperm oil, refined petroleum, olive, rape, and cotton-seed oils.
Ordinary machines	Lard oil, heavy mineral and vegetable oils.

Oils act chemically in a varying degree on most metals, and care must be exercised in selecting the most suitable kind.

HYDRAULIC LIFTING AND SLEWING MACHINERY.

Power required for Lifting Swing Bridges.

This is a simple calculation based on the total weight of the bridge lifted and the friction due to moving parts, leathers, and so on.

Power required for Slewing Swing Bridges.

$P = 0{\cdot}015$, for rim-bearing; $P = 0{\cdot}15\ W \frac{r}{R}$, for centre-bearing; $H.P. = \frac{Pv}{550}$; $v = \frac{R\pi}{2t}$,

where

P = Force required to turn the bridge, acting in centre line of track; W = total moving weight, in lbs.; H.P. = horse power; r = radius of pivot; R = radius of centre line of track; v = maximum linear velocity in centre line of track in feet per second. t = time, in secs., in which maximum velocity must be obtained, or one-half the number of seconds required to open the bridge.

The foregoing formulæ generally give results in excess of the power actually needed under ordinary conditions, and practically cover all contingencies.

If the bridge has to be operated by hand-power, the gearing has to be arranged either for the number of men available or for the time required to turn and operate the bridge. In calculating the strength of the gearing, etc., the power of one man should be taken at 125 lbs., as this is about the force a strong man, with a foothold, can exert for a short time.

Setting and Wedging Blocks.

It is usually not advisable to allow a bridge to rest upon the pivot when undergoing stress due to moving loads.

In some bridges the centre pivot is also the lifting press, bearing blocks being provided at suitable points to sustain the bridge when in position. In this case, however, there is difficulty in preventing the ram from turning in the cylinder.

With a solid pivot, the hydraulic lifting rams are placed at the tail of the bridge, where, when the rams have lifted the bridge off the pivot, a pair of sliding bearing blocks are inserted and the lifting power then withdrawn. In this type four or more rollers are provided to take a portion of the weight of the bridge while slewing, and to keep the bridge 'upon an even keel.'

The two leaves of a double swing bridge are often linked together at the meeting point, the object being to prevent any perceptible difference in level between the extremities of the bridge leaves when a heavy load is transferred from one to the other.

CIRCULAR GIRDERS.

SECTION XIV

PART V

ARCH BRIDGES.

Types and Stresses.

ARCHED RIBS.

The arched rib or roadway girder may be in either of the following forms:—

(*a*) Rigidly fixed at each end.
(*b*) Hinged at each end.
(*c*) Hinged at centre and at each end.
(*d*) Hinged near one abutment.

STRESSES IN ARCHES.

The arch may be looked upon as an inverted suspension bridge, the links of the suspension bridge being in tension and those in the arch being in compression, but the latter would be in unstable equilibrium under any loading, and so in practice the arch is made capable of resisting bending stresses in addition to direct compression.

HORIZONTAL THRUST.

When once the horizontal thrust and the line of the resultant thrust or any given arch has been found, it is a simple matter to obtain the stresses.

The horizontal thrust and the line of the resultant thrust can be determined readily for parabolic arches of uniform section loaded with uniformly distributed load, or with concentrated loads, and the same rules can be taken as applying to flat segmental arches.

LINEAR ARCH AND LINE OF PRESSURE.

A linear arch is one which is theoretically supposed to be subject to direct compressive stress only and incapable of resisting flexure.

The line of pressure is the theoretical line, the ordinates of which vary as the bending moments for the load which the arch supports. It is synonymous with the curve of equilibrium.

Eddy's Theorem is thus:

'The Bending Moment at any point in an arch is equal to the product of the Horizonta Thrust into the vertical intercept between the centre line or neutral axis of the arch and the line of pressure.'

It is almost universally the practice with steel arches to hinge them at the abutments, and often at the crown also. By this means the alterations in form of the arch due to the passage of the load and variation of temperature more readily adapt themselves to the varying conditions. Moreover, the resulting thrusts pass through these points and the axis of the arch, or approximately so, and the bending stresses are thus reduced and can be determined with greater accuracy.

STRESSES IN PARABOLIC ARCH, HINGED AT THE ABUTMENTS.

Let

l = length of span of arch; v = versine or rise; w = load per unit of length, T = horizontal thrust at the crown and abutments; C = compressive stress at any point x from the centre, then

$$T = \frac{w\,l^2}{8v}$$

This expression represents the horizontal component of the pressure at any point in the arch

$$O = \sqrt{\left(\frac{wl^2}{8v}\right)^2 + (wx)^2}.$$

When loaded with a single weight W at the centre of the arch

$$T = \frac{Wl}{4v}.$$

If W rests at a point x from centre of arch, then,

$$T = \frac{W(l - 2x)}{4v}.$$

When loaded with a uniform load over half the span,

$$T = \frac{wl^2}{16v}.$$

Stresses in Three-Pinned Arch.

When loaded with a single weight W (see fig. 1),

$$T = \frac{W\,l}{4v}.$$

If the lines of pressure be inclined at an angle ϕ to the horizontal the direct compressive stress, s, at any section in the rib is

$$s = \frac{W\,l}{4v} \sec\phi \cos\delta,$$

where

δ = angle which the tangent at the section under consideration makes with the line of pressure.

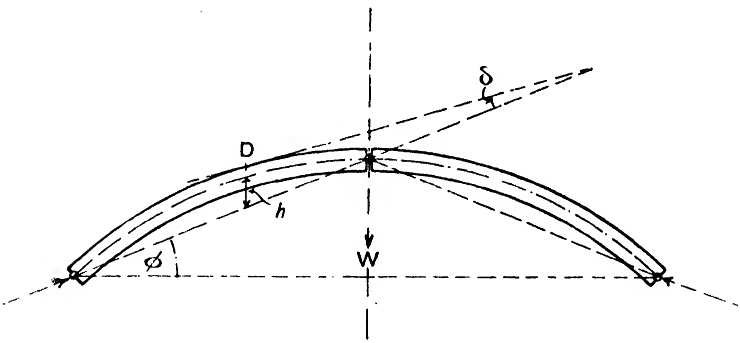

Fig. 1.—Three-Pinned Arch.

The bending moment at section D

$$= \frac{W}{4v} \times h,$$

(h being the vertical distance between the line of pressure and the neutral axis of the rib at the given section).

For other loadings the same rules apply, the line of pressure always passing through the pin joints.

STRESSES IN ARCHES WITH FIXED ENDS.

In the case of a parabolic arch with fixed ends, of uniform cross section throughout, the resultant thrust lines due to concentrated loads are readily determined from the following relations, which can also be taken as applying to flat segmental arches which can be considered as parabolic.

$$AP = \frac{2}{15} \times \frac{C - 5b}{C - b} \times v$$

$$MO = \frac{6}{5} \times v$$

$$CQ = \frac{2}{15} \times \frac{C + 5b}{C + b} \times v$$

where C is half the span, b the distance of the concentrated load from the centre of the span v the rise or versin of the centre line. AP (fig. 2) is measured below the springing line when the value is negative.

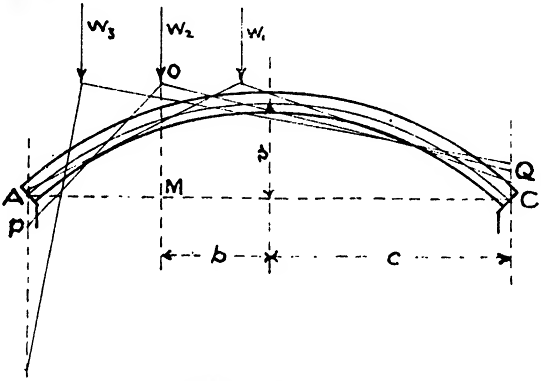

FIG. 2.—Fixed End Arch.

The horizontal component T of the thrust due to a concentrated load W is $15W(C^2 - b^2)^2 \div 32vC^3$, and the reactions R_1 and R_2 are obtained from the relations :—

$$\frac{R_1}{T} = \frac{MO - AP}{C - b}$$

$$\frac{R_2}{T} = \frac{MO - CQ}{C + b}$$

Any given load produces a maximum bending moment n the arched rib when $b = 0{\cdot}45C$, and to obtain the maximum bending moment from a system of concentrated loads these should be placed on half the span with this position as centre.

If the dead load is uniformly distributed and equal to w lbs. per ft. run, the resultant thrust line does not depart sensibly from the centre line of the arched rib, and the horizontal component of the thrust is equal to $wC^2 \div 2v$.

The bending moment due to any load is equal to the horizontal component of the thrust multiplied by the vertical intercept, at the section considered, between the resultant thrust line and the centre line of the arch, and the effect of a system of loads can be obtained by combining the bending moments due to the individual loads.

If T is the horizontal component of the thrust due to the uniformly distributed dead load, T_1, T_2 and T_3, the horizontal components of the thrust due to three concentrated loads W_1, W_2, and W_3, and y_1, y_2 and y_3, the vertical intercepts between the resultant thrust lines due to these loads, and the centre line of the arch at any vertical section, then the total bending moment at that section $= T_1y_1 + T_2y_2 + T_3y_3$, and the distance of the resultant thrust line from the centre line of the arch at the section considered $= \dfrac{T_1y_1 + T_2y_2 + T_3y_3}{T + T_1 + T_2 + T_3}$

Values of y below the centre line are negative quantities.

Combined Stresses in Arched Ribs.

In any arch where the line of pressure does not coincide with the neutral axis of the rib, there will be the following forces at any cross section :—

(1) A maximum compressive stress

$$= \frac{Q}{A} + \frac{M}{Z_c}.$$

(2) A maximum tensile stress

$$= \frac{M}{Z_t} - \frac{Q}{A}$$

(3) A mean shear stress over the section

$$= \frac{S}{A},$$

where

Q = the thrust; S = the shear (obtained by resolving the horizontal thrust along (or tangential) and perpendicular to the neutral axis of the section under consideration); A = the area of the cross section of the rib; M = the bending moment obtained by applying Eddy's Theorem; Z_c and Z_t = the moduli of section in compression and tension respectively.

Stresses in Braced Arches.

Having found the direction and magnitude of the abutment reactions for any loading, the stresses can be found in a similar manner, those in the bracing being conveniently determined by Ritter's Method of Moments, described under 'Lattice Girders,' page 519.

Effects of Temperature Variation.

A rise in temperature causes an increased thrust in two-pinned and rigid arches, but theoretically causes no such increase in three-pinned arches, although practically some slight difference may be occasioned by any stiffness of the pin joints.

For a short research on Temperature Stress, see *The Theory and Design of Structures*, by Ewart S. Andrews, B.Sc., M.I.C.E.

Ratio of Rise to Span.

This is usually taken as from 1 : 5 to 1 : 10, but varies greatly according to local conditions of headroom.

The three-pinned arch over the river Exe—a road-bridge carrying tram-cars, erected in 1905, has a ratio of rise to span of 1 : 13·2, and is probably the flattest steel arch in existence in this country.

SECTION XIV

PART VI

SUSPENSION BRIDGES.

Types and Stresses.

Advantages and Disadvantages of Suspension Bridges.

The principal advantage is their cheapness, and in large spans the advantage of the suspension bridge is so great that bridges of this type of 800 or 900 ft. span can be constructed at much less cost per foot run than girder bridges of half this span.

There are many disadvantages attending suspension bridges, the chief being lack of stiffness and rigidity, both vertically and laterally, which makes them unsuitable for carrying railways unless elaborate means are taken for stiffening them.

A suspension bridge constructed on 'Bridge's System,' in which the suspension rods are inclined, is much stiffer vertically than one in which the rods are vertical.

Types of Stiffened Suspension Bridges.

In order to lessen the changes of shape and oscillations set up by a moving load, the roadway girders may be constructed of rigid form and braced laterally. The principal varieties of this and other types of stiffened suspension bridges are:

(a) Roadway stiffening girders hinged at each end and at centre.
(b) Roadway stiffening girders hinged at each end.
(c) Roadway stiffening girders hinged in either of the above ways and bridge consisting of two cables at each side stiffened by bracing.

Examples of some of the above types are as follows:—

Types (a) and (b).—Williamsburg Bridge, over East River, New York, built 1903, span 1,600 ft. Double line of railway, four lines of tramways, two roadways and two footways and cycle tracks.

Manhattan Bridge over East River, New York, built 1909, span 1,470 ft., four lines of tramway, one roadway, and two footways.

Type (c).—The Hudson River Bridge, New York, clear span 2,880 ft., four lines of railway, four lines of tramway, two roadways, and two footways. A further example of this type is the Tower Bridge, London, in which the side spans are of this type.

An example of a bridge constructed with inclined and vertical suspenders is the Brooklyn Bridge, New York, built in 1884, span 1,595 feet, which carries a double line of tramway, two roadways, and one footway.

Stresses in Cable Uniformly Loaded.

The shape which a loaded cable takes up is the same as the link polygon for the given load system, drawn from one support to the other, with a polar distance equal to the horizontal component H of the pull or tension in the cable.

If

d = the dip of the cable; L = span; W = weight carried by the cable, then,

$$H = \frac{WL}{8d}.$$

A = area of the cable; f = safe tensile stress,

$$fA = \frac{W}{2}\sqrt{\left(1 + \frac{L^2}{16d^2}\right)}.$$

Stresses in Anchor Cables.

There are two chief methods by which the cables of suspension bridges are carried over the piers —

(1) Main and anchor cables passing continuously over rollers fixed to the top of the piers,

(2) Main and anchor cables passing continuously over saddles mounted on rollers on the tops of the piers.

Let

ϕ = angle which bridge cable makes with a vertical at point of support; δ = angle which anchor cable makes with a vertical at point of support; T = tension in bridge cable; T_1 = tension in bridge anchor cable.

Case (1).—Tension in anchor cable is equal to tension in bridge cable, whatever the inclinations,

$$= T_1 = T;$$

Horizontal force acting on piers $= H\left(1 - \dfrac{\sin\delta}{\sin\phi}\right);$

Vertical pressure on piers $= \dfrac{W}{2}\left(1 + \dfrac{\cos\delta}{\cos\phi}\right).$

Case (2).—Tensions in anchor and bridge cables not always the same, but there is no horizontal force on the piers,

$$T_1 = \frac{T\sin\phi}{\sin\delta};$$

Vertical pressure on piers $= \dfrac{W}{2}(1 + \tan\phi\cot\delta).$

Stresses in Suspension Bridges with Pin-Jointed Stiffening Girders. Type (*a*).

Uniform Rolling Load.

With a uniform load over the whole span there is no bending moment on the girders, the whole behaving as an unstiffened suspension bridge.

When the load covers half the span there will be a reverse or negative bending moment on the unloaded girder equal to the positive bending moment on the loaded girder.

$$\text{Maximum negative B.M.} = \frac{wL^2}{64};$$

and occurs at $\frac{1}{4}$-span.

The maximum positive bending moment at any point distant z from the centre pin, the head of the load being distant $x = \dfrac{l^2}{2l + z}$ from ditto

$$= \frac{wz\,(l^2 - z^2)}{2\,(l + z)}.$$

. The absolute maximum positive bending moment = $0\cdot0753\,wl^2$ (or $\dfrac{wL^2}{53}$ approximately), and occurs when $z = 0\cdot53l$, the head of the load being distant x from the centre pin.

Isolated Rolling Load.

With a concentrated rolling load passing over the girders :—

$$\text{Maximum negative B.M.} = \frac{WL}{16}.$$

and occurs at $\frac{1}{4}$ span.

When the load is on one of the girders the bending moment is a maximum at any point when the load just reaches it.

Maximum B.M. at any point distant y from the centre pin

$$= \frac{Wy}{2L^2}(L^2 - 4y^2).$$

Absolute maximum positive B.M. = $0\cdot096$ WL, and occurs when load is $0\cdot289$L from the centre pin.

STRESSES WITH STIFFENING GIRDERS HINGED AT ENDS ONLY. TYPE (b).

In this case the stiffening girders will have to bear considerable stresses due to the increase in dip due to increase in temperature, which may amount to as much as half the safe stresses.

With a uniform rolling load passing over the span—

$$\text{Absolute maximum bending moment} = \frac{wL^2}{54},$$

and occurs at ⅙-span, when the load covers ⅔ of span.

The head of the load is always a point of contraflexure of the girder.

Assuming that the positive bending moment is a maximum at the mid point, then:

$$\text{Maximum bending moment in the length covered by the load} = \frac{wx^2 (L - x)}{8L};$$

when head of load is distant x from the nearest pin.

In the foregoing:—

w = load in tons per foot run; W = concentrated rolling load in tons; L = length of span in feet; l = length of half span in feet.

CHANGES OF TEMPERATURE.

In England the observed expansion of steel structures appears to be about $\frac{1}{2400}$ of their original length from their coldest temperatures. This corresponds to a range of temperatures of 60° F. In suspension bridges, with movable saddles at the tops of the piers, the augmented dip of the central cable is due to increase in length of the anchor cables and consequent movement of the saddles as well as the increase in length of the central cable itself.

Let

l = the half span of central cable; D = central dip; D_1 = augmented dip due to rise in temperature of 60° F.; L = length of semi-parabola measured along curve; then by the properties of the parabola,

$$L = \sqrt{l^2 + \frac{4}{3} D^2};$$

and

$$D = 0 \cdot 866 \sqrt{L^2 - l^2};$$

therefore

$$D_1 = 0 \cdot 866 \sqrt{\left(L + \frac{L}{2400}\right)^2 - l^2}.$$

To this must be added the increased dip due to inward movement of the saddles.

ECONOMIC PROPORTIONS.

Economy in the weight of a cable can be effected by adopting a liberal depth or dip, but it is impossible in practice to increase the depth beyond a certain amount, because the greater the dip the greater will be the distortion and oscillation caused by a moving load.

In most of the existing examples of suspension bridges of various types, the dip does not exceed $\frac{1}{10}$ of the span, and in many cases $\frac{1}{12}$ to $\frac{1}{15}$ has been adopted.

SELF-ANCHORED SUSPENSION BRIDGE.

The new Chelsea Bridge provides an example, claimed to be the first of its kind in this country, of a self-anchored suspension bridge. The stiffening girders, in addition to distributing the effect of local live load over all hangers of the loaded span, also takes the horizontal component of the anchorage pull. These girders are hinged near each tower and, for erection purposes at the centre, but this last hinge was afterwards riveted up. The main dimensions, decided principally by site conditions, are as follows: centre span 352 ft.; side spans each 173 ft.; height of cables at centre 13 ft. above road level; height of towers about 52 ft. above road level; depth of dual stiffening girders 8 ft. 10 ins. over flange angles; width of roadway between towers 40 ft.; width of footpaths outside towers each 12 ft. The towers are hinged at the bases, and independent with no portal bracing.

ADMINISTRATION: GREAT BRITAIN.

Trunk Roads Act, 1936.—The Act makes the Minister of Transport the highway authority for some 4,500 miles of roads, substantially and with some additions, the trunk road system in being, 1936. The Act came into force on April 1, 1937, in England and Wales, and on May 16 in Scotland. The Trunk Roads (Delegation of Powers) Order, 1937, imposed certain functions upon local authorities, in respect of these roads, for a period of two years, in order to secure continuity of administration.

The Trunk Roads Act, 1946.—Provided for the addition, April 1946, of 3,685 miles of existing roads to the previous mileage of 4,500, raising the percentage mileages; England and Wales, from 2·13 to 4·03; Scotland, from 4·6 to 7·5.

The Special Roads Bill.—Presented to the House of Commons, November 1948, it is an enabling Bill, providing powers for the construction of motorways and roads for the exclusive use of cyclists, or pedestrians. Special roads may be trunk, classified or unclassified, and may include parts of existing roads. Orders under the Trunk Roads Act, on which procedure had commenced, or which are made within one year of the Bill becoming law, will take effect as if they were special road schemes.

Restriction of Ribbon Development Acts.—A Ministry of Transport Circular of October 1948 explains how the Town and Country Planning Act of 1947 repeals certain of the provisions of the Restriction of Ribbon Development Act of 1935 and repeals entirely that of 1943.

HIGHWAY LAW.

Speed Limit.—The speed limit in 'lighted areas,' these being mostly built-up areas, is 30 m.p.h. Evidence given on behalf of the Pedestrians' Association before the House of Lords Select Committee on Road Accidents, included, that 30 m.p.h. is too high a speed; that 25 m.p.h. would give a much better margin of safety, and that experiments in America pointed to 23½ m.p.h. as the most effective speed with respect to traffic flow in built-up areas.

HIGHWAY STATISTICS.

Mileages of Public Roads in Great Britain, 1937–38.

(M., Metropolitan Cities and Boroughs; C., County Boroughs.)

England.

[To reduce to km. per sq. km., multiply by $\frac{87}{140}$, or 0·6214.]

Belgium.—In 1934: state roads (*s*), 0·465; provincial roads (*p*), 0·083; local roads (*l*), 1·818. All paved and metalled roads (*t*), 2·366. In km. per sq. km.: (*s*), 0·287; (*p*) 0·052; (*l*), 1·130; (*t*), 1·417.

Persons per Mile of Road: Counties (based on mileages, March 31, 1927, and census, 1921).—*Eleven*, below 61; Radnor 23, Montgomery 32, Cardigan 44, Merioneth 48, Brecon 54, Hereford 56, Devon 57, Westmoreland 57, Rutland 58, Pembroke 60, Norfolk 60. *Sixteen*, below 90; Lincolnshire, Holland, 67; Anglesey 70, Shropshire 70, Lincolnshire, Kesteven, 71; Cornwall 73, East Riding of Yorkshire 76, Carmarthen 77, Lincolnshire, Lindsey, 78; Oxfordshire 79, Denbigh 81, Suffolk, West, 83; Somerset 85, Cumberland 86, Suffolk, East, 87; Wiltshire 87, North Riding of Yorkshire 89. *Twelve*, below 131; Gloucestershire 93, Huntingdon 97, Dorset 98, Carnarvon 101, Hampshire 105, Flint 107, Northamptonshire 114, Berkshire 118, Isle of Ely 120, Leicestershire 124, Buckinghamshire 130, Northumberland 130. *Eight*, below 200; Worcestershire 139, Sussex, West, 143; Warwickshire 145, Sussex, East, 151; Cambridgeshire 153, Huntingdonshire 194, Bedfordshire 199, Nottinghamshire 199. *Nine*, 200 to 300; Staffordshire 201, Derbyshire 209, Monmouthshire 217, Cheshire 223, Soke of Peterborough 223, Isle of Wight 230, Kent 230, Essex 241, Yorkshire West Riding, 260. *Five*, over 300; Surrey 324, Lancashire 384, Durham 424, Glamorgan 450, Middlesex 927.

Great Britain, 248; Canada, 21; U.S.A., 196; Germany, 292; France, 106; Italy: national roads, 3,393; provincial, 1,696; other, 565; all roads, 377.

Australia, 13·8; New South Wales, 22·2; Victoria, 17·3; Queensland, 8·2; South Australia, 9·7; Western Australia, 6·0; Tasmania, 21·1; Nyasaland Protectorate, 475; Northern Rhodesia, 196; Southern Rhodesia, 183.

Mileages per 10,000 *persons.*—See *The Surveyor*, April 21 and 28, 1933, for other figures and discussion.

Examples.—Towns having populations 98,000 to 991,300: Birmingham, 7·24; Liverpool, 7·68; Manchester, 8·71; Sheffield, 8·71; Leeds, 12·3; Halifax, 22·4; Nottingham, 8·3; Tottenham, 4·93; West Ham, 4·33. Population, 40,000 to 98,000: Port Talbot, 16·0; Merthyr Tydfil, 17·5; Bournemouth, 15·3; Lancaster, 11·2; Dudley, 9·34; Grimsby, 7·0; Gellygaer, 5·37. Population 20,000 to 40,000: Scunthorpe and Frodingham, 16·5; Coulsdon and Purley, 15·8; Erith, also Chorley, 10·4; Wednesbury, 8·3; Gravesend, 8·24. Metropolitan Cities and Boroughs: Finsbury, 8·51; Woolwich, Greenwich, Lewisham, nearly 7·3; Kensington, 5·36; Poplar, 4·05; Bethnal Green, 3·7.

Miles of Roads per Square Mile.—Birmingham, 9·9; Liverpool, 17·3; Manchester, 19·5; Sheffield, 8·4; Leeds, 10·4.

ROAD SYSTEMS OVERSEAS.

Australia.—(i) December 31, 1934: Population, 6,691,000; area, 2,450,021 sq. miles; road mileage, 485,931; number of registered motor vehicles, 720,509, or 107·7 per 1,000 of population; per mile of road, persons, 13·8; vehicles, 1·5. (ii) June 30, 1935: State highways, 9,802 (none so classed in South Australia or Western Australia); other main roads, 36,500 (none so classed in Tasmania); developmental roads, 12,907 (none so classed in South Australia or Tasmania); total, 59,209 miles of roads so classified, or 12·18 per cent. of the total road mileage. Expenditure for 1934–35: on classified roads, £8,846,800; on unclassified roads, £6,025,394.

Union of South Africa.—It was anticipated that 5,396 miles of national roads would have been completed by the end of the fiscal year 1940–41, at a cost of about £11,000,000, including about £8,500,000 construction cost, and £2,170,000 interest and redemption on loans.

Features and Costs of Construction.

Many works classed as road-making involve alterations to the fences, ditches, and roadbeds of existing roads or tracks. Costs are not, therefore, generally comparable, the earlier work being, in some cases, largely to the good, in others involving expense additional to that which would have been incurred on virgin ground. In Great Britain, the distinguishing term 'new construction,' or some equivalent, is usually employed in respect of works on a new alignment.

Western Australia.—Works costing £666,431 (1934–35) comprised: cleared, 848 miles; formed, 897 miles; gravelled 339 miles; metalled, 15 miles; sanded, 10 miles; reconditioned, 173 miles; side drains formed, 213 drain miles; bituminous treatment, 95 miles.

Similar work, on comparable mileages, has been continued year by year.

Western Highlands of Scotland.—Programme of reconstruction or improvement on 1,500 miles of roads, including bridge works, £4,500,000, estimate.

Crawley By-pass.—About 2½ miles. Estimate £133,400, for a 100-ft. road, with two 20-ft. carriageways, two 6-ft. cycleways and two 5-ft. footways; and including a bridge over the railway. Opened July 1939. Revised estimate about £180,000.

Winchester By-pass.—Opened February, 1940; nearly 7 miles; cost, £420,000. Normal width, 72 ft.; carriageways, 20 ft., divided by a 10-ft. middle strip; three fly-overs, and 7 other bridges, of spans 26, 42, 44, 45, 50 (two) and 82 ft. Total of excavation, about 600,000 cubic yds.; of embankment, slightly less.

Gloucester By-pass.—A section 1¾ miles long; width, 120 ft.; two 22-ft. carriageways separated by a 26-ft. strip; cycleways (not yet constructed) and footways; allows for future widening of the carriageways to 30 ft.; ultimate width, including service roads, 172 ft.; building lines 20 ft. behind the service roads. Curves 2,000 ft. or more radii; excepting one of 500 ft.; all super-elevated; traffic roundabouts (one in this section) at crossings of main roads; trees spaced 60 ft. apart in both verges between the footways and sites of cycleways, and a line of trees in the middle reservation. Cost about £56,000, of which £45,500 is for road works and £10,500 for land; cost of roundabout, £2,360; rates, per cubic yd.: bulk excavation, 3*s.* 11*d.*; extra for filling, 1*s.* 4*d.*; concrete under kerb, 27*s.* 2*d.*; sewer excavation: not exceeding 5 ft. deep, 5*s.* 1½*d.*, between 5 ft. and 12 ft. deep, 6*s.* 10*d.*; per sq. yd.: 3 ins. consolidated clinker or gravel, 0*s.* 7*d.*; 8 ins. concrete slab, 6*s.* 0¾*d.*; preparing and sowing verges, 0*s.* 5*d.*; per lineal yd.: 12 ins. by 6 ins. precast concrete kerb, 3*s.* 11*d.*; concrete pipes, from 4*s.* 10*d.*, for 9-in., to 22*s.* 11*d.*, for 24-ins.; wire mesh and oak post fencings, 3*s.* 9*d.*; apiece: precast manholes, 7 ft. to 12 ft. deep, £9 to £14; trees, stakes, and wire guards, 9*s.* 11*d.*

Coventry By-pass.—Completed 1940. Length, 6 miles 7 furlongs; cost, including service roads, bridges and incidental works, £350,000; comprising, main road, £259,000; land, £30,000; service roads, £42,000 (recoupment of 30*s.* per foot of frontage); Tile Hill Lane section, £19,000; width, 150 ft.; least radius of a curve, 1,500 ft.; concrete carriageways, chiefly; some of stone pitchings and a wearing course of tar-bitumen macadam; cycleways of tarred limestone.

Schemes in Abeyance.—Schemes estimated to cost over £10,000 and not to be put in hand unless to meet war requirements or urgent needs—as ordered May 1, 1940—totalled £3,133,000 estimated cost.

Haifa-Baghdad Road.—Described in the *Journal Inst. C.E.* January and October issues, 1940, the former containing a paper, by Lieut.-Colonel R. Briggs, describing the works in the sections, Irbid to the Lava Belt, 41 miles; through the Lava Belt, 106 miles, and thence to the Transjordan-Iraq frontier, 56 miles. The length of the road from Haifa to the Iraq frontier is 275 miles and thence to Baghdad, 350 miles; the latter portion including 50 miles of previously existing road.

Rangoon-Chungking Road.—Known as the Burma Road and nearly 200 miles in length, it includes a section of 350 miles, from Shaknoan to the China-Burma frontier, having a minimum formation width of 18 ft., increased to 24 ft. in favourable ground, and a road crust, initially 10 ft. wide, having a base course, 4½ ins. thick, of packed stone and a wearing course, 3 ins. thick, of gravel or broken stone.

Costs of Carriageway Construction.

(Per mile, and maintenance per mile per annum.)

Victoria.—Forming an asphaltic (tar-bound gravel) wearing course on an earthen road, £540, its maintenance cost £50; a gravel crust, £1,000, maintenance, £30; a higher type (for economic comparison, 4 per cent. loan repayment), £4,000, maintenance, £20; cement concrete, 9-7-9 ins., 20 ft. wide, £11,800; crushed rock (presumably crusher-run broken stone), 20 ft. wide, 7 ins. thick, £1,570; 8 ins., £2,000; mixed-in-place, tar-bound gravel wearing course, loose depth, 2½ to 3 ins.,; the tar applied at the second of the three stages of mixing; a sealing coat of bitumen, covered with fine material: cost, £680 per mile for 18-ft. width.

New South Wales.—Analysis: In an expenditure of £247,630; percentages of cost of construction—formation, 34·10; culverts, 7·14; paving, 34·34; bridges, 9·99; fencing, 1·54; maintenance, during construction, 1·71; to the end of the year, 1·09; camp, water-supplies, sundries, 3·88; survey, designing and supervision, 6·21.

Newcastle-Tynemouth Road.—Nearly 4·7 miles; about £43,000 per mile, or, not including the cost of four large bridges, about £31,700 per mile. Half the 102 ft. width made; 30-ft. carriageway; reinforced concrete 7½ ins. at sides, 10½ ins. at centre, on flat bed of ashes; top 2 ins. blue whinstone chippings; single reinforcement.

Reconstruction.—Cardiganshire, including foundations and surfacing with tar macadam, £3,167 per mile. Lincolnshire (Holland), £4,000. Dorset, Wimborne, and Cranbourne R.D.C., £2,791. A moorland road, £5,000.

Costs of Road Maintenance, 1936–37.

(Per mile, per annum.)

Maintenance, Repair, and Minor Improvement.

(Classes I, II. and III.)

'Class III.' here means the then wholly unclassified roads. See p. 541.

Northamptonshire.—1942–43. Ordinary Maintenance.—Classified roads, £255. Unclassified roads, £82, comparing with £451 and £129 in 1938–39.

Holland.—1944–45. Trunk road A16, £195; Class I., £247; Class II., £158; Unclassified, £82; average, £102.

Leicestershire. 1945–46. Trunk (42·5 miles), £333; Class I. (168 miles), £268; Class II. (205 miles), £284; Unclassified (1,280 miles), £119.

ENGLAND.—I., £485; II., £329; III., £135; average, £201.
Counties.—I., £447; II., £309; III., £100; average, £179.
County Boroughs.—I., £592; II., £454; III., £211; average, £269.
London.—County, City and Metropolitan Boroughs: I., £2,076; II., £1,341; III., £533.
Boroughs (non-county) and Urban Districts: unclassified, £196.

WALES.—I., £293; II., £235; III., £69; average, £106.
Counties.—I., £289; II., £227; III., £57; average, £99.
County Boroughs.—I., £416; II., £486; III., £166; average, £213.
Boroughs (non-county) and Urban Districts.—Unclassified, £125.

SCOTLAND.—Classes I., £169; II., £133; III., £92; average, £118.
Counties.—Classes I., £153; II., £129; III., £58; average, £96.
Large Burghs (24).—Classes I., £483; II., £289; III., £341; average, £362.
Small Burghs.—Unclassified, £156.

GREAT BRITAIN.—I., £392; II., £276; III., £123.

Overseas Costs of Maintenance.

(Per mile, per annum.)

Jamaica.—Main roads, 1934: (*a*) £96 14*s.*, including, in the parish of Kingston, £397; (*b*) including special works and the maintenance and construction of bridges, £105. Flood damage in 1933, £163,000, and in 1934, £20,000, compares with the expenditure, under (*a*) of £227,000

Tasmania.—State roads, 1,170 miles, £54 in 1935; estimate for 1936, £56.

Victoria, Australia.—The cost, £35, of maintaining gravel roads by horse-drawn drags or small graders, has been reduced to £20 by using pneumatic-tyred power graders.

Relation of Cost to Traffic.—New Zealand: on the basis of low cost construction at £350 per mile, one coat, for traffic up to 200 vehicles per day, or 2-coat work for 800 to 1,000 vehicles per day. Costs of maintenance, including interest on the capital, short-term repayment, sinking fund, and general maintenance of the road. Vehicles per day and £ per annum: with 1,000 motor vehicles per day, £350; 750 vehicles, £275; 500 vehicles, £223; 250 vehicles, £194.

Analyses of Costs of Maintenance.

Northamptonshire.—Class I. roads, 301·7 miles; expenditure in one year, £115,217. Analysis, percentages of the total: resurfacing, 30·5; strengthening foundations, 22·6; kerbing, 6·41; surface dressing, 19·7; patching, 2·08; sanding and gritting, 1·06; siding and ditching, 5·11; drainage and culverts, 1·9; guide posts and fences, 0·71; footpaths, 7·15; scavenging, 1·52; white lines and caution signals, 0·86.

Cardiganshire (1935).—In a total of £13,265: labour, £4,750; material, £1,990; haulage, £1,245; steam rolling, £460; tarring, £4,020; bridges, £60; various items, £470.

Canada.—Percentage costs: ditching, 1·8; grading, 1·9; resurfacing, 14·6; culverts, 1·6; dragging, 0·1; oiling and patching, 61·3; snow removal, 8·7; cutting weeds, 8·6; bridges, 1·2; drain assessment, 0·2.

Costs per Mile: Directly Maintained Roads.

Maintenance and Minor Improvement.

RESEARCH AND EXPERIMENT.

The Laboratory.

Tests of Road Stones.

(*See Report to the Third International Road Congress, T. E. Stanton and R. G. Batson.*)

The equipment of the National Physical Laboratory, Teddington, enables the following test of road stones to be made :—

(1) A dry attrition test (resistance to wear); (2) a wet attrition test; (3) an abrasion test (for hardness); (4) a repeated impact test (toughness); (5) a test of the cementation value; (6) an absorption test.

Attrition Test.—The machine is of the 4-cylinder Deval type, as used in France and in the United States. The cylinders are 7½ ins. in diameter and 14 ins. long, set at 30° to the axis of rotation. About fifty pieces of the rock, weighing eleven pounds, are placed in one of the cylinders, and the machine revolved 10,000 times at about 30 revolutions per minute. Only the material which will pass a sieve of $\frac{1}{16}$ mesh is counted in measuring the amount of wear, which is recorded both as a percentage and by the French coefficient $\frac{40}{\text{percentage of wear}}$.

In the wet test 1·1 gallon of water is used with 11 lbs. of stone. The wear is usually greater in the wet than it is in the dry test ; but not always.

Repeated Impact Test.—This test is made with the Page impact machine, which has a hammer weighing 4·4 lbs., delivering the blows through a plunger, the surface of which, in contact with the specimen, is spherical to a radius of 0·4 in. The test piece is a cylinder, 1 in. by 1 in., ground to the true diameter, and cut to length by a diamond saw. The test consists of a series of blows, beginning with a fall of 0·4 in., which is increased by 0·4 in. with every successive blow until the test piece is broken. The toughness is measured by the number of blows. Tests can also be made with a constant height of fall.

Abrasion Test.—The test piece is prepared in the same way as for the impact test and is of the same size. The machine is of the Dorry type, and consists of a cast steel disc revolving in a horizontal plane. The test piece is held, with its axis vertical and with a load equal to 3·5 lbs. per square inch, against the surface of the disc 26 cms. from the centre. Standard sand of 30 to 40 mesh is fed continuously through funnels at a definite rate, the same in each case. After about 1,000 revolutions of the disc, at the rate of 28 per minute, the test piece is weighed and the loss of weight noted. The test is repeated on the other end of the test piece, and the average loss of weight by the two runs is recorded. The hardness is measured by $(20 - \frac{1}{3}W)$ where W is the loss of weight in grammes per 1,000 revolutions.

Cementation Test.—Coarsely crushed rock, weighing 1·1 lb., is ground in a ball mill with 0·02 gallon of water, the balls being steel shots (two) 5·1 ins. in diameter. The material is ground for two and a half hours at the rate of about 2,000 revolutions per hour. The resulting paste is moulded into briquettes, 1 in. diameter and 1 in. long, the maximum pressure being 1,880 lbs. per square inch. After twenty-four hours, the briquette is dried for twenty hours in the air, and for four hours in a hot air bath at 200° F., cooled for twenty minutes in a dessicator, and then tested. It is placed on the anvil of the machine, with its axis vertical, and struck through a plunger by a small hammer with an effective drop of 0·4 in., the rebound being measured by the movement of a lever attached to the hammer, and holding a pencil against a paper-covered revolving drum. This records the number of blows required to destroy the resiliency of the test piece, after which there is no rebound. The mean of six tests is taken as giving the cementing value of the material.

Crushing Strength.—The specimen is a cylinder 1 in. in diameter by 1 in. long, ground out of a rough sample by emery-wheels. The cracking stress and crushing stress are measured.

Absorption of Water.—A stone of about 13 lbs. is weighed in air and then in water. It is kept in water for three days and is then weighed in air. If A = weight in air, B = weight in water immediately after immersion, and C = weight in water after immersion for three days, the number of pounds of water absorbed per cubic foot of rock is nearly

$$\frac{C - B}{A - B} \times 62\cdot5$$

Petrological Analysis.—The classification of the rock, in the terms of geological nomenclature and as regards its constituents, is made in the Geological Museum, London, S.W.

Ring Track Testing Machines.—No. 1 and No. 2, described in Road Research Board Report, 1933–35, mean diameter of track, No. 1, 5 ft. 6 in.; No. 2, 38 ft.; No. 3, 110 ft., described in a lecture to the Road and Building Materials Section of the Society of Chemical Industry, by R. H. Stradling. (Published with illustrations in *Roads and Road Construction*, April 1 and May 1, 1935.)

No. 3 was installed in April 1936. Loaded weight of vehicle, 12 tons; maximum speed, 40 m.p.h., effecting a centrifugal pull of 25 tons on the centre post. Traversing gear to give track wear on 2 ft. 6 ins.

Tests of Roadbed Materials.

Unconfined Compression Test.—A convenient and rapid method of measuring the shear strength of clay soils. The apparatus consists of a metal framework in which cylindrical soil specimen, 3 in. long and 1½ in. diameter, is compressed by a helical spring, the load being applied by rotating the handle at the top of the apparatus. An autographic device enables the load-deformation curve to be drawn directly on a chart mounted on the plate in front of the apparatus. For purely cohesive soils the shear strength is equal to half the unconfined compressive strength.

Shear Box Test.—Used to investigate the shear properties of all types of soil, both cohesive and non-cohesive. A soil sample of 6 c.m. square cross section contained in a metal box is constrained to shear along a definite plane, the shear strength being determined for various compressive loads applied normally to the plane of shear. The shear strength is related to the normal pressure by Coulomb's formula: $S = c + p \tan$ 'phi' where S = shear strength; c = cohesion; and p = normal pressure, all in lb. per sq. in. and 'phi' = angle of internal friction.

Triaxial Compression Test.—The test is made on a cylindrical specimen, 3 in. long and 1½ in. diameter. Its cylindrical face is covered with a rubber membrane and then subjected to a known hydraulic pressure, while an increasing axial load is applied until the specimen fails.

Plate-bearing Test.—A circular-plate is loaded on the actual sub-grade and a load/deflection curve obtained for increments of load. The modulus of sub-grade reaction is taken as the pressure required to produce a deflection of 0·05 in. measured in lb. per sq. in.

California Bearing Ratio Test.—A test (C.B.R.) devised in the United States. Related empirically to wheel loads and required thicknesses of road construction. The C.B.R. value of a soil is obtained by relating the load/penetration curve for a circular plunger, 3 sq. in. in cross section, driven into soil compacted into a special cylinder, to the corresponding curve for a standard highly stable soil.

TESTS OF BITUMINOUS MATERIALS.

Penetration Test.—The material to be tested is usually brought to a definite temperature, which for standard comparisons is 77° F. (25° C.). The penetrometer consists essentially of a weighted needle attached to the 'hand' of a dial by a simple mechanism so that the hand on the dial registers the distance moved by the needle. The point of the needle is brought to the surface of the specimen, the dial reading noted, the needle released for one second or sometimes longer, and then held. The difference between the two readings on the dial measures the penetration. It is desirable to make tests with different weights on the needle and at different temperatures.

Solubility Test.—Solubility in carbon disulphide. A small quantity is placed in a weighted flask containing 100 c.c. of carbon disulphide, and afterwards decanted through an asbestos mat and the precipitate dried and weighed.

Other Apparatus and Tests.

Hardness Number Test.—The hardness number of a sample of mastic asphalt is defined as the depth in hundredths of a cm., to which a steel rod of 6·85 mm. diameter, with the end cut off square, will penetrate the sample under a load of 100 kg. per sq. cm. (Illustration and description by D. M. Wilson, Soc. of Chem. Ind. Paper; Ref. (a), 'Roads and Road Construction,' April 1, 1932.)

Deformation Test.—On a test piece 2 ins. in diameter and 2 ins. long, cut from the pavement, or moulded. The test piece, placed as an upright cylinder, is pressed by a steel disc of somewhat larger diameter, to which, centrally, by means of a $\frac{5}{16}$ in. diameter steel ball, an initial load of 20 kg. is applied by a weight of 1,750 grms. and leverage, the load at the lever end being increased by running shot into a can hung from it and the load on the specimen thereby increased by 22·9 kg. per min., until the height of the cylinder (test piece) is reduced by twenty-hundredths of a cm., shown by 20 divisions on a dial. The result is expressed as the kg. load, on the end of the beam required to cause this shortening (ref. as (a) above).

Hutchinson Automatic Penetrometer.—In this new instrument there is no delicate or complicated timing apparatus, nor any part subject to rapid wear. The vernier system of reading penetrations eliminates the rack and pinion operated pointer and dial. A lifting gear for the sample plate provides for rapid and precise adjustment. (Description and illustrations in 'Roads and Road Construction,' October 1, 1932.)

Stability Test.—(1) A machine devised by O. R. Stokes and J. Zapata, for testing the stability of cold emulsions, is described in 'Proceedings of the (American) Association of Asphalt Paving Technologists,' 1932.

(2) (The same ref.) The Hubbard-Field apparatus, of the piston and cylinder type, is an adaptation directed to provide for the testing of coarse aggregate mixture.

(1) *Metro Plastimeter.*—For measuring the consistency of pitch-like substances. A steel sphere is forced, by the application of a weight, into a mould containing the material, the rate of penetration being measured. The sphere is of much less diameter than the mould.

(2) *Metro Trough Viscometer.*—A trough resembling the spirit level of a surveying instrument is so mounted on trunnions that it can be steeply tilted. The tar is placed in the well, or reservoir, of the trough, which is brought to the required temperature and tilted to a given angle. The consistency of the tar is expressed as the time of flow between two marks.

(3) *Capillary Tube Viscometer.*—An upper and a lower vessel, each of about 50 millilitres capacity, are connected by a capillary tube (perforation through a solid mounting) 5 cm. in length. The lower vessel, containing the tar, is put under mercury pressure applied at a hole in the bottom; from the upper vessel, containing a suitable liquid, that liquid, displaced as the tar flows upwards, measures the rate and amount of the flow.

Tar Viscometer.—A viscometer used in investigations into the use of Vertical Retort Tars, at Johannesburg, is Dr. E. H. Selvey's modification of the Metro Trough Viscometer. It was found that with this instrument the tar temperature could be adjusted to within 0·05 ° C. of the surrounding water within 15 secs.

Equiviscous-Temperature Test. The temperature in °C. at which the tar has a time of flow of 50 seconds measured by the tar viscometer. Its use enables the viscosity of any road tar, however fluid or however viscous, to be expressed on a single scale. The value becomes progressively higher as the viscosity increases.

Experimental Determinations.

Coefficient of Slab-on-Road-bed Friction.—(Ministry of Transport Technical Circular. Average values: moist earth, 0·5 to 1·3; clays, 1·5 to 2·0; very rough subsoil (? road-bed), 2·0 and upwards.

Effect of Heat on Aggregates (B. H. Knight).—It was deduced from experiments with Bonawe granite, heated to 250 and 300° F., and subjected to sudden and slow cooling, that no ill results need be feared when such an aggregate is heated as in ordinary practice.

Moisture Content of Soils.—Measured *in situ* by burying a series of electrodes. The method is based on the relation between the electrical 'restivity' (*r*) and moisture content, also the relation between (*r*) and the temperature of the soil. (Report for 1933, National Physical Laboratory.)

Wheel Impact.—The first main section of the 'Wheel Impact Research,' in which a heavy six-wheeled lorry was employed, was nearly completed in 1936. The other vehicles are: a heavy four-wheeler, a medium four-wheeler, and a motor car. Experiments are made to determine the influence of the following factors: speed, unsprung weight, load, type and size of tyre, inflation pressure, shock absorber, driven or trailed axle, and middle or rear axle. (See Report for the year 1936 of the National Physical Laboratory.)

Road Surface Resistance to Skidding.—The subject of Road Research Technical Paper No. 1 (Studies in Road Friction, I.), December 1936, in which experiments are described and the results discussed. In another publication, Road Research Bulletin No. 1, December 1936, information is given as regards the construction and operation of the special motor-cycle and sidecar, and its measuring apparatus; also guidance in respect of the interpretation of the results obtained. The Road Research Laboratory is prepared to give advice on the selection and purchase of a suitable machine, and assistance in training personnel in its proper use. (It is clearly indicated that the co-operation of county and municipal highway engineers, in this important matter, is regarded as desirable.)

Control of Moisture Content of Aggregates.—The title of Road Research Technical Paper No. 4, January 1937, is: 'The Control of the Moisture Content of Aggregates for Concrete, Introducing a new Vibration Method.' In the opinion of the Road Research Board (prefatory note) '. . . the vibration system of control should make possible a considerable improvement in the quality of concrete laid in roads.' The inundation method, devised and employed in the United States, has been fully investigated by the Road Research Board, the experiments being described and the results discussed in the paper. It was found that the method is not generally applicable in Great Britain. *The Vibration Method* is based on experiments made by Dr. G. Glanville at the Building Research Station. The vibration is applied by mechanical means, under full control, and the proportion of water in the aggregate is brought very nearly to a constant value.

Surface Area of Aggregate.—(D. Torrance and R. B. S. Gilmour.) The relationship between surface area and weight of spheres or cubes, as given by Neumann's expression, $S = 6/p.d.$ square centimetres per gramme, gives values somewhat too low. A more accurate relation, assuming that the aggregate contains, in approximately equal proportions, spheres, cubes, pyramids and triangular prisms, is given by $S.A. = 3590/p.d.$ sq. ft. per ton; where p = sp. gr.; d = gauge of stone in inches. An example, taking 65 per cent. of ¾-in. gauge and 35 per cent. ⅛ in., relates 10 gallons of bitumen per ton of aggregate to a film thickness 0·0043 in., considered to be suitable for grading ¾ in. down.

Texture Prints of Road Surfaces.—The earliest prints were taken with a pneumatic tyre, replaced—for convenience in constant use of the method—by a rubber roller giving impressions as nearly as possible the same as those obtained with the tyre. The road surface is carefully inked, over an area about 8 ins. square, with a half-tone black printing ink diluted with about half its volume of paraffin. The operator holds the roller at the nearer edge of the inked patch and rolls forward, allowing the weight of his body to maintain a steady pressure on the roller. The impression is then transferred to a sheet of paper. (*Road Research Bulletin*, No. 3, 1939.)

Lateral Pressure of Clay.—Apparatus described in paper No. 5242, *Inst.C.E.*, by G. M. Binnie and J. A. Price. The principle of the machine is similar to that of Dr. von Terzaghi's tape, in that it depends upon the measurement of friction between metal parts under load; but whereas the tape is based upon sliding friction, the machine depends upon the friction of a rotating shaft between two bearing surfaces. (*Journal Inst. C.E.*, February 1941; discussion in the issue for October 1941.)

RESEARCH.

Chemical Research Laboratory, Teddington.

Drying Time of Tar.—The admixture of 1 or 2 per cent. of calcium soap to tar reduced the drying time of road tar by about 50 per cent.

Rubber-Tar.—Chlorinated rubber, an amorphous powder, was found to be readily mixable with certain kinds of tars. It increased the viscosity of high-temperature tars. The rubber-tar adhered to granite and to glass, under water.

Gypsum Cement.—A new hydraulic gypsum cement of great strength, resisting weathering, with less expansion and contraction than Portland cement, and highly resistant to mechanical wear. (See *The Engineer*, March 4, 1938.)

ROAD MATERIALS.

BRITISH STANDARD SPECIFICATIONS.

(To be obtained from the Publications Department of the British Standards Institution. 28 Victoria Street, London, S.W. 1; price 2*s*., or with postage, 2*s*. 2*d*., unless otherwise stated.)

Granite and Whinstone Kerbs, channels, quadrants and setts (No. 435). Kerbs in a series 4 in. by 9 in. to 8 in. by 12 in.; setts in eight standard sizes.

Asphaltic Bitumen Road Emulsion.- No. 434 1935. Introduces the 'Liability' test. Emulsions for Penetration (Grouting and Semi-grouting) Method and Surface Dressing. Price 3*s*.

Cold Asphalt Macadam (No. 434).—Provides a specification, using the emulsion (No. 433). Examples of suitable grading of aggregates and rates of application of emulsion and blinding materials are given in the appendix.

'*Precast Concrete Flags.*' -No. 368—1936. A revision of the 1929 specification. The loading in the transverse tests has been increased and the specified permissible amount of wear reduced. With an amendment, August 1947.

Precast Concrete Kerbs, channels, quadrants and setts. A revision (September 1936) of B.S.S. 340. The load to be supported in the cross-breaking test has been increased. With an amendment, October 1938.

Sandstone Kerbs, channels, quadrants and setts, No. 706—1936. There are requirements as regards structure, texture, water absorbtion and density.

Hydrated Lime and Mortar.—BS/ARP No. 24—1939; relates to hydrated lime for use in making a cement-lime mortar for bonding brickwork and masonry; provides for hydrated lime produced from high-calcium quicklime or a greystone quicklime.

BS/ARP No. 25—1939, provides for a lime-cement mortar for bonding brickwork, natural or cast stone and other structural units.

Road Stone and Chippings.—No. 63—1939; sizes of road stone and chippings. Specifies square mesh sieves. (B.S. 410.)

Furnace Slag for Concrete Reinforcement.—No. 877—1939. Foamed blast-furnace slag for concrete reinforcement. The standard is restricted to material having a lime content within 50 per cent.

High-alumina Cement. (No. 915—1940.) The compression test is included, without the alternative of a tensile test.

Compressed Natural Rock Asphalt.—No. 348—1948.

Cold Asphalt Macadam.—Penetration (Grouting and Semi-grouting) Method, using Road Emulsion.—No. 433—1931.

Single Coat Asphalt (cold process).—No. 510—1933. Price 3*s*.

Two-Coat Asphalt (cold process).—No. 511—1933. Price 3*s*.

Rolled Asphalt. Asphaltic Bitumen and Fluxed Lake Asphalt (hot process).—No. 594—1945. Price 2*s*. 6*d*.

Rolled Asphalt. Fluxed Natural Asphalt and Asphaltic Bitumen (hot process).—No. 595—1935. Price 5*s*.

Mastic Asphalt Surfacing. Fluxed Natural Asphalt and Asphaltic Bitumen (hot process).—No. 597—1935.

Emulsions of Road Tar and of Road Tar-Asphaltic Bitumen Mixtures for Penetration (Grouting, Semi-grouting) and Surface Dressings.—No. 618—1935. Price 3*s*.

Tarmacadam and Tar Carpets, Granite Limestone or Slag Aggregate.—No. 802—1945. Price 2*s*. 6*d*.

Sampling and Testing of Mineral Aggregates, Sands and Fillers.—No. 812—1943. With an amendment, 1946. Price 5*s*.

Tarmacadam and Tar Carpets, Gravel Aggregate.—No. 1241—1945.

Methods of Test for Soil Classification and Compaction.—No. 1377—1948. Price 7*s*. 6*d*.

Mastic Asphalt (natural rock asphalt aggregate) for roads and footways.—No. 1446—1948.

Mastic Asphalt (limestone aggregate) for roads and footways.—No. 1447—1948.

Foamed Blast Furnace Slag for Concrete Aggregate.—No. 877—1939. With an amendment, April 1947.

Portland Cement. Ordinary and rapid hardening.—No. 12—1947. With an amendment, May 1948. Price 3*s*. 6*d*.

Portland Blastfurnace Cement.—No. 146—1947. With an amendment, May 1948. Price 3*s*. 6*d*.

Girder Bridges. Tables of British Standard Unit Loadings for railway girder bridges and highway girder bridges, No. 153, Appendix No. 1 (1925). With an amendment, May 1930. Price 2*s*. 6*d*.

Girder Bridges.—No. 153, Part 3, 1937. 3—Loads and Stresses. Price 3*s*.

High Tensile Steel for Bridges, etc., and General Building Construction.—No. 548—1934. Amendments, May 1936, February 1938, and June 1942. Price 2*s*. 6*d*.

Roadstone.

When a single word is employed as the name of a rock used for road stone or for paving setts the word may be definite in itself, denoting a rock of a particular composition which does not, as a rule, vary much from the average. In other cases, the general word, or word denoting the normal material, is compounded with another word, usually the name of a mineral which is present in an unusually large proportion, or which is an unusual constituent or one of several, any of which may be present. Thus, a diabase is usually composed chiefly of labradorite and augite, and sometimes olivine; and dolerite, though different in texture, is similar in composition. An olivine dolerite is a dolerite in which olivine is present in a considerable proportion, and a quartz-enstatite diabase is a diabase in which both quartz and enstatite (minerals, not rock names) are present in noteworthy proportions. (See 1941 and earlier issues for a classification of roadstones.)

Roadstone: the Relation of Size to Toughness.—(B. H. Knight): The results of physical tests carried out on relatively large pieces of material are apt to be very misleading if the latter is intended for use in sizes which are much smaller than those actually tested.

In a sett, the number of cracks reaching the outer surfaces will not be very great unless the stone be a particularly bad example, while the number of fissures which reach from one surface to another will be quite negligible. When, however, the same stone is crushed to small sizes, the

SCHEDULE OF REQUIREMENTS FOR ROAD TARS.

BRITISH STANDARD, No. 76—1943.

ratio of fissures reaching the surfaces to the total volume of stone becomes very much increased, and hence the tendency for the stone to fracture under traffic is very much greater. This is the reason why some granites which are perfectly satisfactory as setts fail badly as chippings.

EXPERIMENTAL MATERIALS.

RUBBER PAVINGS.

For descriptions and dates of laying, see the 1937 edition, p. 646. Further information was given in subsequent editions, up to that of 1941. It relates to pavings laid in London, Glasgow, Edinburgh, and the Mersey Road Tunnel; also to rubber latex carpets and to rubber-bitumen mixtures.

In view of the small extent to which rubber can economically be employed for paving roads, and the low coefficients of friction of the surfaces, repetition of the information so far given does not seem to be justified.

RUGOSITY OF RUBBER PAVINGS.

Skidding Tests: surfaces wet. Rubber block surfaces in London: (1) E.C. District, January: Old paving; at 15. 20, 25 and 30 m.p.h., respective coefficients, 0·29, 0·27, 0·26, 0·25; New paving, at 15, 20, and 25 m.p.h., respective sideway force coefficients, 0·25, 0·23, 0·21. (2) S.W. District, September; at 15, 20, and 23 m.p.h.; respective coefficients, 0·23, 0·18, 0·17. (Road Research Technical Paper No. 1.)

Rubber Latex.—(*a*) Latex, 10 per cent. vulcanised, rolled to a carpet ¼ in. thick on open tar-macadam; (*b*) the same latex, trowelled into open tar-macadam. Skidding tests, surfaces wet. February, gave, for 15, 20, 25 and 30 m.p.h., the respective coefficients, (*a*) 0·20, 0·17, 0·16, 0·16; (*b*) 0·63, 0·59, 0·56, 0·50. Later, in August, both surfaces having been dressed with bituminous emulsion and sand, the corresponding coefficients for both surfaces, wet, were 0·40, 0·34, 0·31, 0·29.

CAST IRON PAVING.

Experimental lengths of carriageways have been paved with cast iron blocks (proprietory) at Nottingham, Worcester, Accrington, Stratford-by-Bow, Islington, Birmingham, Burnley, Rochdale, Ilford, Leyton, Hampstead, Stockport, and Folkestone.

Each block is an equilateral triangle of about 11½-in. sides and weighs about 10 lb. It is dished and ribbed to give a depth of 2 in. At each corner a steel stud projects about ⅛ in. on the underside, these preventing the block from rocking. The wearing surface is grooved to about ⅛ in. depth. The blocks are bedded on a bituminous mastic, upon concrete, and the vee joints, ⅜ in. wide at the top, are filled with a special jointing material.

Cardiff.—The city engineer has reported unfavourably on an experimental length of cast iron paving.

Mersey Tunnel.—At the contract price of 16*s*. 9*d*. per sq. yd., 46,000 sq. yds. of cast iron paving was provided for the Mersey Tunnel.

Rugosity.—On some types, the coefficient of sideway force is very low. With a new type of cast iron paving, having a surface pattern of small studs ½ in. square, the coefficients of sideway force ranged from 0·6 at 5 m.p.h. to 0·54 at 25 to 27 m.p.h.

EXPERIMENTAL BINDING MATERIALS.

Salt.—As distinct from its employment as a hygroscopic surface binder, common salt has been used as a road crust, or wearing course, binder on a considerable mileage of roads in the United States and Canada. Recent information relates to the use of a binder consisting of clay, calcium chloride, and common salt, the proportions not being given. It is reported that salt-bound roads become very hard and tough.

Fabric Binders.—Used in bituminous carpeting, or heavy surface dressing. (*a*) Cotton fabric: recent reports from the United States are not optimistic as to the future of this method of reinforcing the surface of a road. The fabrics employed cost, in different districts and according to the weight of the fabrics, $450, $600 and $750, per mile of 18-ft. road. (*b*) Gunny cloth: In experiments recently initiated in India, gunny bags were slit open and trodden into a layer of bituminous road binder, and were covered with chippings at 5 cub. ft. per 100 sq. ft., rolled in. The cost of the gunny cloth was R. 1, An. 8½ per 100 sq. ft., and that of the whole of the surfacing work was Rs. 8, An. 2 per 100 sq. ft.

Sira.—*Kankar* (soft limestone) roads grouted with *sira* (or molasses), a by-product in the manufacture of sugar from sugar cane. The old surface was scarified to a depth of 4 in. and the material screened, ½ in. up being kept on the road and ½ in. down reserved for top dressing. The *sira* was spread at 15 tons per mile of 10-ft. road, which was then sprinkled with water and rammed. The fine material was spread and treated with a diluted mixture of sira and water (sira at 1 ton per mile). It was then rolled, left for 3 days without traffic, and kept wet for a further 4 days. Costs: per mile, 10 ft. wide: sira, 16 tons at Rs. 22 per ton, Rs. 352; tools and plant, Rs. 48; labour, Rs. 238; consolidation, Rs. 106; total, Rs. 744.

The Vehicle and the Road.

REGULATIONS UNDER THE ROAD TRAFFIC ACT, 1930.

Motor vehicles are defined in terms including the following: *Heavy Locomotive*, a vehicle not constructed itself to carry any load and the weight of which, excluding water, fuel, accumulators and tools, exceeds 11½ tons. *Light Locomotive*, similarly, exceeds 7¼ but does not exceed 11½ tons. *Motor Tractor*, similarly, does not exceed 7¼ tons. *Heavy Motor Car*, constructed to carry a load or passengers, unladen weight exceeding 2½ tons. *Motor Car*, similarly, but unladen weight under 3 tons if (1) constructed solely for the carriage of persons and their effects, (2) adapted to carry not more than 7 passengers exclusive of the driver, (3) fitted with tyres of a prescribed type, or unladen weight does not exceed 2½ tons. *Public Service Vehicles*, include three classes, stage, express and contract carriages.

The respective limitations of weight are subject to alteration, as are other of the regulations. The following, which have significance with respect to road design are herein referred to in that aspect only. Information as to the regulations in force at any given date can be obtained from H.M. Stationery Office.

Public Service Vehicles.—All-wheel load (*a*) and load of 2 wheels in a tranverse line (*t*). Four-wheelers: double-deckers, (*a*) 10 tons, (*t*) 6⅜ tons; single-deckers, (*a*) 9 tons, (*t*) 6 tons. More than 4 wheels; (*a*) 12 tons, (*t*) 4½ tons.

Abnormal Indivisible Loads.—(Authorisation of Special Types Orders.) Only one such load may be carried at one time, unless within the normal weight limits. Vehicles or trailers (S.T.), used only for the conveyance of such loads are limited by: all-wheels' load not exceeding 15 cwt. per inch width of tyre in contact with the road. Four days' notice of the transport of such loads must be given, containing an indemnity in respect of any damage which may be caused.

Flexibility of Springs.—In respect of (S.T.) above, the following is ordered: every such trailer constructed after January 15, 1931, which has more than 4 wheels in contact with the road surface must be so constructed that, under any condition of loading, when it is at rest upon a level surface, all wheels shall be in contact with the road surface and, if any wheel is lifted and supported at a distance of 3 ins. above such surface, the weight transmitted to the road surface by any wheel must not be increased by more than 10 per cent.

TYRE WIDTHS IN PROPORTION TO LOADS.

Even when superseded, or no longer applicable to existing conditions, regulations relating to tyre widths in proportion to wheel loads have a bearing upon the design of carriageways. The following paragraphs are, therefore, retained.

Information in regard to the tyre widths which are the least allowed for certain wheel loads, to the unit width per unit of loading and the variations in accordance with the character of the tyre, will be found in reports to the S.I.R.C. (D. A. Crawford, Report No. 80). 6th Question. For a summary relating to eight reports, see the *Surveyor*, September 21, 1934, p. 288. The following information is from a comprehensive table for Australia, relating to the regulations in :—

Queensland.—(1) Regulations of 1933, main roads: solid rubber, single tyres, graduated rom 18 cwt. per wheel on 4 ins. to 73 cwt. on 14 ins.; twin tyres, from 36 cwt. per wheel on (two) 4 ins. to 73 cwt. on (two) 8 ins.

Crawler Tracks: 10 cwt. per in. width of track of flat steel, wood or rubber pads in contact with the ground. To ascertain the maximum weight load in cwt. multiply the sum of the widths by 10.

Tasmania.—Per wheel, 3½ cwt. per half inch width of tyre.

India.—Loads and Tyres of Bullock Carts.—In an article by T. S. Pipe, executive engineer, Bombay Presidency (*Indian Roads*, March 1933), the actual loads carried per inch width of tyre by wheels of bullock or buffalo carts in India are compared with those given on p. 633 (1937 edition). In twenty-seven areas, such as circles (P.W.D.) or districts (administrative) the lowest loadings in lb. per in. width of tyre include only five between 410 and 500, and the others include twelve from 1,000 to 1,800.

Assam.—Tyre widths were prescribed under the Highways Act of 1928. The maximum loadings is 275 lbs. per in. width of tyre.

Burma.—No vehicle with untyred wheels nor any with wheels having less than 2½ ins. bearing width of tyre may be used. For 2-wheeled vehicles the minimum widths of tyre are, for half a ton, 2½ ins.; for 1 ton, 3½ ins. for 1½ ton, 4½ ins.; for heavy loads transport, from 2 tons to 8 tons, 5 ins. to 12 ins.

WHEEL DIAMETER AND LOADINGS.

Queensland.—(1) Four-wheeled vehicles; smooth metal; wheel diameters, inches, and permissible loads in cwt. per in. width of tyre per wheel. Under 15 ins., 3 cwt.; 15 to 24 ins., 4 cwt.; 24 to 36 ins., 5 cwt.; 36 to 48 ins., 6 cwt.; 48 to 62 ins., 7 cwt.; 62 to 76 ins., 8 cwt.; 76 ins. and over, 8½ cwt.; for grooved steel tyres, half, and for peneumatic tyres, one and a half times those loadings. (2) Two-wheeled vehicles, for the same range of diameters, half one cwt. less in every case; grooved steel tyres and pneumatic tyres in the same proportions as above.

South Australia.—Wheel dia. 30 ins. or less, 7 cwt. per in.; more than 30 ins. in dia., 8 cwt.

TRACTIVE EFFORT.

In order to establish, in the economic aspect, relative values for power called for on the level and power called for on gradients (both gradients and power being related to costs), it is necessary to know, approximately, what is the tractive effort required on the level. The investigations, particular in every case, correlate capital expenditure on road construction with running costs of vehicles.

Tractive Effort, Germany.—Report to the S.I.R.C. (1) Not including air resistance, kg. per tonne, with high-pressure pneumatic tyres: small stone setts (Gabbro), 15; gravel-bound, broken-stone roads, 18; broken-stone and asphalt, 15; large stone setts, 16; paving stones, 21. (2) At about 19 miles per hour, including air resistance and that (20 per cent.) due to curvature of the track of 196 yards radius; relative resistances: stone setts, 100; concrete, 103; gravel-bound broken-stone, 106; asphalt, 110; tar surfaces, 111. (3) Torque measurements showed that moments of starting and braking couples are from 2·3 to 6·2 times that when the vehicle is running at 19 miles per hour, it being deduced that wear of the road is in similar proportion.

Tractive Effort, France.—Report to the S.I.R.C. (citing data, M. Castaing, 1932). For Paris motor omnibuses, kg. per tonne: on asphalt, 14·50; on wood, 14·75; on small sett paving, 14·80; on sandstone 'setts,' 16·25. When the flexibility of the springs was about doubled, the resistance to traction increased by about 14 per cent.

Tractive Effort and Speed.—Report from Japan to the S.I.R.C. Low-pressure pneumatic tyres, large sett paving, kilms. per hour, kilogs. per tonne: 10–12·4; 20–14·2; 30–15·7; 40–17·2; 50–18·9.

ROAD ACCIDENTS.

Ministry of Transport Analysis of 1935–37 *Statistics. Result Classification.*—Numbers of accidents: in built-up areas, fatal (f.), 3,999, or 2·6 p.c.; serious injury (s.), 34,894, or 22·6 p.c.; slight injury (l.), 115,507, or 74·8 p.c.; in areas not built up: f., 2,338, or 5·2 p.c.; s., 15,825, or 35·5 p.c.; l., 26,499, or 59·3 p.c.

Responsibility Assigned To.—In the percentages of cases, fatal: pedestrians, 40; cyclists, 17; non-fatal: pedestrians, 30; cyclists, 23. Responsibility, all accidents (percentages): drivers, 33·6; pedal cyclists, 22·8; pedestrians, 30·5; other persons, 2·8; vehicles or equipment, 3·6; miscellaneous causes, 5·8; not traceable, 0·9. Those figures include 14,500 accidents (in a total of nearly 200,000) attributed to the fact that children under seven years of age were unaccompanied or inadequately supervised.

Conditions.—Percentages (fatal, f., non-fatal, n.):—

Road.—At junctions: f., 31·7; n., 41·7; straights, or open bends: f., 60·5; n., 52·6; in built-up areas: f., 63·1; n., 78·0.

Weather.—Clear: f., 81·6; n., 82·7; rain and hail: f., 14·2; n., 14·0; fog or mist: f., 3·3; n., 2·2.

Light.—Daylight: f., 57·4; n., 69·9; dusk: f., 4·7; n., 4·4; dark: f., 37·9; n., 25·8.

Carriageway Widths.—Not more than 20 ft.; f., 22·7, n., 21·1; 20 to 30 ft.: f., 47·8; n., 46·8; 30 to 40 ft.: f., 20·3; n., 21·6.

War-time Road Accidents.—In the year ended August 31, 1940, the number of persons killed was 8,347, comparing with 6,624 in the last 12 months of peace. Pedestrians killed numbered 4,932, an increase of 1,878 on the figure for the preceding 12 months, though the increase for all users was 1,719. There was, therefore, a decrease among other classes of users. The greatest increase in accidents since the war began has been in daylight hours.

FUNDAMENTALS OF ROAD PLANNING.

SEGREGATION OF TRAFFIC CLASSES.

In the planning, or planned development of the road system of Great Britain, it is now realised to be urgently necessary to decide the extent to which the separation of fast through traffic is to be provided for, and in what manner. It is almost generally accepted that two additional one-way carriageways would be required, and majority opinion seems to be that to provide these alongside existing trunk roads would cost more than construction on new locations, or, in another aspect, would make impossible economic capital expenditure in securing shortening of distances and reduction of gradients. Roads for complete separation of fast through traffic from slow and mixed traffic may best be called 'speedways,' since the main separation is no longer that of motor vehicle traffic from horsed vehicle traffic.

SPEEDWAYS: POLICY AND RECOMMENDED PROVISIONS.

The Institution of Highway Engineers.—The council of the Institution of Highway Engineers has approved a report of a committee whose recommendations included: (1) Fast through traffic should be separated from mixed traffic. (2) Speed routes should be provided exclusively for motor traffic. (3) Such speed routes should be designed, constructed and maintained by the Minister of Transport through his own staff.

Other Opinions.—Opinions favourable to the policy of providing special roads for through traffic have been expressed by: Mr. D. Edwards, in his presidential address to the Institution of Municipal and County Engineers; by Mr. T. G. Wilkins, in his presidential address to the Institution of Civil Engineers Northern Ireland Association; and by a considerable number of county surveyors. Such provision seems to be contemplated by highway engineers in the United States, as a development of the near future. It was accepted, in principle, by the Government of the Netherlands, in which country the construction of a speedway, without level crossings, between Arnhem and Nijmegen was approved before the war.

Main Features of Speedways as Contemplated.

Great Britain.—(J. E. Swindlehurst, Institution of Highway Engineers). A series of new trunk roads, the traffic on which is limited to defined classes of vehicles. Of the twin carriageways type, of width to suffice for expected traffic for many years to come. By-passing large centres of population. Connected, at defined points, with main trunk roads, by means of link or radial roads. Accommodating only high-speed motor traffic of the pleasure-car class, and motor transport vehicles. Additional traffic lanes would be provided where the route links two busy centres of population. No road junctions or crossings on the level.

Many other descriptions of the speedway as proposed for Great Britain have been furnished. Substantially, they tally with the provisions made in respect of Italian and German motorways, as regards main features and lay-out and connections with existing roads.

Location.—Opinion seems to be, on the whole, favourable to such location of the speedways and such excavation and embankening as would reduce expropriation costs, but would involve high construction costs in order that distances travelled might be reduced and gradients be made very easy, compensation being found in reduced running costs of vehicles.

Proposed Speedway in Lancashire.

In a report of the Highways and Bridges Committee of Lancashire County Council, the construction of an entirely new road was recommended, as preferable to the widening of an existing route and the construction of many by-passes. The length of the road from the Preston boundary to the Cheshire boundary would be about 23 miles, with crossings or junctions at 10 classified roads, 16 minor roads, 20 farm or occupation roads, and 35 public footpaths. The proposed lay-out is shown as providing: two outer verges, each 9 ft. 6 ins. wide; two 22-ft. carriageways, and a 22-ft. middle reservation.

Features of German Speedways.—The system aggregates about 5,000 miles. Usual provisions: dual carriageways, each 7·5 (24·6 ft.) wide; a middle strip (along which a hedge is sometimes planted) 5 m. (16·4 ft.) wide; flanking strips of bituminous macadam, 1 m. (3·28 ft.) wide; outer grass margins of 1 m. Minimum radii of curves; in level country, 2,000 m. (6,562 ft.); in irregular country, 1,000 m. (3,281 ft.); in mountain country, 400 m. (1,312 ft.).

Designing in Respect of Speed.

Speed versus Safety on Curves.—The title of an article in *Civil Engineering* (U.S.A.), February 1937, presenting the second part of Prof. R. A. Moyer's summary of the results of investigations for determining uniform speed-control standards, published in Bulletin No. 120 of the Iowa Experimental Station. Points from the article:—

(1) A significant feature of the slippage tests is the magnitude of the slippage as the speed of the car is increased. The trend indicates that the slippage at speeds of 80 m.p.h. or more is so large on curves sharper than 3 deg. that the most skilful driver will have difficulty in steering the car and holding it within a 10-ft. traffic lane.

(2) Even on a good road surface with excellent brakes, an expert driver operating at 80 m.p.h. cannot stop the car safely in less than 500 ft. after he first recognises the danger, or if he desires to overtake a car travelling 70 m.p.h. in the face of another car approaching at 80 m.p.h., a clear space of at least one-half mile is necessary.

(3) Engineers are accustomed to build structures with a factor of safety consistent with the risk of failure involved? Yet in highway safety work engineers are very prone to determine safe driving speeds without any regard for a factor of safety. Records of automobile accidents indicate that driving cars with little or no factor of safety is certain to lead to dire consequences. Traffic engineers and drivers should recognise the fact that the law of averages holds true and is as certain to be enforced as the law of gravity.

(4) There are many factors which indicate that it may prove far cheaper and possibly equally safe to take to the air when speeds above 60 m.p.h. are desired.

In reference to (3), and to the growing opinion amongst American engineers that there should be factors of safety in road designing, it was observed in an editorial note, *The Surveyor*, April 16, 1937: 'This logically involves the stultification of nearly all recent dispositions in respect of sighting distance and other features of lay-out.'

Road Surface Rugosity

For convenience of reference and memorising, the stopping distances in the following table are, when not multiples of 5 ft., brought to the next higher multiple of 5 ft. Except for that modification, they substantially represent the values in Major C. Cook's graph (Paper No. 5105, *Proc. Inst. C.E.*, December 1936), based on a reaction time of one second. Major Cook's values are given as related to braking efficiences expressed as percentages, which, divided by 100, correspond to road rugosity coefficients available with full mechanical efficiency of the brakes.

Approximate Stopping Distances in Feet.

Speed m.p.h.	Coefficients of Road Rugosity.					
	1·00	0·60	0·50	0·40	0·30	0·20
20	45	55	65	70	75	100
30	75	95	110	120	145	195
40	115	150	170	190	240	325
50	160	215	240	280	350	490
60	210	285	325	380	490	—

Sideway Force Coefficents.

Road Research Technical Paper No. 1.—The following values of coefficients of sideway force are from the text or graphs of that publication. The road surfaces were wet, in all cases. (Extrapolations by the section editor.)

(*a*) Surfaces laid in 1930 and tests made in 1933. Single-coat hot asphalt, as left by roller: At 20 m.p.h., 0·65; at 30 m.p.h., 0·40 (as judged by extrapolation: at 40 m.p h., 0·26; at 48 m.p.h., 0·23).

Mastic asphalt, B.S.S. 346: ½-in. coated chippings spread over and rolled in with ¾-cwt. hand roller. Fine sand then sprinkled on, and surface rolled with 3-ton petrol roller. At 20 m.p.h., 0·75; at 30 m.p.h., 0·53. (By extrapolation: at 45 m.p.h., 0·33.)

Single-coat, hot process tar macadam: granite aggregate; sprayed with tar and covered with ¼-in. to ⅜-in. chippings. Rolled with 8-ton roller. At 20 m.p.h., 0·76; at 30 m.p.h., 0·57.

Single-coat hot process tar macadam: slag aggregate; nine weeks after laying, ⅜-in. granite chippings spread over tar-sprayed surface and rolled with 7-ton roller. At 20 m.p.h., 0·80; at 30 m.p.h., 0·50. (By extrapolation: at 40 m.p.h., 0·28; at 48 m.p.h., 0·23.)

Two-coat cold asphalt: sealing coat of ⅛-in. to $\frac{1}{32}$-in. granite grit, treated with flux oil and asphalt cement. Rolled with 8-ton roller. At 20 m.p.h., 0·81; at 30 m.p.h., 0·52. (By extrapolation: at 40 m.p.h., 0·34.)

Two-coat cold asphalt, left as finished: at 20 m.p.h., 0·53; at 30 m.p.h., 0·37 at 35 m.p.h., 0·32. (By extrapolation: at 45 m.p.h., 0·28.)

Cold asphaltic concrete, painted with bitumen emulsion and spread with ⅜-in. chippings: (1) At 20 m.p.h., 0·72; at 30 m.p.h., 0·45. (By extrapolation: at 35 m.p.h., 0·30; at 40 m.p.h., 0·20; at 45 m.p.h., 0·15). (2) At 20 m.p.h., 0·77; at 30 m.p.h., 0·55. (By extrapolation: at 35 m.p.h., 0·42; at 40 m.p.h., 0·32; at 45 m.p.h., 0·24.)

(*b*) Other cases. Asphalt, at 30 m.p.h.: 0·48 in June and 0·58 in October; 0·42 in June and 0·51 in October; 0·24 in November and 0·38 in December.

(*c*) Granite and gravel surfaces gave sideway force coefficients of 0·59 to 0·78 at 30 m.p.h. about three years after surface treatment. (See also figs. 50 to 56 in Technical Paper No. 1, noting the small decreases in the values of coefficients with increase in speed, in the light of the information as to methods of preparation and treatment.)

Coefficients of Rugosity.—In Paris. Coefficients ranged from, wet asphalt, 0·2 to 0·33 to, dry wood, 1·05. 'Non-skid' surfaces, wet, 0·84; stone, dry, average 0·60 in the range 0·5 to 0·8. Cement concrete, wet, 0·25 to 0·80, average about 0·55; dry, consistently approximating to 0·75.

DESIGN IN PLAN AND PROFILE.

Visibility at Summits.

The Ministry of Transport Memorandum of August 1930 advises that curves of parabolic form shall be provided at all changes of gradient and be such as will provide a clear view of 50 yds. on each side of a summit to drivers of mutually approaching vehicles. In many States (U.S.A.) it is required that a 500-ft. line of sight must be provided 5 ft. above the crown of the road.

New Zealand.—The Main Highways Board of New Zealand recommend for the classes: I., 300 ft.; II., 200 ft.; III., 100 ft. view. The height of the driver's eye is usually taken as 4 ft. At summits a vertical curve of 1,250 ft. radius is provided. (This gives 100 ft. between two drivers approaching from opposite directions.)

Steepest Gradients.

New Zealand.—Standards aimed at: road classes: I., 1 in 15 to 1 in 20; II., 1 in 12; III., 1 in 10.

Radius at Bends.

The Ministry of Transport Memorandum of August 1930 advises that where conditions are favourable, a minimum radius of 1,000 ft. should be aimed at; failing which, the width of the carriageway at the bend should be increased. Normal practice in open country in the United States is to provide 5 degs. (1,146 ft. radius) or 6 degs. (955 ft.) curves. The German reporters to the Sixth International Road Congress prescribe a minimum radius of 300 metres in level and rolling country.

The Main Highways Board of New Zealand recommend, in easy country, 6, 4½ and 3 chains. (100 ft.) radius, for first, second and third class roads; in difficult country, 2, 1½ and 1 chain. Additional widths, on the inside of the bend, are given, up to 3 chains, 5 ft.; 4 chains, 4 ft.; 5 chains, 3 ft.; 10 chains, 2 ft.

Superelevation at Bends.

A convenient approximate formula for balance of centrifugal and gravity accelerations, or of centrifugal force and component of weight is:

$$\frac{h}{l} = \frac{v^2}{15 \times r}$$

where h is the height of tilt, l the horizontal width, in the same units; v the speed in miles per hour, r the radius in feet.

The reporters to the Sixth International Road Congress, October 1930, recommend the following superelevations: for radius 50 to 100 ft., 1 in 10; 200 to 500 ft., 1 in 12; 500 to 800 ft., 1 in 16; 800 to 1,000 ft., 1 in 24. The German reporters indicate 4 in 100 as normal, 5 in 100 on sharp curves and 6 in 100 where the curve is on a steep gradient. The French reporters give, for roads in Morocco, a limit of 1 in 10 on curves of short radius, and on mountain roads, where the radius r corresponds to superelevation 1 in 10 the superelevation of a curve of radius R is

$$d = \frac{r}{R \times 10}$$

The Main Highways Board of New Zealand employ a formula

$$O = \frac{6 \times S^2}{1000\ R}$$

in which O is tilt in inches per foot, S, speed in miles per hour and R, radius in 100 ft. chains. It gives superelevations three-quarters of those for balance, and is a modification of h in inches $= l$ in feet $\times \frac{S^2}{R} \times \frac{4}{5}$ in which R is in feet.

The Board recommends tilts in inches per foot: 2 chains, 1¼; 3 to 7 chains, 1; 8 to 15 chains, ¾; 16 to 40 chains, ½; high-class pavements not more than 1 in.

Ayrshire (D. Torrance).—A crossfall steeper than 1 in 12 should not be adopted if conditions safe both for fast traffic and slow, horse-drawn traffic are to be obtained. Example: radius 400 ft., superelevation for 30 m.p.h. gives a crossfall of 1 in 6·66, very dangerous for a horse-drawn cart loaded high with hay. The transition length is often 100 ft. If it be impracticable to use a transition of this length a shorter one may be used, and a small vertical curve inserted at each end of the transition. (The consideration in respect of the hay-cart applies to high-loaded motor vehicles, when obliged to slow down or to stop on a bend.)

Winchester By-Pass.—Dual 20-ft. carriageways; minimum radius of bends, 1,000 ft.; steepest gradiant, 1 in 25; minimum vertical sighting distance at 3 ft. 9 in. above road surface, 400 ft.

Roads designed for High Speeds.—Oregon. Designed speeds (S) 80 per cent. of critical speeds (attainable with safety only by highly skilled drivers). Relations of speeds to some limiting factors: Curves of 2 and 3 deg.; vertical sight distance (*v.s.d.*), 1,500 ft.; S, 80 *m.p.h.*; stopping distance (*p.u.*) in feet, dry pavement, 490, wet 740; sight distance (*s.d.*) on curves, 2 deg., 960; 3 deg. 785 ft. Curves of 4 deg.; *v.s.d.* 1,500 ft.; S, 75 *m.p.h.*: *p.u.*, dry, 290, wet, 430 ft.; *s.d.* on curves, 675 ft. Curves of 6 deg.: *v.s.d.*, 1,000 ft.; S, 60 *m.p.h.*; *p.u.*, dry, 190; wet, 290; *s.d.* on curves, 450 ft. Curves of 10 deg.: S, 45 *m.p.h.*; *p.u.*, dry, 120; wet, 175; *s.d.* on curves, 355. On tangents: S, 80 *m.p.h.*; *p.u.*. dry, 330; wet, 490. Length of transition curve, in feet:

$$l = (1 \cdot 0517 \, V^3)/r.$$

where V = speed in *m.p.h.*, r = rad. of curve, in feet. (R. H. Baldock, *Engineering News-Record*, May 23, 1935. Abstract, *The Surveyor*, June 14, 1935.)

Overtaking and Passing.—For speeds, S_1 of the passing vehicle, S_2 of the vehicle overtaken and passed, S_3 of a vehicle approaching from ahead, the sight distances, x, are:

$$x = (S_1 + S_3)\left(\frac{A}{S_1 - S_2} + t\right)$$

in which A is the distance in feet from the back of the car S_1, to the front of the car S_2, at the moment when the decision to overtake and pass is made, and t is the time required (about 3 sec.) for the passing vehicle to return to the left-hand (in G.B.) or right-hand (U.S.A.) side of the road. (Oregon. R. H. Baldock.)

Hedges in Relation to Snowfalls and Glare. (*The Surveyor*, March 19, 1937.)—The essentials of the hedge provision are, first, that it must be thick enough to check the wind effectively, so that a drift shall form on the windward side and, if it is a low hedge, on the lee side also; next, that it must either be high enough to hold back nearly all the snow, or be far enough from the carriageway or footway to allow space, on the verge, for a drift on the lee side; thirdly, that where it must be kept low to allow of sighting over it, its width should be increased beyond the normal for a hedge, in order that a body of snow may be formed between the windward and the lee drifts.

Where it is desired to afford protection from the dazzle of vehicle lamps, for pedestrians, by planting between the footway and carriageway, or for drivers of vehicles, by planting in the middle strip, the proper provision is a series of clumps of shrubs or bushes, not more than a few feet in width, in the direction along the road, but of considerable breadth transversely. Their spacing is a detail of surveying, in respect of the lines of sight and positions of oncoming vehicles; the wider the clumps are, transversely to the road, the greater can be the spacing. On bends, the spacing will be inversely proportional to the radius. Should hedges be provided, snowdrifts may form against them, and, unless they are on wide dividing strips, block the carriageway or footways.

Standard Road Widths.

A Ministry of Transport Circular of March 1936, No. 454 (Roads), prescribes as minimum standard widths 'appropriate in ordinary circumstances':—

Single carriageway, not exceeding 30 ft.; with footpaths, 60 ft.: with cycle tracks, also, 80 ft. Dual carriageways, each of two traffic lanes; with footpaths, 80 ft.; with cycle tracks, also, 100 ft. Dual carriageways each exceeding two traffic lanes; with footpaths, 100 ft.; with cycle tracks, also, 120 ft. Where further provision is required, for wider cycle tracks, additional width of verges for improved visibility or for equestrian traffic, greater space for services or improved amenities, 140 ft. 'Extended standard widths' include increments of 20 ft. in cutting or on embankment; otherwise, the width should not exceed 160 ft. The traffic lane unit is 10 ft., the cycle track minimum is 6 ft. and increments 3 ft. The standard widths adopted should provide for such future widenings of carriage-, cycle-, and foot-ways, as may be necessary. There should, therefore, be ample central reservations, margins and verges.

Dual Carriageways.—Will be desirable where 'an existing road carries or a proposed road is expected to carry' 400 vehicles in the peak hour.

Road Widths: Typical Provisions.

Widths including Embankments and Cuttings.—It is usual to specify that the widths of embankments and cuttings shall, for widths between improvement lines, be added to the normal widths for roads on the flat.

Worcestershire.—Highways Committee recommend as least widths: between buildings, Class I. roads, 120 ft.; Class II., 100 ft.; highway widths, Class I., 60 ft.; Class II., 50 ft. *West Riding*: Highways Committee recommends, for widenings, when necessary and economically practicable, Class A, 80 ft.; B, 60 ft.; C, 45 ft.

Carriageway Widths.—Nottinghamshire, approximate verge width, by calculation, of 361 miles of tarred and other surface-treated roads (in a total of 561 miles of main roads), the treated width, 18 ft. Similarly, Isle of Ely, average treated width of tarred roads, 15 ft. 8½ ins. Berkshire, Bradfield rural district, 196 miles, approximate metalled width, by calculation, 13 ft.

New Zealand.—Normal widths of carriageways, or surfaced widths: Classes I., 18 to 20 ft.; II., 14 to 18 ft.; III., 10 to 14 ft. Normal widths of formation, exclusive of water tables: I., 24 to 30 ft.; II., 18 to 24 ft.; III., 14 to 18 ft.

Nigeria.—For Classes I., II. and III. respectively. In normal ground: between inner edges of ditches, I., II. and III., 40 ft.; at top of embankment, 24, 20 and 16 ft.; in cuttings, between edges of side ditches, 22, 18 and 14 ft.

Acceleration and Deceleration Lanes.

Calculations (*a*) of the lengths and widths necessary to allow for acceleration to traffic-flow speed, with a further pulling up distance (in a blind alley), in case there should be no opportunity to weave into the traffic flow, and (*b*) of the length allowing for deceleration, to a stop or to a gateway or turn-in speed, are given in a paper by A. Mitchell, senior traffic engineer, State Highway and Public Works Commission, North Carolina. (*Proc. Am. Soc. C.E.*, March 1941 : Abstract, *The Surveyor*, June 20, 1941.)

Settlement of Embankments.

(*A. H. D. Markwick and G. C. Wilson, of the Road Research Laboratory.*)

The embankments, on the Mickleham and Caterham by-pass roads, Surrey, are of chalk and rest on solid chalk at shallow depth. A main result is that where settlement of less than about ½ in. occurred, there was no appreciable cracking in the concrete carriageway. More or less serious cracking occurred where there were settlements of 1 in. or more, and serious damage where differential settlements on the slabs exceeded 1½ ins. in 25 ft. The settlement/time curves are of the same type in all cases. Among the conclusions are, that on an embankment on a curve of small radius, greater settlement occurs on the outside of the curve ; that the movements were continuing, more than two years from the initiation of the measurements ; and that wide variations occur in the settlements observed even over quite small distances. The work as a whole shows that, if damage to rigid surfacings is to be avoided, only very slight settlements can be permitted after the construction of the final surfacing.

[The last conclusion is a fact well known, for many years past, to all experienced road engineers. It is one of the basic facts.—*Section Editor.*]

CARRIAGEWAY CONSTRUCTIONS.

Reinforced Concrete Slab Carriageways.

Depth of Slab.—Much thinner slabs than those usually employed would be theoretically sufficient in most cases, and usually more economical of materials, but practically it is found to be better to have thicker slabs for the following reasons : (*a*) With a deeper spacing between the upper and lower grilles, less steel is needed, the mesh can be larger, larger stones may be used in the aggregate, and the filling in of the concrete is done more easily. (*b*) Any fairly large piece of road metal, left accidentally on the foundation or in the aggregate, may lead to the formation of a tension crack on the under side of the slab. (*c*) In some cases the depth which must somehow be filled is not sufficient to make it worth while to provide a firmly rolled hard-core foundation, the cheaper solution being to employ a relatively low-stressed slab, with a somewhat reduced proportion of cement and relatively light reinforcement. (*d*) Lastly, 7 ins. of fairly tough concrete, with large-mesh reinforcement, is more easily cut through, for excavations, than 4 ins. of very tough concrete with a smaller mesh reinforcement.

Coefficient of Expansion.—(1) *Milan* (A. di Renzo), 53 millionths per deg. F., in the temperature range 76 deg. F. (2) *Harmondsworth*, 78 millionths, in the temperature range 46 deg. F.

Concrete Carriageways : Normal Thicknesses.

(Usually reinforced.)

Great Britain.—A large mileage has been constructed with the thickness of 8 ins., but, for comparable conditions, 6 ins. has often been adopted. It may be considered that thicknesses greater than 8 ins. are excessive. It should be possible, everywhere, so to design and construct that 6 ins. or less will suffice, unless it be more economical to provide 8 ins. depth of poor concrete. For estate roads with very little traffic, 6 ins. is usual in Greater London.

Germany.—Usually about 8 ins., or on old, consolidated crust, 4 to 6 ins. ; usually not reinforced, and seldom double reinforcement.

France.—On good foundations, and for light traffic, 4 to 5 ins. ; on normal foundations, 6 to 7 ins. ; on poor foundations, 8 ins. or more.

Sweden.—Usually 8-6-8 ins. ; also on main roads in Spain.

Switzerland.—About 6½ ins., usually reinforced.

Southern Ireland.—Normal practice, 6 ins.

Reinforced Concrete Slabs : Computations.

Length.

(1) *Ministry of Transport* (Technical Circular).—Where L is the length of the slab in ft. ; f the tensile resistance of the concrete ; F the coefficient of friction (see under ' Experimental Determinations,' p. 552) : w the weight of the slab in lb. per sq. ft. ; d the slab thickness in inches ;

$$L = 12df \div wf.$$

(2) *Empirical Formula* (*R. A. Ryves*).—Where F is the range of air temperature in deg. F., C the range in deg. C., and K a coefficient, 1·0 for full exposure; 1·1 to 1·2 for situations such as hillsides facing south, where the range of ground surface temperature is high in proportion to the range of air temperature; 0·9 to 0·6 for protected situations (0·6 where very well protected from sun and from radiation).

$$\text{Length in feet} = \frac{2500}{KF} = \frac{1389}{KC}$$

$$\text{Length in metres} = \frac{423}{KC}$$

Slab Lengths and Widths.—In Belgium and in Spain the usual length is 10 m.; In Germany, 10 to 15 m.; in Switzerland, 6 to 10 m., the range of temperature in some situations being very great; in France, up to 30 m., but now not usually exceeding 10 m.; in Sweden, usually 18 to 25 m.; in North Dakota, where the range of temperature is 153° F., very short lengths; in Benares, India, 50 ft. was adopted, after 66 ft. had proved satisfactory, the range of temperature being only 50° F. For a normal temperature range of 85° F. in England the corresponding slab length is 29·4 ft., for North Dakota, 16·3 ft.

Lengthwise joints are usually provided for widths exceeding: in France, 7 to 9 m.; in The Netherlands, 6 m.; in cold-winter regions of the United States, 10 ft. In Switzerland it is considered (*R. Dutron*) that it is the anchoring effect of thickened edges which makes lengthwise joints necessary, though these are still usually provided, the individual slabs being 3 to 5 m. (say, 10 to 16 ft.) wide.

Transverse Joints.—Owing to the anchoring effect when there is more than one slab in the width of the carriageway, the transverse joints should be, as in Switzerland, in line or not more than some 16 ins. out of line.

Kingston By-pass Road.—Construction joints at 30 ft. intervals; expansion joints at every 120 ft.

A Swiss Construction.—(H. S. L. Knight.) Bottom course, gravel, 5-mm. to 35-mm. gauge, 58·82 per cent.; sand, 0·5 mm. gauge, 41·18 per cent., by volume; cement, 250 kg. per cub. in. of concrete (421 lb. per cub. yd.). Top course, broken limestone, 20-mm. to 35-mm. gauge, 66 per cent.; sand, 0·5 mm. gauge, 34 per cent., by volume; cement, 350 kg. per cub. m. of concrete (590 lb. per cub. yd.).

German Motorways.—Concrete carriageways are provided on a large proportion of the mileage. The slabs are usually 20 cm. (7·9 ins.) thick, and 6·0 m. to 20 m. (19·7 ft. to 65·6 ft.) long, according to the degree of friction of slab on road bed. Transverse joints at right angles to centre line. Estimate, for the German climate, maximum movement of a slab of 10 m. (32·8 ft.), ± 3 mm. (0·12 in.). Slabs usually in two courses, the lower, about 5¼ in. deep, of gravel concrete; the upper 2¾ in. deep with an aggregate of hard stone chippings. The slabs are usually reinforced at the junction of the two layers, to prevent cracking (Ref. *Bautechnik*, vol. 14, pp. 579 and 586).

Vibration of Concrete.—Investigations carried out by a research committee (Inst. C.E. and Inst. Struct. E.) pointed to the following provisional conclusions, which, it was pointed out, may have to be revised for larger masses of concrete, different types of vibration, or mixtures other than that employed, 1 : 1·8 · 4·2. (*a*) The use of vibration allows of consolidation with a reduced water/cement ratio. (*b*) The acceleration should be above some critical value (with the mixture used, $4g$ for a water/cement ratio 0·40, decreasing to $1·5g$ for ratio 0·60). (*c*) The frequency of vibration is not usually of such importance as the acceleration. (*d*) The time of vibration is, for a particular acceleration, greater for high than for low frequencies, particularly with dry mixes. As regards (*a*) it may be observed that one of the objects of hand vibration is to reduce the water content—in effect, to reduce the water/cement ratio.

Vibration of Aggregate.—From a lecture (Society of Arts) by Dr. R. E. Stradling. On a road construction job, the *plus* or *minus* variation of water content from the mean was: without vibration, 17 per cent.; when the sand was vibrated, 5 per cent.; when both gravel and sand were vibrated, 2 per cent. The variations in the crushing strength of the concrete from the mean were *plus* or *minus*, 50, 18 and 18 per cent. in the respective cases.

Brick Paving Data.

Great Britain.—Brick paving has been tested in Birmingham, on a Staffordshire main road, in Denbighshire, on a Lancashire main road, in Ayrshire, in Doncaster. The British reporters to the Sixth International Road Congress conclude: that brick roads have *advantages* in respect of freedom from undulations, negligible expansion, contraction, and absorption factors, no tendency to lift or float as the result of heavy or prolonged rain, the, as nearly as reasonably possible, non-skid surface; *disadvantages*, in respect of not being so easy to repair and renew as some other block pavements. In respect of essentials the reporters noted important advantages of brick paving and not one disadvantage.

Brick Paving, experimental. Wolverhampton-Walsall main road, concrete foundation, blue brick on edge. North Midlands, (1) Birmingham, wire-cut blue brick on concrete strength crust, floated ½-in. sand-cement: joints grouted 1½ to 1 mortar; laid Sept. 1922; (2) Stone-Newcastle, Class I. main road, very heavy traffic 7-in. to 8-in. 6 to 1 concrete strength crust; 9 ins. by 4½ ins. by 3 ins., common blue wire-cut bricks on edge, laid 1922; (3) Wolverhampton-Stourbridge, Class I. main road, two test lengths laid 1923 and 1925; (4) Walsall-Wolverhampton, Class I. main road, 3,000 sq. yds. blue brick grouted with cement, on concrete strength crust; (5) West Bromwich, Class II. road; exceptionally heavy steel-tyred traffic. From a report by J. E. Swindlehurst, M.Inst.C.E., on inspection in the summer of 1926. Relating to (1) little signs of wear under heavy traffic: (2) speaking broadly, surface good after 3½ years; (3) generally in a good state; (5) indications of wear after 3 years.

Birmingham (H. Humphries).—Laid in 1932. On a 10-in. reinforced concrete strength crust, with reinforcement at 2 in. and 8 in. from the bottom. A ½-in. bed of well damped 1 : 2 cement-sand mortar. Himley bricks laid on edge and 'double grouted' with 1 : 1½ grout. The bricks were laid as close as possible, the joints being about 1/16 in. Traffic includes motor omnibus services and iron-tyred, horsed vehicles.

SPECIFICATIONS : DESCRIPTIONS : COSTS.

With Portland Cement as the Binder.

Concrete Roads, Great Britain.—Replies to a questionnaire of the Technical Advisory Committee. 132 replies, 102 relating to two-course work and 30 to single-course work. *Thickness*, 6 to 8 ins. in 90 per cent. of the cases. *Costs*: in 82 per cent. of the cases between 1*s.* and 1*s.* 9*d.* per sq. yd., per inch of thickness, or, taking 1*s.* 3*d.* and 8 ins., 10*s.* per sq. yd.; 1*s.* 6*d.* and 8 ins., 12*s.* per sq. yd.; 1*s.* 6*d.* and 6 ins., 9*s.* per sq. yd.

Lincolnshire.—A 10-in. slab with upper and lower reinforcement: the lower 8 ins. crushed quartzite aggregate, the upper 2 ins. granite, 12*s.* 4*d.* per sq. yd.

London Area.—Six-inch reinforced slabs, including a layer of ashes, 7*s.* 5*d.* per sq. yd.

Deptford.—Old metalling removed, surface regulated with 3 ins. of rubble; an 8-in. reinforced concrete slab, 1 : 6, Colne River ballast, with a 1-in granolithic surface; 9 ins. total thickness, 10*s.* per sq. yd.

Concrete Road Crust.—Southwark; lower course, contains 18 per cent. of stone ¾-in. to 2-in. gauge; upper course, 3 of crushed gravel to 1 of cement; the gravel, 8 of ¾ in. to ½ in., 17 of ½ in, to ¼ in., 75 of ¼ in. to dust, per cent. Such a crust, on roads with 22,000 tons of traffic per week, is treated with silicate of soda, with good results.

Concrete Road Crust.—Epsom R.D.C., Class B road, 2,752 tons per day; reinforcement to have ultimate resistance across the road of 12,500 lbs. per foot; slab, 7 ins. of shingle concrete finished with 2 ins. of granite concrete; shingle portion: aggregate, by weight, 54 per cent. passing 1½ to ⅜-in. square mesh, 24 per cent. passing 3/16 square mesh, 22 per cent. passing 3/16 mesh; sand, all passing 3/16, not more than 5 per cent. passing 100 mesh sieve; cement, rapid-hardening ('ferrocrete'), 370 lbs. to each wetted and mixed cubic yard of concrete; surface layer, 1½ in. dolerite containing sufficient ¾-in. to ⅛-in. chippings to reduce the voids to 30 per cent. by volume, of this 3 parts; sand 1 to 1½ parts; rapid-hardening cement, 550 lbs. per cubic yard. This cost 9*s.* 8½*d.* per square yard for carriage way 20 ft. wide. Cost, including excavation and surface treatment with bitumen, £9,086. per mile.

Cement-bound Macadam.

Southern Ireland (J. Caffery and E. J. Duffy, Trans. Inst.C.E.I., vol. lviii.).—Grouted crusts, fully satisfactory, can be made at costs 5*s.* per sq. yd. less than those of pre-mixed concrete. Normal consolidated thickness, 7 ins.; transverse joints, 30 ft. apart.

Quantities and Costs.—Great Britain. A crust 4 ins. thick, made by the sandwich method. Per 100 sq. yds.: stone, 2-in. B.S.S. gauge, 15 tons; sand, 4 tons; cement, 1¼ tons. Typical cost: per 1,000 sq. yds., stone, 150 tons at 12*s.*, £90; sand, 4 tons at 6*s.*, £12; cement, 18¾ tons at 50*s.*, £46 17*s.* 6*d.*; total for materials, £148 17*s.* 6*d.* Labour, including use of roller and mortar mixer, and water supply, at 7*d.* per sq. yd., £29 3*s.* 4*d.*; incidentals, such as timber, fencing, and lighting, at 2*d.* per sq. yd., £8 6*s.* 8*d.* Total cost, £186 7*s.* 6*d.*, or 3*s.* 9*d.* per sq. yd., with a trained gang of 16 men, laying 400 sq. yds. per day. The estimate does not include any preparation (Brit. Portland Cement Assoc.).

Cement Grouting, Australia (W. T. Sunderland).—(1) Transverse joints are sometimes provided, the spacing being 50 or 60 ft. Stone, 95 per cent. of it 2½-in. gauge; grout, 1 : 2½ with 1½ of water; depth before rolling about 8 ins. Steel reinforcement, laid on the top of the first layer, is sometimes employed. The cost has been about 7*s.* to 9*s.* 2*d.* per sq. yd. The ratio is 1 : 2½ : 12, comparing with 6-in. 1 : 2 : 4 concrete in Melbourne, costing 14*s* per sq. yd.

(2) *Items of Cost in £.*—Relating to (1), 2,141 sq. yds. on a sand foundation: formation and metalling, 323·3; rolling, three days, 10·5; laying and fixing reinforcement, 4·45; No. 14 B.R.C. fabric, 2,231 sq. yds., 130·15; sand, 2,495 cu. ft. bags, at 5*d.*, 62·35; cement, 998 cu. ft, bags, at 4*s.* 6*d.*, 224·55; labour in grouting, 3 days, 22·55; petrol and oil, 0·8; interest and

depreciation on the plant, at 4·0 per week, 2·0 : supervision, 5 per cent., 39·55 ; royalty on process, at 1½*d.* per sq. yd., 13·4 ; total, £833·55, or 7*s.* 9·4*d.* per sq. yd. The labour cost (wages 14*s.* to 16*s.*) was nearly 2*s.* per sq. yd.

The Sandwich System (*R. D. Jackson*).—(1) Practice in Jersey. Timber forms with iron-plated tops were used to give 5 ins. thickness in the middle and 3 ins. at the sides of the road. The stone is rhyolite, or a close-grained granite, of 2-in. gauge. Costs : about 4*s.* 8*d.* per sq. yd.

(2) *At Kirkcaldy* (*A. Walker*).—The road is scarified to 3 ins. if necessary ; rolled and formed to 1 in 32 ; a 2½-in. layer of whinstone, 1½-to 2½-in. gauge, is rolled, the roller passing twice over every part ; a mortar, 2 parts of clean sand to 1 part of rapid-hardening cement, spread to about 1¼ in. thick ; a 2½-in. layer of stone spread over it ; the whole rolled until the mortar comes to the top ; surplus slurry brushed forward. This forms a good holding surface for horses. For 200 sq. yds., 26 tons of cubical stone, 1¼ to 2½ ins., 5 cu. yd. sand, 52 cwt. rapid-hardening cement. Cost of the surfacing only, 3*s.* to 4*s.* 6*d.* per sq. yd.

Bituminous-Bound Constructions.

Top Courses and Carpets.—British report to Fifth International Road Congress : bituminous and asphaltic work ; ordinary costs, with five years' maintenance included : 2-coat work, 4 ins., 11*s.* 6*d.* to 13*s.* ; single-coat, stone and sand aggregates, 3 ins., 9*s.* to 10*s.* ; 2½ ins., 8*s.* to 9*s.* 3*d.* ; 2 ins., 6*s.* 6*d.* to 7*s.* 6*d.* ; clinker, 2-coat, 3 ins., 7*s.* 6*d.* to 8*s*. 8*d.* ; single coat, 2 ins., 6*s.* 3*d.* to 7*s.* 3*d.* ; mastic, 2 ins., 8*s.* 9*d.* to 10*s.* 6*d.* ; compressed rock asphalt carpet, 12*s.* to 15*s.*

Coarse-graded Bituminous Concrete (*T. W. Allen*).—United States practice. Aggregate : passing 1½ in. and retained on ½-in. screen, 30 to 60 ; passing ½ in. and retained on 4-mesh screen (*sic*), 15 to 25 ; passing 4-mesh and retained on 10-mesh screen, 5 to 15 ; passing 10-mesh screen, 20 to 25. The part passing the 10-mesh sieve (*sic*) when tested separately has the grading : 10–40, 15 to 40 per cent. ; 40–80, 22 to 50 per cent. ; 80–200, 15 to 20 per cent. ; passing 200, 10 to 15 per cent. Asphaltic cement, 8 to 12 per cent.

Asphalt.

Two-coat Asphalt.—Binder course, 2-ins. thick ; stone, ½-in. to 1½-in., 69 per cent. ; sand, 23 per cent. ; fluxed Cuban asphalt, penetration 60/65, 8 per cent. Wearing course, 1 in. ; stone, ⅜-in. to 1½-in., 30 per cent. ; filler, 10 per cent. ; sand, 48 per cent. ; fluxed Cuban asphalt, penetration 40/45, 12 per cent. (See next item.)

Single-coat Asphalt.—Three inches thick ; ¾ in. to 1 in., 45 per cent. ; sand, 36 per cent. ; filler, 9 per cent., fluxed Cuban asphalt, 60/65 penetration, 10 per cent.

In both cases the specification includes : the final operation is rolling in ½-in. or ¾-in. chippings, coated with 2 or 3 per cent. of 70/77 penetration bitumen.

Clinker Asphalt Paving (Sheffield : *Mr. W. J. Hadfield*).—Hard-burnt destructor clinker is used, crushed and screened ½-in. mesh for the bottom coat and ¼-in. mesh down for the top coat. The rejections are used for ordinary tar macadam. The material is heated to 300° C. There is about 10 per cent. bitumen in the bottom coat and 17 per cent. in the top coat. The bottom coat is spread to rather more than 1 in. in thickness and slightly rolled. The top coat has a thickness of rather less than 1 in when rolled, giving a total of 2 ins. Rolling is continued till no further impression can be made on the material. A 12-ton roller is preferred.

Granite Asphalt.—(1) London-Folkestone Road : consolidated thickness, 3 ins. Stone, graded granite, 1½ in. to ½ in., 54 per cent. ; graded silica sand, all passing ½-in. mesh sieve, 28 per cent. ; filler (80 per cent. passing 200 mesh sieve), 8 per cent. ; Mexican bitumen to British Standard Specification and requisite penetration 10 per cent. (2) Kingston By-pass Road : Length No. 10. Cold asphalt. Percentages : binder course, 1½ in. thick ; granite, ¾ in. to ½ in., 35·8, ⅜ in. to ½ in., 34·5 ; coarse sand, 19·2 ; bitumen emulsion, 10·5. Wearing carpet, ¾-in. thick ; granite, ¾-in. to ½ in., 48 ; coarse sand, 17·8 ; fine sand, 15·0 ; filler, 5·5, bitumen emulsion, 13·7.

Tarmacadam.

Tarmacadam—Quantities of Tar (*J. C. Mann*).—Gallons per ton : for stone of 2-in. to 2½-in. gauge, 7 to 8 gals. ; 1½-in. gauge, 7½ to 9 gals. ; ½-in. gauge, 10 galls. ; ¾-in. gauge, 11 gals.

Laying Tarmacadam (*J. Young*).—Bituminous tarred macadam : stone gauge 1½ to 2 ins., usually a course 2½ to 3 ins. thick ; the tarred stone, after being laid, is covered with about 1 in. of ¾-in. tarred chippings, the road being then rolled, after which the surface is brushed over. The road is then sprayed with a hot composition of tar and bitumen, 60–40, or a cold coat of bituminous mixture is brushed in, and the surface coated with a mixture of dry limestone, slag, and whinstone chippings, ½ in. to ¾ in., and lightly rolled.

Tar-grouted Macadam (*E. W. Cone*, verbatim).—A grouted macadam road is constructed by laying approved mineral aggregate upon a prepared foundation to a sufficient depth to provide a consolidated thickness of 3 ins. after dry rolling. Tar is then applied by hand or pressure, the Surface being finally covered by chippings. The requirements as to the permissible size of the aggregates are not very rigid, but the objective should be to secure a structure of uniform moderate void content after dry rolling. If the surface is too dense, difficulty will be experienced in getting the tar to penetrate into it, and if it is too open, the tar will collect at the bottom. As it is desirable to have as great mechanical stability as can be obtained, it is better practice to use coarse aggregate (2½ ins. and 1½ ins.), and if the voids are large, they can be partially filled with chippings during the dry rolling.

The tar should comply with the British Standard Specification for Tar, No. 3, and should have a viscosity of between 180 and 240 secs. It should be heated to a temperature between 250° and 300° F., and applied evenly and steadily to the rolled dry aggregate, 1 gal. being used to treat each sq. yd.

After the application of the tar the surface should be covered immediately with hard, dry chippings and should be rolled until there is no further movement. The construction of a grouted macadam road requires the utmost care in every detail, if the best results are to be obtained.

Recent Costs of Tarmacadam.—(1) Per sq. yd.: 3½ ins., 3*s.* to 3*s.* 6*d*; for moderately heavy traffic, the surface so finished that periodical spraying is not necessary, 4*s* 6*d.* to 5*s.*; in London, 3 ins., 6*s.* 8*d.*, 3½ ins. limestone tarmacadam, 5*s.* 7*d.* (2) Midlothian: Mixed at the quarry and taken direct to the roads: wearing courses, 2*s.* 6*d.* to 3*s.* 3*d.*, according to the distance from the quarry.

Grouted Work.

Hot Grouting (G. S. Barry).—With tar No. 2, or with a compound of tar and bitumen. The metal is spread over the old road surface at 9 sq. yds. to the ton, and rolled until there is very little movement of the stones. Chippings of ¾-in. size are brushed into the interstices and rolling continued until the coat is fairly rigid. The tar No. 2, or compound, heated to 250° F., is poured over the surface by means of cans with flat nozzles.

The application is best done in strips first in one direction and then in the opposite direction. This action gives the hot material a better chance to penetrate into the coat. It is important that the metal is dry, and that the work is not done during damp weather. The tar, or compound, is applied at from 1 to 1½ gals. per sq. yd. Thereafter the surface is spread with more chippings, which are brushed into the interstices and then rolled.

The surface may now be left for a few weeks, after which the sealing is done. This consists of brushing off all loose chippings and applying the heated tar, or compound, at or about half a gallon per sq. yd., and spreading ½-in. or ¾-in. chippings, well rolled. The cost per sq. yd. ranges from 2*s.* 9*d.* to 3*s.* 3*d.* (Scotland), and the method is suitable for roads carrying 2,000 to 3,000 tons per day.

Cold Emulsion Grouting.—The methods, as regards the laying of the stone and procedure generally, are very similar to those employed in hot grouting.

Penetration Work with Emulsion.—(Ayrshire). The metal, of 2½-in gauge, was lightly rolled and sprayed with slow-setting emulsion at 1½ sq. yd. per gal. Next day it was thoroughly rolled. After a week it was sprayed with ordinary emulsion at 2½ sq. yd. per gal., covered with ¾-in. whin chippings and again rolled. The cost, including the scarifying and shaping of the old worn road, was £85 11*s.* 5*d.* for 1,956 sq. yds., or 10½*d.* per sq. yd. Unit costs were: emulsion, slow-setting, 7½*d.*, ordinary, 5½*d.* per gal.: 2½-in. road metal, 5*s.* 2*d.* per ton, ¾-in., 10*s.* 1*d.* per ton. Items: roller, £2 0*s.* 10*d.*: haulage, £7 10*s.* 0*d.*; labour (155 hours at 1*s.* 3*d.*), £9 13*s.* 9*d.* Of each gauge of road metal, 24½ tons were used.

Quantities of Cold Emulsion (H. J. Prentice).—Grouting work. Gallons per sq. yd. Full grouting: for stone of 2-in. gauge, 1 to 1¼ gal.; 2½-in., 1¼ to 1¾ gal.; 3-in., 1½ to 2 gals. Semi-grouting: for stone of 2-in. gauge, ½ to 1 gal.; 2½-in., ¾ to 1¼ gal.; 3-in., 1 to 1½ gal.

Analyses of Costs.

Oxfordshire (C. E. Dolphin).—Cold emulsion work. Surfacing main roads with field flints and gravel, the flints from the Chiltern Hills, the gravel from the Thames Valley; flints, 3-in. downwards, hand-picked from fields, cost 5*s.* per cu. yd., laid to depth of 3 ins. on the scarified road crust, all shapes together; watered and rolled; bound by grouting with cold emulsion, ¾ gal. per sq. yd., or 1 gal. per 1⅓ sq. yd.; covered with ⅜-in. shingle, 160 sq. yds. per cu. yd.; traffic for a few days, then a sealing coat of emulsion, ¼ gal. per sq. yd.; blinded with fine sand and rolled. Costs, per sq. yd.: flints 8·5*d.*, shingle 0·75*d.*, sand 0·54*d.*, roller and horse hire, 2·41*d.*, labour 0·3*d.*, grout 8·25*d.*, sealing coat 2·75*d.*: total, 2*s.* 2·2*d.* A similar but cheaper process is also employed. For roads carrying up to 600 tons per day, a gravel, shingle, sand, grout, sealing coat road costs 1*s.* 11·3*d.* per sq. yd.

Road Crusts for Steep Gradients.

Bituminous-bound Slag.—Has been provided on gradients of considerable length, 1 in 14 and 1 in 12.

Bituminous-grouted Stone.—Cornish granite, no sealing coat, has been provided on a gradient of 1 in 6.

***Bituminous-bound Destructor Clinker.*—Muswell Hill: a long gradient of 1 in 10; varied traffic, including London omnibus services.**

Tarmacadam.—Aberdulais-Resolven Road, 1 in 11. Has been laid on gradients of 1 in 6.

Cement-bound Crusts.—For (*a*) considerable lengths of gradient exceeding 1 in 10; (*b*) any gradient on which parts of some length are 1 in 8 or steeper; (*c*) any gradient parts of which, however short, are 1 in 6 or steeper: most surveyors prefer cement-bound crusts, the trend of practice being in favour of the sandwich method. On a gradient mostly 1 in 6, a portion 1 in 4 has been consolidated by tamping.

Cement-grouted Wearing Course.—A wearing course 2½ ins. consolidated thickness, grouted with a slurry of 1 : 2 cement and sand, well swept in. The surface was then brushed to leave the stones standing proud, and was tarsprayed. Cost, 2*s.* 6¾*d.* per sq. yd.

Concrete (*O. Barker*).—Brow Hill, Haworth: 2-course concrete, 1 : 2 : 4; bottom course graded 1½ ins. down; top course 2 ins. B.S.S. gauge. When tamping was completed, the surface was brushed with stiff brooms, leaving the stones exposed and slightly proud.

NOTES FROM BRITISH AND OVERSEAS PRACTICE.

Dry-bound Macadam (*G. S. Barry.*)—In Scotland. The success of this method may depend upon the formation of stone powder in the period before rain falls, a powder fine enough to form, with water, a paste which hardens into a cement. (*The Surveyor.*)

Cement-Lime-Concrete.—Hyderabad (Report No. 9, S.I.R.C.). Laid on each side of a 19 ft. middle strip of the carriageway made of plain cement concrete. Proportions, cement, lime, sand, road metal: 1 : 1 : 5 : 8.

Clay-bound Gravel.—Michigan (W. O. Dow, 'Good Roads,' May 1934). A mixture of clay and gravel laid to a depth such as 4 ins. to give 3 ins. consolidated wearing course. A *fully wet process* is described, found effective in remedying the soft and unstable condition of the course when awaiting rain after it had been laid.

Bamboo-Reinforced Concrete.—China (C. H. Chang and H. Tsai, Report No. 4, S.I.R.C.). In slabs 18 cm. thick, bamboo reinforcement was placed in various ways. Transversely, the rods were 20 cm. apart and, when longitudinal rods also were placed, these were 8 cm. apart. The rods were 1 to 1½ cm. square, placed 5 cm. from the bottom of the slab. The following values were found by experiment.

Bamboo.—Ultimate strengths in lbs. per sq. in., compressive, 5,500; tensile, 14,000; bending, 13,000; in shear, 450. Modulus of elasticity, 1,660,000. The outer layer of the stem of a bamboo has a tensile strength of at least 25,000 lbs. per sq. in. ('Ligno-concrete' was described by G. O. Case in *The Engineer* many years ago.)

Strip Roads.—Southern Rhodesia: Concrete strips 2 ft. wide and 2 ft. 9 in. apart between inside edges; thickness, 6 in.; mixture, 1 : 2½ : 5, somewhat wet, the trench being previously soaked with water. In lengths of 30 ft. with ½-in. felt joints. Hardened by two coats of silicate of soda. Cost, 800*l.* to 1,000*l.* per mile. Traffic capacity 250 to 300 vehicles per day. Described in a paper by S. Chandler, chief engineer, Roads and Bridges, South Rhodesia Government (Extracts, *The Surveyor*, June 14, 1935).

Heating Blacksoil Road-beds (*L. H. R. Irvine*).—Described in a paper, Inst. of Engineers, Australia (see 'Roads and Road Construction,' October 1, 1931). The 'blacksoil' seems to be similar to the 'black cotton soils' of India, which contain a very large proportion of colloid clay and a relatively large content of humus. A trial of the method is being made in Queensland, on the Brisbane-Toowoomba Road. The process is, essentially, one of heating the road-bed until the soil cracks, forming interlocking paving elements of brick, the joints between which are then filled with bitumen.

Silicated Road Crust.—French practice (Jacques-Thomas): aggregate hard or semi-hard Jurassic limestone or similar porous limestone; gauge, passing a ring of 1½ in. to 2 in. diam.; coarse sand (the finer kinds, having a tendency to form pasty mortars, are to be avoided). About 40 litres of silicate and ½ cub. m. of sand to each cub. m. of broken stone; say, 6¾ gals., ½ cub. yd., 1 cub. yd. Maximum, of silicate per cub. m., 55 litres, say 9½ gals. per cub. yd. Proportion of silica to soda in the solution, 3·0 to 3·5, the lower figure for porous materials. A 4-in. layer of broken sandstone mixed with silicated limestone contains, per cub. m., 45 litres of silicate of soda and 300 litres of sand (by volume, 4½ : 30 : 100). Hydraulic lime is added to the sand in wet weather. This layer is rolled until the viscid mud exuding from it is ready for the top course of broken sandstone, 1½ to 2 ins. thick. After a month, the surface is treated with emulsion. Such road crusts are provided on roads in very damp situations.

Gloucester By-pass Road.—A bottoming of ashes, 3 ins. deep; a bare, unreinforced concrete slab, laid for full width, on the alternate bay system, bays 18 ft. 6 ins. long laid first, followed 2 or 3 days later by the 9-ft. bays. The slab is in two layers, the bottom layer 5 ins. thick, 6 parts Frampton gravel, one part rapid-hardening cement; the top layer 3 ins. thick, 1 : 1½ : 3, rapid-hardening cement, Bideford sand, ¾-in. to ⅛-in. Tytherington limestone. Butt transverse joints at 60° to the kerb, except that the 2 ft. nearest the kerb is at 90° to it, to avoid a corner of less than 30°. Camber, 1 in 40. A ⅜-in. bituminous joint between the slab and the kerb.

Mixed Roadstones.—(1) Stroud Rural District: granite and limestone in equal proportions for all work when chippings are required for road surfaces. (2) Stalybridge · pink granite (such as Shap granite) 3 parts; Scotch granite (milky-white or grey) 1 part; 'blue granite' (Derbyshire or Welsh basalt) 2 parts; Derbyshire grits, 1 part.

Rolled Concrete Road Crusts.—(Victoria Country Roads Board, Australia; Mr. L. F. Loder, chief engineer.) Mixtures of 1 : 2½ : 10 or 1 : 2½ : 12 can be employed, the voids to be filled by the mortar being in a proportion less than in ordinary concrete. It seems that vibration is employed as an alternative to rolling.

SURFACE TREATMENT.

Tar for First Treatment.—Successfully followed for some years past in France, the practice of using tar alone for the first dressing of a water-bound or dry-bound broken-stone crust is now normal practice in Scottish and many English counties.

Hot Tarring and Gritting.—Relating to 375 miles of roads in Hampshire. Six sq. yds. per gal. on water-bound surfaces, about 16 sq yds. per gal. on tarmacadam. Partly on tarmacadam and partly on other surfaces, some previously tarred, the general average cost, including gravel and granite chips, was 3·16*d*. per sq. yd.

Spraying Material (J. C. Mann).—The viscosity of the spraying material used must vary with the size of the chips. Where a 15/25 viscosity tar would make a satisfactory job with ¼-in. or ⅜-in. chips, it would fail if ¾-in. to 1-in. chips were used. The recommended scale is:

Viscosity and Chip Size.—Chips ¼-in. to ⅜-in., 15/25 seconds tar; ½-in. to ⅝-in., 25/35 secs.; ¾-in. to 1-in., 40/60 secs. The high viscosity tars give results amply repaying some trouble experienced with the barrels. It is recommended:

Overheating.—A temperature of 180° F. should not be exceeded with tar, and it is best to keep it between 150° and 160° F.

Cold Emulsion and Gritting.—Hampshire: 17½ miles of roads, average cost 3·73*d*., or, not including sealing coats on semi-grouted surfaces, 3·77*d*. per sq. yd.

Surface Treatment. Costs per sq. yd.:—

Northamptonshire.—1944–45: 'Refreshment of road surfaces with tar and chippings.' Classified roads, 5·10*d*.; unclassified, 4·11*d*.

Holland.—1944–45: 'Tar-sprayed,' 7·22*d*. 1945–46, surface treatment: classified roads, 4·39*d*.; unclassified, 4·12*d*.

Somerset.—1947–48: surface dressing, 5·94*d*.

ANALYSES OF TARRING COSTS.

Dorking.—Tar-spraying: manual labour, 17·3 per cent.; team labour, 16·7 per cent.; tar, at 7½*d*. per gal., 33 per cent.; grit (at about 1 ton per 30 gals. of tar, costs 14*s*. 1*d*. per ton), 25 per cent.; tradesmen's bills, 8 per cent.

Consett, Durham, 1929 (*T. Hutton*).—Hot work: tar at 5½*d*. per gal., 5 sq. yds. per gal.; limestone chippings at 14*s*. 1*d*. per ton, 127 sq. yds. per ton; cost: chippings, 1·34; tar and bitumen, 1·12; labour, 0·72; transport, 0·21; plant, etc., 0·05; total, 3·44*d*. per sq. yd.; Cold work: emulsion at 9*d*. per gal., 4½ sq. yds. per gal.; chippings, 115 sq. yds. per ton; cost: chippings, 1·44; emulsion, 2·31; labour, 0·52; transport, 0·21; plant, 0·05; total, 4·53*d*. per sq. yd.

FOOTPATH CONSTRUCTION.

Ayr Burgh (J. Young).—All footpaths are now laid as *in situ* concrete pavements in liftable panels conforming to the sizes of standard concrete flags; to the following:

Specification.—On 4 ins. thick of broken stone bottoming, blinded and rolled, covered with 1 in. of sand, is laid cement concrete composed of ¾-in. chippings and cement (3 to 1) 2 ins. thick; well beat down, on top of this is laid, while the under-bed is moist, 1 in. thick of ⅛-in. to dust granite chippings and cement, and the upper surface straightened and smoothed off, margin lines formed and the panel surface indented with a brass roller. Before the concrete forming the slabs is put in, strips of iron 3½ ins. by ⅜ in. are placed round the panels transversely and longitudinally so as to divide the panel into slabs as near as possible 3 ft. long by 2 ft. wide, the joints breaking bond in the courses. These dividing strips of iron are slightly tapered in section and have handles fixed to the upper edges, and can be readily lifted, leaving clean joints the full depth of the slab. After the cement slabs are thoroughly set the joints are filled in flush with lime and mortar, well packed and brushed in.

Midlothian.—New footpaths provided on main roads are coated with tarred gravel, at a cost of 1*s*. 6*d*. to 2*s*., usually at the end of the year, after the road work is completed. Subsequent treatment, for maintenance, spraying with cold emulsion and strewing with clean sand or ¼-in. gravel.

Tarmacadam Footpaths.—Market Harborough: reconstruction; new materials, tar, ashes for bedding, and slag dust for top-dressing. A portable 'cracker' used for breaking up the old material. Ten gals. of tar mixed with 7 barrows of the broken material, by hand; rolled with

an 8-cwt. roller. Cost per sq. yd.: labour 6*d*.; haulage, 1½*d*.; tar, at 7½*d*. per gal., 5½*d*.; slag dust, ½*d*.; petrol and oil, ½*d*.; surface tarring, 3½*d*. Total, 1*s*. 4½*d*.

***Ayrshire*.—More especially a method adopted on roads near towns and villages. Excavation as deep as is necessary, usually 4 to 6 ins. Refilling with ashes which, after being rolled until firm, are left for from 4 to 6 weeks before the path is trued up. It is then sprayed with bitumen at 3 sq. yds. per gal., covered with ⅜-in. chippings, and rolled. Cost, 1*s*. to 1*s*. 2*d*. per sq. yd.**

ROAD MACHINERY AND PLANT.

Machines for Concrete Roads.

Based on the paper, 'Equipment for Concrete Carriageway and Cycle Path Pavement Construction,' by C. M. Willcock and N. E. Kerridge (Public Health and Municipal Engineering Congress, November 1948.

Spreading Machines.—All these machines, also finishers, are arranged to run on the tops of the forms containing the concrete or on rails which are mostly attached to the forms, the latter practice being preferred. To deal with concrete slabs of different widths, these machines are made telescopic or are made adjustable by other means. On both spreaders and finishers provision is made for cross flow of the concrete. Both are most often driven by diesel engines, sometimes by petrol engines.

The Blade Type.—For this type of spreading machine the concrete is dumped on to the subbase between the forms and is distributed across the full width by means of a blade which moves to and fro. The incident face of the blade is inclined at about 45° in plan, so that it moves the excess concrete forward as well as across. Immediately behind the blade there is a striking-off plate which spans the full width. The bottom edges of both blade and striking-off plate are adjustable to about the same height, and that is the level to which the concrete is spread. The machine travels forward into the heap of concrete as the blade moves from side to side.

Finishing Machines.—This machine comes into operation after the concrete has been evenly spread—preferably by a machine, a sufficiently slight excess of concrete being left by the spreader in front of the screed of the finishing machine to allow it to perform its first function of striking off the concrete immediately in advance of the compacting beam. Machines for use on dry-mix have two beams; the screeding beam which oscillates across the width between the forms to produce a level surface for the compacting beam, which, by means of an intense vibration compacts the concrete and leaves a suitable finish. The beam has a either a rotary vibration or a purely vertical vibration. The acceleration varies between 4½ g. and 10 g., at frequencies of between 3,000 and 4,000 cycles per minute.

The amplitude is up to $\frac{1}{64}$ in. The different mixes of concrete used, and variable weather when the concrete is laid make it desirable that machines should have a variable travelling speed.

Pressure Grouting.—A recent application of the method is described in an article by C. K. Tallach, County Surveyor, Lindsey (*The Surveyor*, November 12, 1948). The concrete slabs are 10 ins. thick, 22 ft. wide and 16 ft. 6 ins. long. Some 40 slabs had settled, 19 of the worst being raised. The grout consisted of 1 part of rapid hardening Portland cement and 3 parts of building sand. Two-inch injection holes were drilled through the slab and about 6 ins. into the sub-base and injection made through steel tubes inserted in the drilled holes, sealed with paper packing and held by wooden wedges. Other drilled holes through which the grout began to escape were sealed with wooden plugs. They gave indication of the travel of the grout under the slab. Injection was made at one hole at a time. Holes were not drilled nearer to edges or joints than 2 ft. The pressure was usually 50 lbs. per sq. in., but that had, in some cases, to be exceeded. When the grout very soon began to escape at edges or through other drilled holes, injection was stopped until the grout had hardened. The next injection, though usually more difficult, and requiring greater pressure initially, moved the slab. At three sites, the maximum settlements and the areas of slab settlement were: 1·8 ins., 315 sq. yds.; 4 ins., 135 sq. yds.; 6½ ins., 405 sq. yds.: and the grout used, tons: 27·95, 22·55 and 72·65. Costs per sq. yd. were: 23·3*d*., 38·2*d*. and 28·5*d*. Tons of grout used per cu. yd. of lift: 4·04, 3·05, 2·16.

Note.—In essentials, the operation is the same as that of Poulter (see p. 569), and when the 'sub-grade' is not a laid course of material, but is a roadbed of firm earth, mud with a small proportion of cement may be a fully satisfactory grout.

Excavating and Earth-Moving Machines.

Victoria, Australia (*L. F. Loder.*)

***Trailbuilders.*—The machine consists essentially of a blade, say, 10 ft. wide by 3 ft. 3 ins. deep, with cutting edges along the bottom and both sides. Using 60 drawbar b.p. machines the cost of getting and placing earth on an average lead of about 120 ft. was 7*d*. per cu. yd. On some sections of the Kiewa Valley Road where the work was almost 'pure side cut,' the cost of making an 18-ft. formation was about 3*d*. per cu. yd.**

Self-loading Scrapers.—Costs vary greatly, but as a guide the following figures are given: 7 to 9 cu. yd. four-wheeled scoop, 1,000 ft. lead, 9*d*., 250 ft. lead, 5*d*. per cu. yd.; 5 to 6 cu. yd. two-wheeled scoop, 1,000 ft. lead, 1*s*.; 250 ft. lead, 7*d*., per cu. yd.; for solid measure and exclusive of overhead charges, but including all plant charges, both capital and operating.

EARTH-MOVING MACHINES.

The Drag-Shovel.—This single-bucket excavator combines certain advantages of the shovel and the dragline.

Loaders.—Have been replaced to a large extent by small power-shovels, some of which are built around the power unit of agricultural tractors.

Bulldozers and Bullgraders.—These machines have practically replaced the older type of grader. They are becoming indispensable on many excavating jobs and can move earth lengthwise for distances of 100 ft. to 200 ft. more cheaply than other equipment.

Scrapers.—The most popular type in Great Britain is the machine which dumps its load between its four wheels, and is efficient for hauls of 300 to 1,500 ft. or, subject to careful calculations, for hauls up to 3,000 ft.

Crawler Excavator.—Weight, 75 tons; tools, shovel, dragline, grab, back-acting trencher, skimmer-scoop, crane. Petrol-paraffin engine, 4-cyl., 32 b.h.p. (or steam, or electric), 1 to 1¼ gals. of paraffin per hour. Three digs per minute when working shovel.

Roadside Excavator.—For road-widening work: cut, 18 ins. wide up to 2 ft. high; speed, 30 lin. yds. per minute (presumably average soil). May be adjusted to work below road level, or above (up to 18 ins.) and below at the same time. Can be fitted to any tractor or roller.

Elevating Grader.—Equipped with a 65-h.p. engine and with power controls, and drawn by a 95 h.p. tractor; output, when loading into large wagons, 400 cu. yd. per hour.

Carrying Scraper.—One 13-cu. yd. scraper drawn by a 95 h.p. tractor can move earth at the following rates: length of loaded haul, 400 ft., cu. yd. per hour compacted load, 115; as 400–115, also, 600–92; 800–76; 1,000–65; 1,200–57; 1,400–50; 1,600–45; 1,800–41; 2,000–38.

OTHER PLANT.

De-aerated Concrete Mixers.—Have been employed on road works in Surrey. In place of the standard drum, a cast-iron drum is provided, having a machined face to ensure airtight contact between the drum and the mixer door, which consists of a light steel pressing mounted on ball-bearings. A 26-in. vacuum can be obtained in half a minute.

Road Surface Heaters.—The heating of bituminous road surfaces facilitates the removal of worn materials, renders surfaces from which material has not to be removed more amenable to treatment for the re-dressing of inequalities, and may be employed, in some processes, for laying carpets of bituminous materials. One type of machine heats air in a furnace, the hot air being delivered under a hood, beneath the edges of which, close to the road surface, it escapes. Progress is by stages, the machine being stationary during the heating. In another machine the heat is radiated from a hot plate, and the machine crawls forward at the pace necessary to allow of the road surface being adequately softened.

A recently introduced heater, in which the low-pressure, air-forced draught system is employed, is rated at 80 to 100 sq. ft. per hr. It is designed for either direct flame heating or indirect heating. The hood is 4 ft. 6 in. long by 4 ft. wide. The burner is of the pressure-jet type.

Road heaters are (1948) available with single, twin, or multiple burners, the fuel usually being light diesel oil or gas oil. Some very small units burn paraffin. In one type, the heater is suspended from the overhanging frame of a self-propelled vehicle resembling a small motor lorry.

Poulter's Mud Pump.—Successfully employed in the United States in raising sunken road-slabs to their proper levels. The process is interpreted (*The Surveyor*) as one by means of which force is exerted to move a part of a structure, compressing, in the reaction, plastic materials enclosing the operating space, and filling hollows with cheap material. A small proportion of cement mixed with the mud greatly expedites the setting of this material.

Toronto.—A portion of reinforced concrete pavement, 1,000 ft. long by 46 ft. wide and 8 ins. in thickness, having settled transversely, was brought up 1¾ in. without cracking, by this method, but using cement grout and air pressure. Poulter's initiative is, perhaps, as significant as regards the material as in respect of the method.

Power Cost Data (E. Dalton).—Quarrying: oil-engine compressor, drills, etc., 100 h.p.; fuel oil nearly 0·4*d*. per brake horse-power-hour: average load factor, 50 per cent.; fuel oil and lubricating oil, 0·75*d*. per ton of rock quarried, the calorific value of the fuel oil being 19,400 B.Th.U., and lubricating oil 3*s*. 6*d*. per gallon.

PLANT AND MACHINES FOR BITUMINOUS-BOUND ROADS.

Mixers for Bituminous Materials.—Modern units are either trailers, four-wheeled if large, two-wheeled if small or are self propelled. The usual fuel is paraffin, light diesel oil, or gas oil. Mechanical stirrers, usually power operated through a safety drive worm reduction gear, provide for thorough mixing.

Storage Tanks.—The best storage tanks for binder are electrically heated, the heating being thermostatically controlled.

Spreader-Finishers.—The use of spreader-finishers effects important saving of time and cost. In the year 1944–45 the Barker-Greene machine was introduced in Leicestershire. Employed on two road works, its outputs were 169 and 183 tons of bituminous material laid per day, saving 2¼*d.* per sq. yd. in the cost of laying.

In the years 1945–46, nearly all the tarmacadam surfacing laid in Northamptonshire was spread and consolidated by machines.

Spreader-finishers handle successfully all types of mixes. The advantages of tamping finishers over machines that spread and level only are described (E. L. Harber) as that they will lay material with uniform density at varying thicknesses, eliminating depressions due to uneven compaction and reducing the amount of rolling required; also that they effect a well bonded joint even against cold material of the temperature of the material laid produces a workable mixture. The tamper has a ⅛-in. vertical stroke. The screed directly behind the tamper slides on to the mix as it is struck off and compacted by the tamper, smoothing and ironing the surface for final compaction by rollers; an operation reduced and simplified by the uniform density obtained with the tamper and the level surface obtained by the operation of the screed and levelling arms.

Developed, in the United States, over a period of seven years, the Barber-Greene machine was put on the market in 1937. To-day its merits are generally recognised by road engineers.

Road Planers.—It is usual practice to heat and plane a considerable stretch of road at one time. The material removed may be used for making up foot paths and other purposes. By planing, the corrugations are *eliminated*, so that a new carpet laid on a planed road retains a true running surface for a long time; which is not likely to be the case when the corrugations are for a time *obliterated* by a confirming carpet of accommodating thicknesses.

Planers usually have power-operated blades with an oscillating action, and are adjustable as to height and camber by power-operated rams. More than one cut over a heated surface may be needed to obtain the desired result.

At present most heating and planing work is done by independent heaters and planers, but manufacturers and others are giving consideration to machines which combine both operations, the machine being a single unit mounted on a chassis, self propelling or trailed. (J. E. Hobbs—see 'Literature,' No. 11, p. 572.)

ROADSIDE TREES.

TREES IN THE HIGHWAY ENGINEERING ASPECT.

(*R. A. Ryves.*)

***Shade in Summer.*—The value of shade, apart from comfort, is in a reduction of evaporation from macadam and flint roads, reducing the tendency to disintegration in dry spells. On tarred roads it prevents licking-up of the tar and the formation of ruts, and prolongs the life of the film. In the case of concrete roads the reduction of maximum crust temperatures reduces the tendency to the forming of cracks. On asphaltic and bituminous roads it either reduces the rutting and wearing effects of traffic, or, when its effect is taken into consideration in designing the crust or carpet, it is possible economically to construct a more efficient carpet, less hard and less slippery than one intended to withstand the effects of a whole day of hot sunshine.**

***Screening Effects.*—While some trees, such as the elm, have a greater frost-screening effect than others, such as the ash, all have an important effect in decreasing the range of temperature to which the road crust is subjected, in one day or in one year. Generally, they reduce very much indeed the number of occasions on which a road is slippery because frozen. By lessening the severity of freezing and by afterwards screening the frozen surface from the full effects of sunshine, trees save macadam and flint roads from most of the licking-up after frosts. They also, by mitigating the effects of severe frosts, save such roads from disintegration due to the formation of ice within the crust. Slipperiness due to hoar forst, or to the freezing of condensed mist or drizzle on a cold road, is much worse on the new surfaces than it is on water-bound macadam, so that, in this respect, the value of the tree is increased by the new conditions in winter and early spring.**

***Costs per Mile, 60 ft. apart.*—Basis for independent calculation: per penny per tree, 7*s.* 4*d.* per mile; per shilling per tree, 4*l.* 8*s.* (vi) Single line of trees, stakes at 9*d.* each: at 2*s.* 6*d.* per tree,**

14*l*. 6*s*.; at 3*s*. per tree, 16*l*. 10*s*.; at 3*s*. 6*d*. per tree, 18*l*. 14*s*.; at 4*s*. per tree, 20*l*. 18*s*.; at 4*s*. 6*d*. per tree, 23*l*. 2*s*.; at 5*s*. per tree, 25*l*. 6*s*.; at 5*s*. 6*d*. per tree, 27*l*. 10*s*.; at 6*s*. per tree, 29*l*. 14*s*.; at 6*s*. 6*d*. per tree, 31*l*. 18*s*.; at 7*s*. per tree, 34*l*. 2*s*.; at 7*s*. 6*d*. per tree, 36*l*. 6*s*.

(vii) *Hedges*, such as (v) (above), taken as 2 ft. apart; as stakes are not required, other spacings are in proportion: for *single hedge*, at 2*s*. 6*d*. per tree, 330*l*.; at 3*s*., 396*l*.; at 3*s*. 6*d*., 462*l*.; at 4*s*., 528*l*.; at 4*s*. 6*d*., 594*l*.; at 5*s*., 660*l*.; at 5*s*. 6*d*., 726*l*.; at 6*s*., 792*l*.; at 6*s*. 6*d*., 858*l*.; at 7*s*., 924*l*.; at 7*s*. 6*d*., 990*l*.

(viii) *Hedges*, such as (iii) (above), taken as 1 ft. apart, other spacings in proportion; double the values in (vii).

Quickset Hedge (thorn).—Taken as 7 to the yard: at 5*l*. per 1,000, 61*l*. 12*s*.; at 7*l*. 10*s*. per 1,000 92*l*. 8*s*.; or, with *a* per yard and *b* shillings per 1,000, the cost of *one* hedge is £ $\frac{a \times b \times 88}{1{,}000}$.

BRIDGE DESIGN.

Allowable Stresses on Concrete.

Increased stresses on concrete in bridge members are allowed by the Ministry of Transport, provided that: (1) The cement complies with current B.S.I. specifications for Portland cement; (2) Crushing tests on 6-in. cubes made with concrete taken from the mixer during progress of the work show consistently the results as in the table; (3) The cement is weighed and not measured by volume.

Allowable Stresses on Concrete in Bridge Members and Corresponding Requirements.

Concrete Mixture Cement : Fine Aggregate : Coarse Aggregate.	Working Stress.	Modular Ratio.	Crushing Strength of Concrete in 6-in. Cubes. At 28 days with ordinary Portland cement. At 7 days with rapid hardening Portland cement.	Crushing Strength of Concrete in 6-in. Cubes. An additional test (if required) as an indication at 7 days with ordinary P.C. at 3 days with R.H.P.C. should give results :
lb. cu. ft. cu. ft.	lb./sq. in.	n.	lb./sq. in.	lb./sq. in.
A : 2 : 4	5A + 300	—	15A + 900	10A + 600
90 : 2 : 4	750	15	2250	1500
120 : 2 : 4	900	15	2700	1800
150 : 2 : 4	1050	12	3150	2100
180 : 2 : 4	1200	10	3600	2400

Heavy Vehicles on Bridges.

Section 25 of the Road Traffic Act, 1930, provides that: The bridge authority of any bridge may, by means of conspicuous notices, prohibit the use of the bridge: (*a*) by a vehicle exceeding a defined maximum laden weight, not less than five tons; (*b*) in respect of the laden weight of a vehicle when travelling at more than a defined speed. Provision is made for appeal to the Minister, who may order a prohibition or restriction to be removed, or may refer the matter to an arbitrator. The method of calculating the weight is laid down in Section 26, and procedure in respect of the weighing of vehicles in Section 27.

ROAD TUNNELS.

Dartford-Purfleet Tunnel: River Thames.

As designed in 1936. Length, not including open approaches, nearly 1 mile. Estimated cost, £3,200,000. Section, a semi-circle of 30 ft. diameter on a segmental invert. Shell, cast-iron segments, concrete-filled and concrete-lined. Provides a 20-ft. carriageway and two 2-ft. patrol footways. Ventilation: fresh air enters from a longitudinal duct under the soffit, the spent air being drawn to a suction duct, through orifices along the kerb line. Construction, by means of a 12-ft. diameter pilot tunnel and the two 18-ft. diameter ventilating shafts, about 100 ft. deep and terminating in shield chambers, 35 ft. in diameter, from which the full-section tunnel will be driven.

THE MERSEY TUNNEL.

(Described and illustrated in *The Engineer*, July 13, 20, and 27, 1934.)

Total length, including open approaches and branches, 15,191 ft.; main tunnel, portal to portal, 10,584 ft., branches, 3,216 ft.; length between waterside ventilating shafts, 4,500 ft., outside and inside diameters of the under-water tunnel, 46 ft. 3 in. and 44 ft.; width of main carriageway, 36 ft.; two footways, for patrol only; two-way (four lanes) traffic; headroom, 13 ft. 6 ins.; maximum depth to invert below H.W.O.S.T., 103 ft.; maximum gradient, 1 in 30; estimated traffic capacity, 4,150 vehicles per hour; carriageway paved with cast-iron blocks; lining, segmental rings of cast iron, metal thickness, 1¼ ins., the segments filled with concrete. Cost of the works, £7,077,800. Opened July 18, 1934.

THE ANTWERP, RIVER SCHELDT, TUNNELS.

(Described in *The Surveyor*, September 2, 1932.)

Total length, including open approaches, 6,923 ft.; portal to portal, 5,803 ft. (cast-iron-lined, 4,053 ft., reinforced-concrete-lined, both ends, 1,750 ft.); length between waterside ventilating shafts, 2,836 ft.; outside and inside diameters of under-water tunnel, 30 ft. 9 ins., and 28 ft. 6 ins., of the reinforced-concrete-lined portions, upper half ring and invert, 34 ft. 6 ins., and 28 ft. 6 ins. nearly, sides continued downward as walls, externally; width of carriageway, 22 ft. 2 ins.; one footway, for patrol only; two-way (2 lanes, one each way) traffic; headway 14 ft. 9 ins.; maximum gradient, 1 in 28·6; maximum depth to invert below H.W.O.S.T., 99 ft.; below the bed of the river, about 54 ft.; estimated traffic capacity, 2,000 vehicles per hour. The segments of the cast-iron-lined portion are filled with concrete. Cost of the works, inclusive of land and property, buildings and engineering costs, £1,425,000.

A separate tunnel, at some distance, has been constructed for foot-passengers; length between centres of lift shafts (the design following Barlow's precedent), 1,877 ft.; tunnel diameters, 15 ft. 7 ins. and 14 ft. 1½ in.; footway width, 12 ft. 5½ ins. at floor level; space for pipes and cables under the footway; estimated capacity, 16,000 persons per hour. Cost, including electrical and mechanical equipment, about one-fifth that of the vehicular tunnel.

Papers, Articles and Lectures (to 1939):—

'Soil Mechanics as Related to Road Construction.' A lecture (M.I.Mech.E.) delivered March 9 1938, by Dr. L. Casagrande. Abstract, *The Surveyor*, March 18, 1938.

'Road Engineering and its Development in Australia.' A paper (epic and technical) by H. H. Newell (Eng. Conf., Sidney, March 1938). *Trans. Inst. E. Australia.* Abstract, *The Surveyor*, May 6, 1938.

'American Highways and Highway Practice.' By E. E. R. Tratman. Article, *The Engineer*, October 8, 15, 22 and 29, and November 12, 19 and 26, 1937.

'The German Motor Roads.' Article, *The Engineer*, August 20 and 27, 1937.

'Architectural Principles of Bridge Design.' By W. J. Watson. An address delivered in January 1938. Abstract, *Civil Engineering (United States)*, March 1938. Extracts, *The Surveyor*, May 27, 1938. Mr. Watson cites Vitruvius' treatise, written nearly 2,000 years ago, in which the Roman architect enunciated six principles or elements of architectural design: Order, Symmetry, Arrangement, Eurythmy, Propriety, Economy—and finds, in modern conceptions in regard to bridge design, recognition of the same six principles.

Report of the Select Committee of the House of Lords on the Prevention of Road Accidents. Issued April 1939. Comment: An editorial note in *The Surveyor*, April 7, ends: 'Because the committee have ruled out considerations of natural law in regard to matter and motion as involved in the running of vehicles, their report has the aspect of an elaborate piece of special pleading on behalf of those who find pleasure in swift travel on the roads. Nevertheless, it is of very great value as providing, in all other aspects, the basis for an immediate and for a long-term policy in regard to road safety.'

EARTHWORKS.

'Methods of Excavation Work at Home and Abroad.' By W. Barnes. The Dugald Clerk Lecture, 1940. *Journal Inst. C.E.*, January 1941.

'The Dragline Excavator.' By W. Barnes, *Journal Inst. C.E.*, March 1940.

'Earth-Moving Plant.' By L. F. Loder. Article, *The Commonwealth Engineer* (see also *The Surveyor*, October 11, 1940).

'Observations of Settlements on Embankments.' By A. H. D. Markwick and G. C. Wilson, of the Road Research Laboratory. A note (Crown copyright reserved), *The Surveyor*, July 5, 1940.

'Cliff Stabilisation Works in London Clay.' By J. Duvivier. Paper, No. 5233, *Journal Inst. C.E.*, October 1940, and discussion thereon; in the course of which the bearing of the paper upon problems of the stabilising of the slopes of railway and road cuttings was very usefully considered. Abstract, *The Surveyor*, November 29, 1940.

'Run-off Disposal on Divided Highways.' Article, *Engineering News-Record*, January 2, 1941. Extracts, *The Surveyor*, February 28, 1941.

BRIDGE DESIGN.

'Rigid Frames without Diagonals: the Vierendeel Truss.' By L. Baes. Paper, *Proc. Am. Soc. C.E.*, January 1941. Abstract, *The Surveyor*, March 21, 1941.

'Simplified Theory of the Self-anchored Suspension Bridge.' By C. H. Gronquist. Paper, *Proc. Am. Soc. C.E.*, February 1941. Abstract, *The Surveyor*, April 18, 1941.

'Bridge Design and Construction in the United States.' By W. G. Bowman. Article, *Engineering News-Record*, February 13, 1941.

'Trends of Bridge Design in the United States.' Editorial note, *The Surveyor*, April 4, 1941. The writer discusses the failure of the Tacoma Narrows suspension bridge, in the light of Mr. Bowman's observations thereon (*v.s.*), and with regard to Mr. L. S. Moisseiff's recent explanations of the reasons for the adoption of new or changed features of suspension bridges, including very much reduced truss depths. See 'Growth in Suspension Bridge Knowledge.' By L. Moisseiff, *Engineering News-Record*, August 17, 1939. Abstract, *The Surveyor*, September 29, 1939.

'The Suspension Bridge Tower Cantilever Problem.' By B. Birdsall. Paper, *Proc. Am. Soc. C.E.*, April 1941.

'The Graphical Solution of Portal Frames.' By J. W. H. King. Paper, *Journal Inst. C.E.*, December 1940.

'Aesthetics of Engineering Structures.' By O. Faber. Paper and Discussion, *Journal Inst.*, *C.E.*, April 1941.

ADDENDA 1945.

'Relative Merits of Wire and Bar Reinforcement in Pre-stressed Concrete Beams.' By R. H. Evans. Paper, *Journal Inst. C.E.*, February 1942. Presents experimental results in regard to deflection, hysteresis loops, permanent set and cracking loads, for increasing values of initial pre-stressing force. The test beam was 10 in. deep, 4 in. wide, and 11 ft. long, the load applied on a span of 10ft. The permanent set in all the pre-stressed concrete beams was exceedingly small, no more than that in plain concrete beams. The cracking load of the pre-stressed beams with bar reinforcement was considerably lower than that of pre-stressed beams with wire reinforcement, about half for an initial pre-stressing force of 25 tons. That, the author maintains, is important, because the working load should not exceed that necessary to produce tensile stresses in the concrete. The experiments showed that piano wire having a tensile strength of 150 to 175 tons per sq. in. is a very efficient type of reinforcement in pre-stressed concrete.

Birchenough Bridge.—A two-hinged arch with a span of 1,080 ft. in 27 panels of 40 ft.; lower chord parabolic with a rise of 216 ft. Depth, at crown 37 ft. 6 in.; at end posts, 46 ft. Arch trusses 45 ft. apart. The deck of cross girders, stringers and transverse joists supports a light reinforced concrete road slab, 68 ft. wide and 5 in. thick, and two 3-ft. timber footways. The roadway is about 25 ft. above springing level and, except at end panels, the cross girders are suspended from the arch by hangers of wire cable. An expansion joint is provided at panel point from the west end and an articulation joint at panel point 4 from the east end.

The Ristna Bridge.—Described by Mr. C. G. Sexton, in the May 1946 number of the *Journal of the Institution of Civil Engineers*, this outstanding work is notable with respect to its design, the method of construction and the manner in which were overcome difficulties of the site and of conveyance of materials to the site. The rainfall at the site, which is in a gorge in jungle country, averages 200 ins. a year, and there are very severe floods. The middle arch has a span of 276 ft. and a rise of 132 ft. On one side there are two approach spans of 52 ft., on the other, three spans of 56 ft. 6 in., curved to a radius of 120 ft. The method of erection was to build out as cantilevers, finally 78 ft. each, two part-arches, and to close the gap by lowering the steel frame, or skeleton, of a Melan arch, concreted after being attached to the part-arches. In the erection of the cantilever part-arches, each increment of concreting left protruding stout steel rods, stiff enough and strong enough to sustain the next increment of concreting. Study of Mr. Sexton's paper makes it clear that the erection-design was adopted for good reasons in preference to the method of building as cantilevers two half-arches of steel skeleton and concreting afterwards.

Brathay Church Footbridge.—Erected in 1946, this bridge, which crosses a swift mountain stream, links Lancashire and Westmorland. It is an arch of 50 ft. span, 10 ft. rise, 7 ft. wide over parapets and 4 ft. wide inside parapets. The arch, weighing 50 tons, was erected by means of tubular steel scaffolding. The stone of the arch was obtained from the spoil banks of two slate quarries, one stone being of a lighter and the other of a darker green. The masonry of the arch has been described as 'rubble,' but a photograph shows large stones of the appearance of voussoirs. Between the ring faces the remainder of the arch is reinforced concrete. The whole of the exposed concrete face in the arch soffit was painted with a half-and-half mixture of cowdung and butter-milk, to encourage the growth of moss, facilitated by the use of sawn segments for the centering timbers.

LITERATURE.

(to 1945).

'Post War Development.' A report of the Institution of Highway Engineers. Reviews, *The Surveyor*; of the report April 9, 1943; of discussion on the report, January 14, 1944.

'Road Construction Plant.' Road Paper No. 13, *Inst. C.E.*

'The Strength of Cast-Iron Girder Bridges.' By C. S. Chettoe, N. Davey and G. R. Mitchell. *Journal Inst. C.E.*, October 1944. Abstract, *The Surveyor*, February 16, 1945.

'Road Safety.'—Interim Report of the Committee on Road Safety. Parts I, General; II. Road Users; III. Roads; IV, Vehicles. Eighty pages. H.M. Stationery Office, price 1*s*. net. Published December 1944.

'The New Waterloo Bridge.' By E. J. Buckton and J. Cuerel. Paper, *Journal Inst. C.E.*, June 1943. Discussion in the Supplement to the October, 1943, number.

'The Burma-Yunnan Road.' By J. F. H. Nicolson. Paper, *Journal Inst. C.E.*, January 1942. Abstract, *The Surveyor*, February 20, 1942.

'Some Experiments on the Consolidation of Clay.' By L. F. Cooling and A. W. Skempton, *Journal Inst. C.E.*, June 1941. Abstract, *The Surveyor*, September 5, 1941.

'A Laboratory Study of London Clay.' The same authors. *Journal Inst. C.E.*, January 1942.

'Soil Mechanics Nomenclature.' Am. Soc. C.E. Manual of Engineering Practice, No. 22. Twenty-four of the terms, the less familiar and those the definitions of which are not fully in accord with English terminology, are given in *The Surveyor*, December 26, 1941.

'Highways in Latin America.' By Major B. P. Root, Dept. of Commerce, Washington, D.C. *The Surveyor*, June 26, 1942. For the 7 Latin-American countries in North America, 3 in the West Indies, and 10 in South America, the author gives area in sq. mi.; road mileage and area per mile of road, also, for each country, 50 to 250 words of description of the roads.

NAVIGABLE WATERWAYS.

CLASSIFICATION.

(1) Natural Channels, i.e., those rivers, or portions of rivers, including estuaries, the normal flow of which is not interfered with by artificial works;

(2) Canalised Rivers, frequently called 'Navigations,' the flow of which is more or less under artificial control, and

(3) Canals, proper, entirely artificial in conception and construction.

The distinction between the three classes is fundamental and important. In the case of the natural channel, improvement works are limited to a rectification of the bed, and no attempt is made to control or augment the natural flow of water, which, being derived from the drainage of the basin, is normally sufficient for purposes of navigation, within the limits of the channel capacity. The canalised portions of rivers consist of sections in which the natural flow is conserved and controlled, as in the manner of a canal, but generally without extraneous sources of water supply. Canals, being works of an entirely artificial character, have to be fed with supplies obtained by the interception of streams, or from other external sources, frequently necessitating pumping and reservoir storage.

IMPEDIMENTS TO NAVIGATION OF RIVERS.

In the seaward section the most pronounced disability, where it exists, is the bar. For its removal a very efficient means, producing immediate amelioration, is dredging; but the effect in the majority of cases is merely temporary, and operations must be continuous if the improvement is to be maintained. Where bars are not in evidence, or not very pronounced, a river mouth is often encumbered by shoals, due either to detritus brought down by the river itself or to coastal erosion and drift. In this case also, dredging may be resorted to with immediate advantage. For permanent benefit it is requisite to supplement this temporary expedient by training works of a scope and magnitude dependent on circumstances. Such works comprise longitudinal training walls, or embankments, and groynes, dykes, or jetties, to be alluded to later.

In the upper sections of rivers, the principal difficulties encountered are irregularities in flow, due to floods in rainy seasons and depletion of water in periods of drought, excessive current velocity, instability of channels and the formation of shoals. In low-lying lands, it is often necessary as a protection against inundation to raise the river banks with impervious material, well supported from behind. Insufficiency of water may be met by the introduction of weirs, or the formation of storage reservoirs. The remedy for excessive and irregular currents lies in training works of a suitable character.

Velocity of Flow in Rivers.

The velocity of river flow varies very considerably, as will be seen from the following table. As regards navigation, currents exceeding three to four miles an hour or four and a half to six feet per second make a serious deduction from the speed of propulsion of vessels proceeding upstream, and render control difficult in the case of small craft travelling downstream. See also par. on Horse Traction, page 597.

River Seine at Meulan	2·45 ft. per second.	River Rhine at Basle	6·36 ft. per second.
" " at Paris	4·00 " " "	" Aar at Berne	7·50 " " "
" Thames at London Bridge	3·00 " " "	" Durance, below Sisteron	8·65 " " "
" Tiber at Rome	3·40 " " "	" Maranon, S. America	13·00 " " "

Velocity Observations are taken by means of (*a*) Floats, (*b*) Current Meters, and (*c*) Pressure Tubes.

Floats.—For surface velocities an orange is excellent, floating almost wholly immersed. In the winter season, fragments of ice give similarly good results. The topmost layers of water, however, are frequently affected by the wind. To obviate this the float should extend some distance below the surface. A corked bottle, weighted at the bottom, has proved satisfactory for the purpose. Tube floats are also employed, consisting of tin cylinders about 1 in. diameter, weighted so as to maintain perpendicularity, and leave two or three inches projecting above the surface. Double floats are sometimes used, consisting of a small surface float connected by means of a cord to a float of larger bulk below. In Mississippi experiments, the lower floats were kegs 9 ins. high and 6 ins. diameter, or 12 ins. high and 8 ins. diameter, according as depth was less or greater than 5 ft. They were without top or bottom, and ballasted with lead. The connecting cords were $\frac{1}{16}$ in. to $\frac{1}{8}$ in. diameter. The upper float was of light pine, $5\frac{1}{2}$ ins. square by $\frac{1}{2}$ in. thick, or of hollow tin, $5\frac{1}{2}$ ins. by $1\frac{1}{2}$ in.

Current Meters.—These record velocity by means of the revolution of a screw, being calibrated by drawing through still water at various speeds. The Price current meter, used by United States Geological Survey, consists of six cups attached to a vertical shaft, which revolves on a conical hardened steel point when immersed in moving water. Meter measurements can be made from a bridge, from a cable and car specially installed for the purpose, from boats or by wading. Current meters are affected by friction, and are not very suitable for low velocities; in fact, in feeble currents they cease to act.

Pressure Tubes.—Pitot tubes, which are L shaped with the lower horizontal limb pointing upstream, record the velocity by the height to which the water in the tube is forced above surface level by the pressure of the current. Darcy's adaptation consists of two tubes in communication, enabling the differential reading to be taken more accurately and eliminating the effect of ripples and oscillations. The apparatus gives good results in small channels with currents of fair velocity, but it is not suitable for large rivers or for very low rates of flow.

Position of Maximum Velocity may be taken generally at or about surface level, but is not infrequently below. The view is generally held that the velocity varies as the abscissæ of a parabola, whose axis is parallel to the surface. The equation for the parabola in the case of the Mississippi was found to be

$$v = -0{\cdot}79222\, d^2 + 3{\cdot}2611$$

where,
v = velocity in feet per second and d is distance from axis in fractional parts of whole depth considered as a unit.

Mean Velocity.—The position of mean velocity has been found by repeated experiments in U.S. Geological Survey to be located at about 0·6 of the total depth. The mean of velocities obtained at 0·2 and 0·8 of the depth gave the mean velocity of the stream very accurately.

In ordinary cases the least, mean and maximum velocities may be taken in the ratio 3 : 4 : 5. In very slow currents they are nearly as 2 : 3 : 4.

Prony's Formula:

$$\frac{\text{Mean velocity}}{\text{Maximum velocity}} = \frac{\text{Maximum velocity} + 7{\cdot}71 \text{ ft. per sec.}}{\text{Maximum velocity} + 10{\cdot}28 \text{ ft. per sec.}}$$

Computed Velocity.—A great number of formulæ have been published connecting the velocity with the hydraulic mean radius (R) $= \dfrac{\text{area of stream}}{\text{wetted perimeter}}$, and the sine of slope (S) $= \dfrac{\text{fall in level}}{\text{length of channel}}$. Most of these expressions can be reduced to the form

$$v = c\sqrt{\text{RS}},$$

where c is a coefficient varying with the class and nature of the channel, as well as with the personality of the observer. Some of the coefficients are very complicated, and the values are variable to a considerable degree. Mr. A. A. Barnes ('Hydraulic Flow Reviewed,' 1916) proposed to modify the powers of R and S so as to admit of a coefficient of constant value. His expression is

$$v = 58{\cdot}4 \ \text{R}^{\cdot 694}\text{S}^{\cdot 496}$$

or, approximately,

$$v = 60 \ \text{R}^{\cdot 7} \ \text{S}^{\cdot 5}$$

In nineteen observations with ranges in width of stream from ·26 ft. to 2,598 ft., in depth from ·19 ft. to 69 ft., in hydraulic mean radius from ·0786 ft to 53·6 ft., and in slope from 1¼ to 241·2 ft. per mile, velocities of from 1 to 7½ ft. per second were computed and found to agree, within 1 per cent., with actual observation.

In the course of investigations made during three years in connection with the regulation of the Whangpoo and Yangtse Rivers, Dr. Herbert Chatley found that in fairly straight and uniformly sectioned reaches when the flow is steady the above exponential form $v = c\text{R}^{\cdot 7}\ \text{S}^{\cdot 5}$ gave consistent results. But when the flow was unsteady he found it more satisfactory to take the expression

$$v = c\text{R}^{\cdot 7}\left(\text{S} - \frac{a}{g}\right)^{\cdot 5}$$

where a is the acceleration. In other words, the effective slope was equal to the algebraic difference between the actual slope and an 'acceleration' slope determined by the ratio of the actual mean acceleration of the water to the gravitational acceleration.

Critical Velocities.—The following is a statement founded on the researches of Dubuat and Beardmore of velocities at which various materials in a river bed commence to be eroded:

Soft clay	3 ins. per second.	Rounded pebbles, 1 in. diam. .	2 ft. per second.
Fine sand	6 „ „ „	Rough gravel „ „ .	2½ „ „ „
Coarse sand and pea gravel	9 „ „ „	Pebbles 1½ in. „ .	3½ „ „ „
Gravel as large as French beans	12 „ „ „	Heavy shingle	4 „ „ „

TREATMENT FOR EROSION.

Protection of River Banks.—Water plants form a very efficient natural protection and they assist in retarding the current—sometimes not an unmixed advantage.

Earthen banks of a soft and erodible character may be artificially protected, where stone is procurable, by rubble pitching, laid at a slope of 1½ or 2 to 1, from 8 to 12 ins. thick at the top, and increasing in thickness downwards at the rate of 3 ins. per yard. The foot of the slope should be adequately secured to some firm abutment, such as piling, otherwise the pitching may be undermined and, in that case, it will subside.

Where stone is not procurable, fascine aprons or mattresses, formed of brushwood, may be utilised. These are bundles of branches and twigs (usually willow) from 9 to 12 ins. in diameter, about 12 ft. long and bound with tarred rope at intervals of 4 ft. or so, laid side by side and tied together so as to produce a surface covering of the desired extent. The 'fascines,' as they are termed, should be secured by stakes or short piles to the bank upon which they are deposited.

Reinforced concrete slabs in various forms have been employed, notably the De Muralt systems, in Holland and elsewhere.

A plantation of small willows above water level is useful in counteracting the more deleterious effects of floods.

River Bank Protection of the Missouri.—Regulation work on the Lower Missouri, comprising the formation of a 6-ft. navigable channel as far as Kansas City, a distance of about 390 miles from the mouth, was put in hand on an intensive scale in 1927.

'The cheapest form of bank protection on the Missouri has been found to be a mat below low water and a paved bank above. The mat is woven continuously, with an average width of about 85 ft. (26 metres), laid from the low-water line out into the river, and, after weaving on the surface of the water, sunk on the bottom by ballast. Willows, with "basket weave," were used for the mat, where available; otherwise it was built of 1-in. plank, with suitable bracing. Some 716,000 ft (230.000 metres) of such mat have been completed, and are in place (1930). Some individual mats in long bends were 5 miles or more long, woven continuously and sunk as they were woven. Above the water line the bank was graded by hydraulic jet to a slope of 1 on 3, and paved with broken stone, the fragments weighing from 40 to 80 lbs. This type of protection was first built, on a small scale, 30 or 40 years ago, and with adequate maintenance will apparently stand indefinitely. It costs about \$20,00 per ft., the maintenance averaging about 3·5 per cent., or \$0,70 per ft. per year' (*Extract from Report by Major G. R. Young to International Navigation Congress at Venice*, 1931).

Mississippi River Bank Protection.—The banks of the Lower Mississippi are protected where necessary from erosion below water surface level by means of brushwood mattresses loaded with stone. The portion of the bank above surface level is protected by a covering of stone only, 10 ins. thick, laid to a suitable slope.

The mattresses were deposited from a single barge, or from a couple of barges, placed end to end, so that the combined length of the barges exceeded the width of the mattress. The ordinary size for mattresses was 800 ft. by 250 ft., but some mattresses were 1,000 ft. long by 300 ft. wide. 'The mattresses are constructed on the mattress-barge by laying parallel to the shore, and, 8 or 10 ft. apart, a series of poles, whose aggregate width equals nearly that of the proposed mattress. These poles are small trees from 3 ins. to 6 ins. diameter at the butt, and 25 ft. to 30 ft. long. Smaller poles are then placed at right angles to the larger series, so as to pass alternately beneath and above the successive larger poles, as in basket-work. These smaller poles, when forced into close contact with each other and with the other series, form a tolerably compact web or mattress. When so many of the small poles have been added that they approach the ends of the larger series, whose poles are parallel to the shore these larger poles are each continued by having another large pole spliced to it, and so on, for the length of the mattress. The brush in the mattress is fastened together frequently with iron wire and cross poles. The whole mattress is strengthened by wire cables about 20 ft. apart, and by ⅜ in. to ⅝ in. wire ropes running longitudinally the whole length of the mattress. Transverse cables of wire, about 16 ft. apart, also strengthen the mattress; and transverse wire ropes in addition are sometimes used.'

As each mattress was woven it was allowed to be floated down stream off the barge by the current, and when a sufficient length had been accomplished it was loaded with stone and sunk the upper end being sunk first. The customary under-water slope did not exceed 1 in 3, and the depth of the outer edge often ranged from 60 ft. to 100 ft. (*From Report by General C. B. Comstock, on Mississippi River Improvement, to Chicago International Congress*, 1893.)

Flexible mattresses of reinforced concrete are being experimented with on the Mississippi.

CHANNEL TRAINING WORKS.

The instability and eccentricity of channels is remedied by training works, comprising (*a*) projecting jetties and groynes, (*b*) longitudinal dikes and embankments, and (*c*) ground sills.

Groynes or Jetties project from the banks to the stream at right angles, or thereabouts (generally within 70° to 90°) to its course, and have the effect of reducing the channel and concentrating the scour of the current within certain bounds. The beneficial effect, however, is largely local, and, in the absence of restraint between the jetties, the stream tends to diffuse itself over a wider area, so that while the bed may be deepened and improved opposite the ends of the groynes it often becomes actually shallower in the intermediate spaces. To be effective, groynes should be spaced apart not more than five times their own length, and this often renders them less economical than a system of longitudinal diking, which, on the whole, will be found far more satisfactory and is often ultimately adopted. Groynes should, in fact, only be looked upon as of the nature of a temporary expedient. They may be formed of piling, fascine work, or rubble.

Groynes on River Missouri.—For contracting the river in a reach or at a crossing, or from the convex side of a bend, lateral groynes or longitudinal dikes were found equally efficient, the former being cheaper since they could nearly always be spaced more than their own length apart. They were, therefore, commonly used.

'The most satisfactory device is an openwork fence built nearly normal to the channel, consisting of several rows of stout piles, or clusters of piles, suitably braced, driven an average of 20 ft. (6·1 metres) into the bottom, the top of the structure being a foot or two below the natural bank from which they are built. (Two alternative designs, about equally efficient, are in use.) A striking feature is that it is not necessary to screen these dikes, or to provide any device other than the dikes themselves for arresting the flow of the water. While the dikes are entirely permeable when first built, being merely a skeleton framework, they rapidly accumulate driftwood at high stages of the river, which banks up behind them and forms a mass, sometimes many acres in area. This drift retards the water sufficiently to cause it to precipitate the sediment that it carries, and to produce an almost immediate fill between the dikes almost to their outer ends' (*Extract from Report by Major G. R. Young to International Navigation Congress at Venice*, 1931).

Groynes on the River Waal.—These are so arranged as to point upstream with the axis of the groyne on the concave bank forming an angle of 80° with the projected channel, and that on the convex bank an angle of 70°. This system has been found favourable to the deposit of alluvium between the groynes.

The groynes themselves are formed of a core of sand extending to 11 ft. 6 ins. below ordinary low water. The core is covered with mattresses of fascine work, having a lateral slope of 6 to 4, surmounted by a layer of broken brick and rubble stone. The slope towards the river is 1 in 4. The width of the crown of the groynes is 11 ft. 6 ins., and their height along the boundary of the normal river bed 1 ft. 6 ins. above ordinary low water level, corresponding to about 1 ft. 6 ins. below mean water level.

It is stated that sand forms a satisfactory core if banked in large quantities at a time, and that no harmful results ensue from the slipping away of a certain amount during submergence. A few years after formation the groynes receive a protective covering of basalt.

The River Waal has a velocity varying between 2½ and 3½ ft. per second. The discharge is about 21,000 cubic ft. per second at lowest water level, and 220,000 cubic ft. during highest floods. (*From Report by M. Baucke to Philadelphia Navigation Congress*, 1912.)

Longitudinal Dikes are walls or embankments of timber, stone, concrete, fascines, or other material built up so that the channel is rigidly confined within definite limits throughout the length treated. At the outlet of the Fen Rivers in the Wash, banks of fascine faggots and clay were constructed 22 ft. wide at the base, 17 ft. high, and 13 ft. wide at the top, at a cost of about 1*s*. 8*d*. per cubic yard. On the River Weser, stone and gravel embankments have been found preferable to fascines on the ground that the surface slopes may be rendered less steep than 45°, which is stated to be the limit for fascine work.

River Training Works at the Mouth of the Danube.—Operations for the improvement of the navigable channel at the Sulina mouth of the Danube have been in progress for more than half a century, under the direction of the European Commission of the Danube, an international body, constituted in 1856 by the Treaty of Paris.

There are three main arms, or branches, of the Danube delta, at its influx into the Black Sea. The Sulina arm, with the port of Sulina at its mouth, was chosen for treatment by reason of its greater depth and general use, despite the fact that its discharge was scarcely 10 per cent. of the total.

Rudimentary timber piers, consolidated by concrete mass-work and stone rubble, were constructed in the first instance, thus concentrating the outward current, and by the scour so occasioned, the depth across the bar of the river was increased from 9 ft. to 17 ft. rapidly; and subsequently more gradually to 20½ ft., at which figure it remained, naturally, for a period of 22 years until 1894, when dredging was commenced and a depth of 24 ft. obtained, necessitating, however, continuous maintenance work. In 1915 the depth of 24 ft. was lost and three dredgers proved incapable of re-establishing it. On account of the progressive advance of the delta, the action of natural forces, aided by artificial means, had become insufficient to cope with the deposit of alluvium, which, indeed, threatened to destroy serviceable access to the river for shipping.

In 1922 a prolongation of the piers or jetties was begun, and in 1925 was completed to a point about 3,300 yds. from the Sulina Lighthouse, which is located at the port entrance. On July 25, 1925, the new channel, 200 ft. wide, was opened to traffic with a minimum depth of 20 ft., which within a month was increased to 23 ft. Deposit, however, continued to take place at the outer extremities of the piers, and a further prolongation was necessary in order to reach deeper water for the pierheads.

Levees constitute a type of longitudinal dike. They contract the river channel in its higher stages and protect the adjacent country from inundation. As used in American practice, they are generally banks of earth or spoil, well consolidated, with a central trench forming an impervious connection with the natural ground.

Channel Curves.—The natural tendency of river channels is to form a series of deep water pools on the concave sides of bends, with shoals at the intervening points where the current passes over from one side of the river to the other. A judicious system of training will maintain the natural sequence of these deep pools, at the same time suppressing any unduly sharp bends which might be awkward for navigation. Generally speaking, for vessels of 400 to 600 tons moving at a fair rate of speed a radius of 550 yards should be regarded as a minimum—at low speeds, 220 yards will suffice. The minimum for vessels of very small tonnage (say, 200 tons and under) may be as low as 66 to 88 yards.

Ground Sills are serviceable where there is excessive scour of the bed or undue restriction in width of channel. They have the effect of rendering the fall of the stream more uniform. In German practice they are set from 40 to 50 feet apart, and found to be better than continuous pitching or filling of the bed. They are laid across the river so that their highest levels at the bank are about 12 inches below the normal surface, and they slope downwards to the centre of the stream at an angle of about 1 in 40. On the Mississippi the ground sills consist of either rubble mounds or cribs filled with rubble, or, again, of brush mattresses and stone in alternate layers. Whatever form be adopted, the top should be finished off smoothly to prevent injury to passing vessels. Ground sills may be used where it is desired to raise the low water level or lengthen out a slope.

Storage Reservoirs.—For the augmentation of the flow in dry seasons storage reservoirs have been advocated, and in two instances—the Mississippi and the Volga—have been adopted. Circumstances, however, have to be favourable if they are to prove a satisfactory and economical arrangement. The Volga has its source in a lake and swamp region where land is cheap and unfit for agriculture. The dams required were only 17½ feet high, and a storage capacity of 35.000 million cubic feet was obtained. On the Upper Mississippi above St. Paul, five reservoirs were formed out of an extensive lake area of 480 square miles, with a storage capacity of 93,400 million cubic feet. It is stated that the increase in height obtained at St. Paul during the low water period—about 90 days—averages only 14 inches. The system is not regarded as sufficiently satisfactory to justify its extension elsewhere in the United States. Where there is no original headwater accumulation its adoption is out of the question.

RIVER DREDGING.

The improvement of river channels by means of mechanical dredging has received considerable impetus of late years by reason of the development in power and capacity of dredging plant. The various appliances are described in detail in connection with harbour dredging (*vide* p. 634 *et seq.*). In some cases, as for instance the Volga, with its tributaries the Oka and the Kama, the application of dredging alone, without the assistance of artificial training works, has proved sufficient to ensure the maintenance of a serviceable channel, while in other cases, notably on the Mississippi and the Mersey, engineers employ both systems conjointly.

RIVER CANALISATION.

The canalisation of rivers is effected by dividing their beds into a series of reaches separated by dams, or weirs, which are provided with a communicating lock, or locks, arranged generally at one side. Dams are either fixed or movable, and they may also be permeable or impermeable. Fixed, impermeable structures are generally resorted to as being more economical in construction and more convenient in action. Movable dams may be said to be required only in cases of excessive flood flow, or where the conditions admit of free navigation during appreciable periods. Fixed weirs are usually constructed of solid stonework, rubble, piling or concrete provided with the requisite sluices and overflows. Movable weirs are more often of timber or iron framework with mechanism for lowering and raising them, either wholly or in part by means of leaves or panels. They are of various types with distinguishing names, such as Needle, Chanoine, Boulé and Bear-trap.

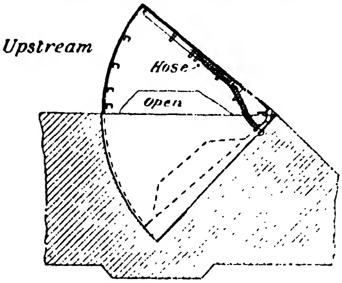

Fig. 1.—Section of Weir near Bremen.

Sector Weir near Bremen.—A notably large sector weir which constitutes a development of the bear-trap type, across the River Weser, near Bremen, is illustrated in cross sectional outline in fig. 1. The weir is in two lengths of 177 ft. each, and holds up the water on an average to a height of about 12 ft.; in winter, the height rises to 18 ft. The structure forms the hollow horizontal sector of a cylinder of 21½ ft. radius turning on a horizontal shaft, the angle of the sector being about 45 degrees. The weight of each sector is 129 tons. A description of the weir with the method of raising and lowering is contained in *Engineering* of July 7, 1916.

Lateral Canals.

As an alternative to river canalisation and where the channel exhibits features which do not conveniently lend themselves to treatment, an independent lateral canal may be constructed, generally following the lie of the river, but also making use of any facilities which may offer themselves for straightening and rectifying the course.

The River Rhone, in the chequered history of its amelioration, has been furnished with three lateral canals to overcome the difficulties of navigation at its natural mouth. Each in turn of the earlier two became inadequate for dealing with the traffic which accrued from its construction, and now there is a recently constructed artificial waterway to the port of Marseilles which is described in detail on p. 587.

BRITISH CANALS.

The following summary of the conditions prevailing in Great Britain is extracted from the Report of the Royal Canal Commission (1909):

'On the whole, the waterways may be roughly divided into two classes, those having locks of more, and those having locks of less, than 14 ft. in width. Corresponding with these two classes of locks are two classes of vessels usually known respectively as barges and narrow boats, the latter being often called "monkey boats," and chiefly in use on the Southern and Midland canals of England. The barge usually measures from 60 to about 72 ft. in length by 14 ft. in width of beam; the narrow boat is about 70 to 72 ft. in length, but only 7 ft. in width. The narrow boat when loaded, and drawing about 3 ft. 3 ins. of water, will carry about 30 tons over many of the canals. The barge will carry about twice that weight, with the same draught. Both the narrow boat and the barge could carry a heavier cargo if the depth of water were increased sufficiently.

'The usual length of lock, both on the wider and the narrower waterways, in the South and the Midlands, is, accordingly, about 75 ft. But on the wider, or barge canals, the locks are usually between 14 and 15 ft. or more in width, and on the narrow canals between 7 ft. and 8 ft. In both classes of lock the depth of water on the sill varies, speaking very generally and with many exceptions, from 4 ft. to 5 ft.'

DEVELOPMENTS IN CANAL CAPACITY.

In France and South East Belgium the standard boat carries about 300 tons, while in Germany the newest canals are adapted to boats of 600 tons and upwards. In this country opinion as to future policy is divided between the adoption of the 300-ton type and the retention of the smaller class of boat in general use, not exceeding 100 tons. The following are the dimensions

recommended for the two classes respectively by Sir J. Wolfe Barry and Partners, who were called in to advise the Royal Commission on the matter.

Dimensions.	100-ton Boat. Canal.	300-ton Boat. Canal.
Length of barge over all	80 ft.	115 ft.
Beam " "	14 "	21½ "
Draught	5 "	6½ "
Area of immersed midship section of barge	69 sq. ft.	138 sq. ft.

A boat, 24 to 25 ft. wide by about 200 ft. long, with 6½ ft. draught, has been recommended by experts as a suitable type for a 600-ton barge on the Canal du Nord.

On the Rhone, barges of the same width and 220 ft. long have been put into service, carrying 650 tons on a draught of 6 ft.

The type of boat on the Rhine is the lighter of 246 ft. by 36 ft., which with the same draught carries about 900 tons, but when immersed to 6½ ft. is capable of taking 1,200 tons, with a displacement coefficient of 0·75.

(*'Annales des Ponts et Chaussées,' March–April* 1920.)

CONTINENTAL CANALS.

Canal du Nord, France, duplicating the St. Quentin Canal, which forms part of the navigable waterway connecting Paris with the Northern parts of France.—The ordinary cross-

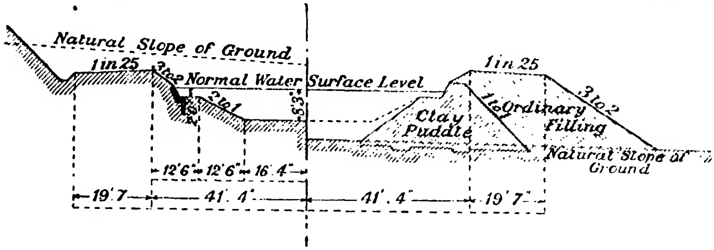

FIG. 7.—CANAL DU NORD

Section in Excavation. Section in Filling on Impermeable Ground.

section has a minimum width of 33 ft. at the bottom and 39 ft. at a depth of 6½ ft., with a navigable depth of 8 ft. Towpaths, 13 ft. to 20 ft. wide on each bank, one for upstream and one for down-stream traffic. Locks provided to accommodate two 300-ton barges in tandem; dimensions, 279 ft. long by 19½ ft. wide by 8 ft. deep. Lifts, 13 ft. to 22 ft., with minimum reach of 1,100 yards between locks. Tunnels of two types: those for single train of boats are 33 ft. wide at springing of arch, and those for double trains of boats abreast are 52½ ft. wide at springing. Each type has two side platforms, 6½ ft. wide carried on piles. Largest tunnel at Ruyaulcourt, which is 2¾ miles long. Canal designed for mean speed of two miles per hour, with barges mechanically hauled. Fig. 7 gives typical sections.

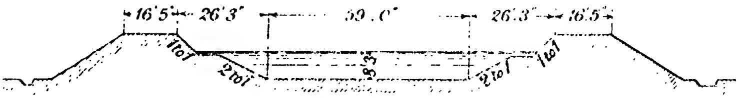

FIG. 8.—Brussels-Charleroi Canal.

The Rhone-Marseilles Canal.—Opened in 1926, the cross-section in the straight lengths gives a width of 82 ft. at a depth of 6½ ft., while the normal depth is 8 ft. 2 ins., and that in the outer portion approaching Marseilles 10 ft. Sills and inverts throughout are laid to this lower level, in order to admit of future deepening. The width of the canal is narrowed to 59 ft. where it passes through the Nerthe Mountain (Rove Tunnel). The canal section on the straight portion has been fixed at five times the immersed section of the present Rhone barges, when loaded to their maximum capacity of 600 tons on a 5 ft. 9 in. draught. These barges have a beam of 26 ft. 3 ins. The dimensions of the locks are 525 ft. internal length, by 52½ ft. in width. The lock at Arles has a lift of 23 ft. at low water. The total cost of the canal is stated to have exceeded 3,560,000*l*. The section of the Rove Tunnel shown in figs. 9 and 10 cost 52*l*. per ft. run, of which the masonry work accounted for 16*l*. per ft. run.

Modern German Canals.—Herr Germelmann, in a Report to the Philadelphia Navigation Congress 1912, remarks that in Germany high economic value is attached only to large efficient canals, suitable for vessels of 213 ft. in length by 26¼ ft. in breadth (600 ton barges), or, at least, for vessels of 180½ ft. in length and 26¼ ft. in breadth (400-ton barges) with draughts of 5 ft. 9 ins. The cross-sectional area of canals recently constructed is as follows:—Spree-Oder Canal from 705 to 760 sq. ft.; Dortmund-Ems Canal, in cuttings, 640 sq. ft.; in embankment, 810 sq. ft.; Teltow Canal, 662 sq. ft.; Ems-Weser Hanover Canal, in cuttings, 662 sq. ft.; in embankment, 780 sq. ft.; Rhine-Ems Canal, 986 sq. ft., Berlin-Stettin Canal, about 732 sq. ft.

Trollhatta Canal, Sweden.—This canal, first opened in 1607 and recently enlarged and extended at a cost of about 1,300,000*l*., has a length of about fifty-two miles, and connects Lake Vanern with the Kattegat, between which there is, at ordinary water level, a vertical difference

EXAMPLES OF MODERN GERMAN CANALS.

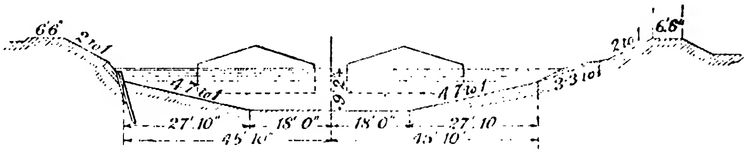

FIG. 11.—Spree-Oder Canal.

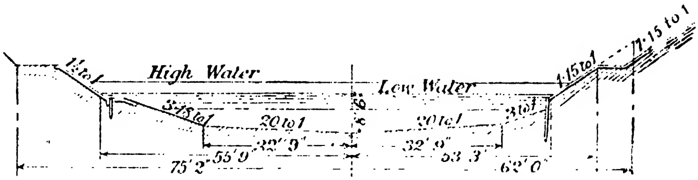

FIG. 12.—Teltow Canal.

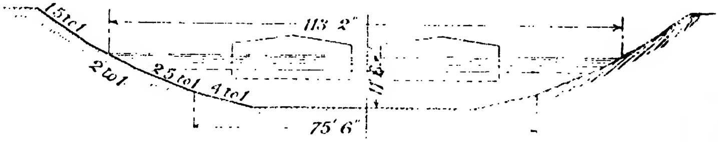

FIG. 13.—Rhine-Ems (Herne) Canal

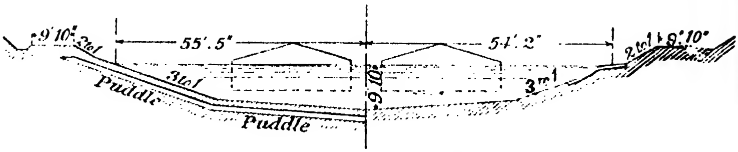

FIG. 14.—Berlin-Stettin Canal.

of 146 ft. The canal is built to accommodate vessels of 13 ft. 1½ in. draught, but with a view to future developments the locks are constructed to pass vessels of 16 ft. 5 ins. draught. The normal bottom width of the canal is 79 ft., but this, at passing places, is increased to 95 ft. and 115 ft. The maximum depth in rock cutting for vessels drawing 13 ft. 1½ in. is 14 ft. 5 ins., and in earth excavation, 18 ft. 3 ins. For the 16 ft. 5 in. vessel these dimensions are increased to 18 ft. and 19 ft. 7 ins. respectfully. The lock chambers have a length of 295 ft. and a width of 45 ft., with 18 ft. of water over sills. The greatest change in level at any one lock is 26 ft.

New York State Barge Canal.—This canal, the inception of which dates back to the beginning of last century, has recently been enlarged so as to afford accommodation not only for the largest class of barges at present constructed, but also for those up to 3,000 tons which may be built in the future. A minimum depth of 12 ft has been provided, with a minimum width of 94 ft. in rock cuttings and of 125 ft. in earth excavation. The locks, 57 in number, have chambers 310 ft. long and 45 ft. wide and are capable of passing vessels with maximum dimensions of 300 ft. by 42 ft. The lock at Little Falls has a range of 40½ ft., exceeding any single lift on the Panama Canal. The syphon lock at Oswego is the first of its type in the United States, and with a range of 25 ft. is probably the largest of its kind in existence. A description of it is as follows (*vide Engineering*, August 2, 1918). The general design of the culverts is not unlike that of an ordinary lock, except that at the upper and lower ends the culverts are curved upwards so as to form necks. These rise a little above the highest water level and are shut off from all communication with the outer air, except through the operating pipes. The flow of water in the syphon is started by means of tanks, one of which is built in each wall near the upper end, and communicates through pipes with the upper and lower levels and with both syphons in the same wall; they are shut off from all other communication with the outer air. The cycle of operations is as follows: The tank is first filled with water, then the intake valve is closed and the outlet valve opened. In consequence there is a body of water suspended by its weight, but tending to escape into the lower pool, and thus producing the necessary vacuum. Therefore, on opening the air valve, the air in the syphon rushes towards the vacuum, and water begins to flow up and over the crest in the neck. When using both syphons, the lock chamber can be filled in from 4½ to 5 mins., and it can be emptied in from 5½ to 6 mins. It has been found that the draught of the vacuum is such that, soon after the flow has started, the direction of the air is reversed and the vacuum is restored in the flask. The operating power is accordingly self-renewing except for a small amount of air leakage.

Cost of Canal Construction and Improvement in Great Britain.

In 1905 Mr. J. A. Saner estimated the constructional cost of new canal, suitable for two lighters of not less than 250 tons carrying capacity, or 200 tons when self-propelled, with locks 230 ft. by 22 ft. having 6½ ft. draught of water over sills, the canal itself being 40 to 45 ft. wide at bottom, 80 to 85 ft. wide at top, and 8 ft. deep in centre, at 30,000*l.* per mile, and the cost of improving existing routes to reach the same standard at 15,000*l.* 'These figures are based on the actual cost of the Weaver Navigation and the Manchester Ship Canal; the former has cost about 42,000*l.* per mile, and the latter about 440,000*l.* per mile, inclusive of docks in each case. The Worcester and Birmingham Canal originally cost 20,000*l.* per mile; and between 1879 and 1891 the French improved 2,500 miles of river, 2,250 miles of canal, and built 875 miles of new canal, for a total of 21,000,000*l.*, or an average of 3,734*l.* per mile; so that the foregoing figures should be ample.' (*Saner on Waterways in Great Britain, Min. Proc. Inst. C.E.*, vol. clxiii.)

RELATIVE ADVANTAGES OF LOCKS AND LIFTS ON CANALS.

Changes of level in canals and canalised rivers are effected by (1) locks, and (2) mechanical lifts, the latter being either (*a*) vertical or (*b*) on an inclined plane.

Locks are the simplest and most stable means of attaining the desired object. There is no question of their superiority for all differences of level up to 12 or 15 ft., and circumstances are generally favourable for their adoption for differences up to 25 or 30 ft., and even more. Among

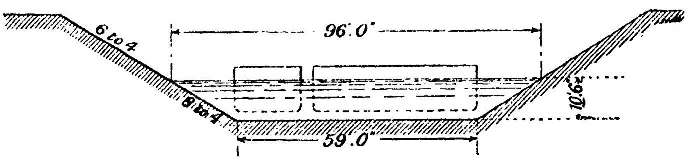

FIG. 15.—Bruges-Ghent Canal (General Section).

the older canals may be instanced a lock on the River Moldau, which has a lift of 29 ft., and another on the St. Denis Canal, which has a lift of 32½ ft. Such heights used to be considered as marking about the limit of the advantageous employment of locks over mechanical appliances. For greater lifts, the strain on the lower gates became very considerable, and the consumption of water in the majority of cases was more than could be afforded.

It is true that by the aid of side ponds and syphons a large proportion of the water used in lockage could be saved—as much as 50 or 60 per cent. in many cases—but even allowing for this the loss was heavy and a mechanical lift was almost universally substituted.

In modern German practice, however, a very striking advance has been made owing to the development in size of vessels, which have now reached to a tonnage of 600 to 1,000 tons. A lock at Henrichenburg has a lift of 46 ft. It is provided with five side ponds for the economisation of water, the saving amounting to about 76 per cent. The chamber (312 ft. long by 33 ft. wide with 9 ft. 10 ins. depth of water over sill) is built in concrete on a rock foundation requiring an invert only 19½ ins. thick. Other locks have been constructed with lifts up to 60 ft. and over. The former limit, therefore, can no longer be said to apply, except in so far that, if it be exceeded, due provision will have to be made for the increase in strength of the gates and side walls, and for the economisation of water.

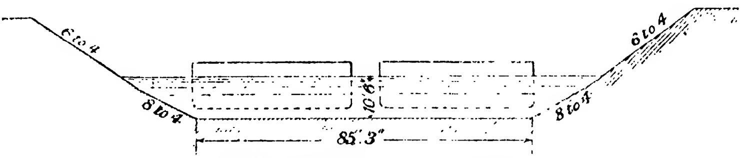

FIG. 16.—Bruges-Ghent Canal (Side Bay).

An appropriate test to apply to the serviceability of locks is the gradient or slope of the canal route. Where this is fairly regular and does not exceed 1 in 100 the rise lends itself to convenient subdivision into reaches of a quarter of a mile each, or more, separated by single locks of about 13 ft. lift. Under ordinary circumstances this is found to be a suitable standard for barge traffic, with barges of moderate tonnage, such as are customary in this country.

Where, on the other hand, the level of the ground changes abruptly, locks of higher lift or a series of locks may be employed, but only if an adequate supply of water is forthcoming to make good the loss from lockage. Where water is scarce it will be necessary to fall back upon some system of mechanical transfer.

Mechanical Lifts are generally more expeditious and time saving in action than locks, but they are also as a rule more expensive, and from their nature they are less durable and more liable to derangement.

From a number of examples of direct acting vertical lifts may be mentioned those at Anderton (Cheshire), Les Fontinettes (France), and Peterborough (Canada), *vide* figs. 17–19.

Lift at Anderton.—In this case the difference in level is 50 ft. The lift consists of two wrought-iron troughs each 75 ft. long by 15½ ft. wide, originally worked hydraulically and counterbalancing one another so that it was only necessary to reduce the depth of water in the lower trough by 6 ins. in order to set the apparatus in action. Owing to excessive wear and tear which developed in the hydraulic rams and cylinders, these were replaced in 1907–8 by a system of suspension gear passing over pulleys on an overhead gantry with counter weights at the free ends of the ropes. The total weight so suspended is 1,000 tons, each of the caissons weighing 250 tons, of which 80 tons is iron and the remainder water. The reconstructed lift is worked electrically. The main 30 B.H.P. motor runs at about 750 revs. per min., and the large 6 ft. pulleys make about 1 revolution in 2 minutes.

Lift at Les Fontinettes, near St. Omer, France.—The lift consists of two iron troughs containing water and each capable of taking a boat of 300 tons. Each trough is bolted at its centre to the head of a ram or piston, working in an hydraulic press. The two presses are in intercommunication by means of a pipe and constitute an hydraulic balance, vertical movement being obtained by admitting a surcharge of water to the upper tank. The surcharge is 12 ins. in depth, equal to about 64½ tons weight. The difference in level is 43 ft. The troughs are 129 ft. 7 ins. long by 18 ft. 4½ ins. wide, with a minimum depth of water of about 7 ft. The ends are closed by lifting gates. The rams or pistons are 57 ft. long, 6 ft. 6¾ ins. diameter, and 2 ft. 8 ins thick. They are formed in sections 9 ft. 2 ins. long, flanged inside, bolted together, and made water-tight by a ring of sheet copper inserted between the flanges. The hydraulic presses are 71 ft. high and 6 ft. 10 ins. diameter, resting upon concrete foundations at the bottom of excavated pits.

When one trough is raised to summit level there is a margin of 1⅞ ins. between its upstream extremity and the downstream end of the canal aqueduct. At the moment of lifting the gates to allow of the passage of a boat in or out, the joint is made good by indiarubber hose running round the end of the aqueduct and protected by springs. This hose is inflated by air at a pressure of 1½ atmospheres. The same connection is made at the lower level.

The machinery consists of two turbines, one of 50 H.P. and the other of 15 H.P.

The actual time of descent and ascent of the troughs is five minutes. An entire operation, including entry and exit of barges, takes twenty minutes.

The total cost of the lift was about 74,800*l*.

Lifts on the Trent Canal, Canada.—**There are two large lifts, one at Peterborough and the other at Kirkfield. The former consists of a pair of tanks, or chambers, 137 ft. long by**

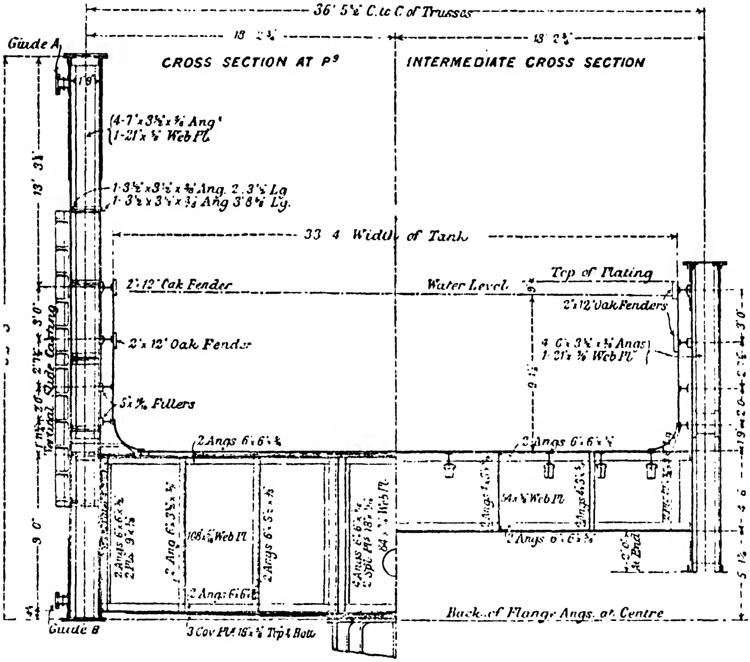

FIG. 17.—Cross-Sections of Canal Lift Lock at Peterborough, Canada.

33 ft. 4 ins. wide, and with 9 ft. depth of water. Each tank is supported by a ram 7 ft. 6 ins. diameter worked hydraulically, so that the descent of one chamber automatically forces up the other. The range of lift is 65 ft. Under ordinary conditions the upper chamber is held in position at a level about 6 or 8 ins. below the limit of stroke, and this surcharge of water is sufficient, when the by-pass is open, to overcome friction and give the necessary movement. The tanks are supported by openwork lattice trusses, and the total load of water and steel is carried to the top of the ram by four plate girders 9 ft. deep. The following is a description of the gates, which are in pairs, one closing the chamber end and the other the canal reach. 'Each gate is made up of three main 15-in. channels, with a small plate and angle girder at the top, and is stiffened vertically by 10-in. I beams. In every space between these vertical I beams there are placed two galvanised iron air chambers about 11 ft. long. These have the effect of making the gates practically buoyant, and this decreases markedly the amount of work which has to be done in raising the gates from a horizontal to a vertical position. The water-tight plating is, in

each case, on the outside of the gate, and the hinges are at the bottom. In the case of the lower reach gates and chamber gates, the hinge for the reach gate is 2 ft. 4 ins. below the hinge of the chamber gate, and 1 ft. 10 ins. separates them in a longitudinal direction. Consequently, the chamber gate is approximately 10 ft. deep, while the reach gate is about 12 ft. 6 ins. deep. As it is never necessary to operate any gate singly, the gates are arranged to work in pairs. At each end of the reach gate there is a pinion meshing into a circular rack set into the dock wall. The centre of the pitch circle of this rack is, of course, coincident with the centre of the hinge of the reach gate. The pinions above referred to are connected by a horizontal shaft running right across the gate, and power is applied to this shaft by means of a sprocket with chain, driven from another shaft, the centre of which is the same as that of the hinge. This shaft is actuated by one of the hydraulic gate engines provided.

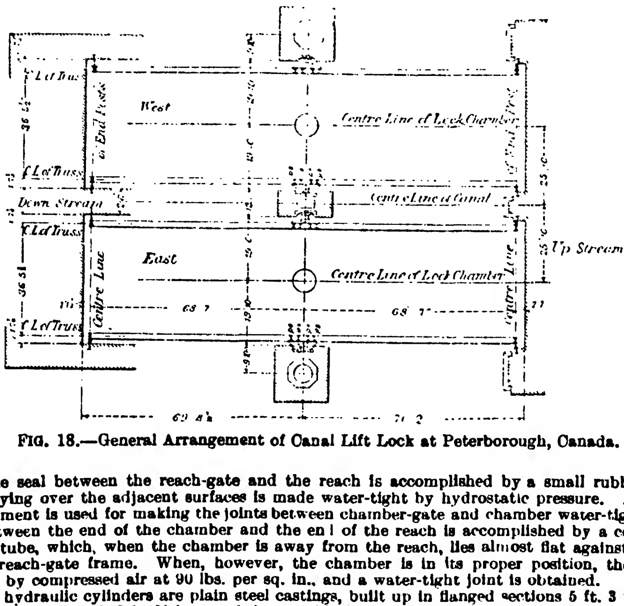

FIG. 18.—General Arrangement of Canal Lift Lock at Peterborough, Canada.

'The seal between the reach-gate and the reach is accomplished by a small rubber strip, which lying over the adjacent surfaces is made water-tight by hydrostatic pressure. A similar arrangement is used for making the joints between chamber-gate and chamber water-tight. The seal between the end of the chamber and the end of the reach is accomplished by a collapsible rubber tube, which, when the chamber is away from the reach, lies almost flat against the end of the reach-gate frame. When, however, the chamber is in its proper position, the tube is inflated by compressed air at 90 lbs. per sq. in., and a water-tight joint is obtained.

The hydraulic cylinders are plain steel castings, built up in flanged sections 5 ft. 3 ins. long. The inside diameter is 7 ft. 8½ ins., and the metal is 3¼ ins. thick. The joint packing is of copper, ¾ in. wide and $\frac{1}{16}$ in. thick, with $\frac{7}{16}$ in. diameter lead wire in press sections. The rams are of cast iron in flanged sections, also 5 ft. 3 ins. long, 90 ins. external diameter, thus giving a water space of 1¼ in. completely round the rams. The jointing is the same as that for the cylinders, except that the lead ring is omitted.

A very full description of this lift appeared in *Engineering* of June 9 and 16, 1916, from which the above particulars were extracted.

Inclined Planes represent a class of mechanical appliances suitable for intermediate conditions, viz., a route gradient too steep for single locks with intermediate reaches, and not sufficiently abrupt at any one point for a vertical lift. Generally speaking, gradients of between 1 in 8 and 1 in 10 are most favourable but they may run up to 1 in 75, or 1 in 80, and, on the other hand, inclined planes have sometimes been adopted where the rise is much steeper as, for instance, at Foxton on the Grand Junction Canal, where the gradient was 1 in 4. The Foxton incline now dismantled was similar in character to the balanced vertical lift, consisting of two caissons travelling transversely, each maintaining a barge of 70 tons afloat. It is claimed for inclined planes that, in comparison with locks, they save water, and, in comparison with vertical lifts, they save time, since a boat is travelling forward simultaneously with its alteration in level. Moreover they do not require such deep or expensive foundations as the lift proper. In spite of these advantages inclined planes have not attained a very marked degree of acceptance among canal engineers.

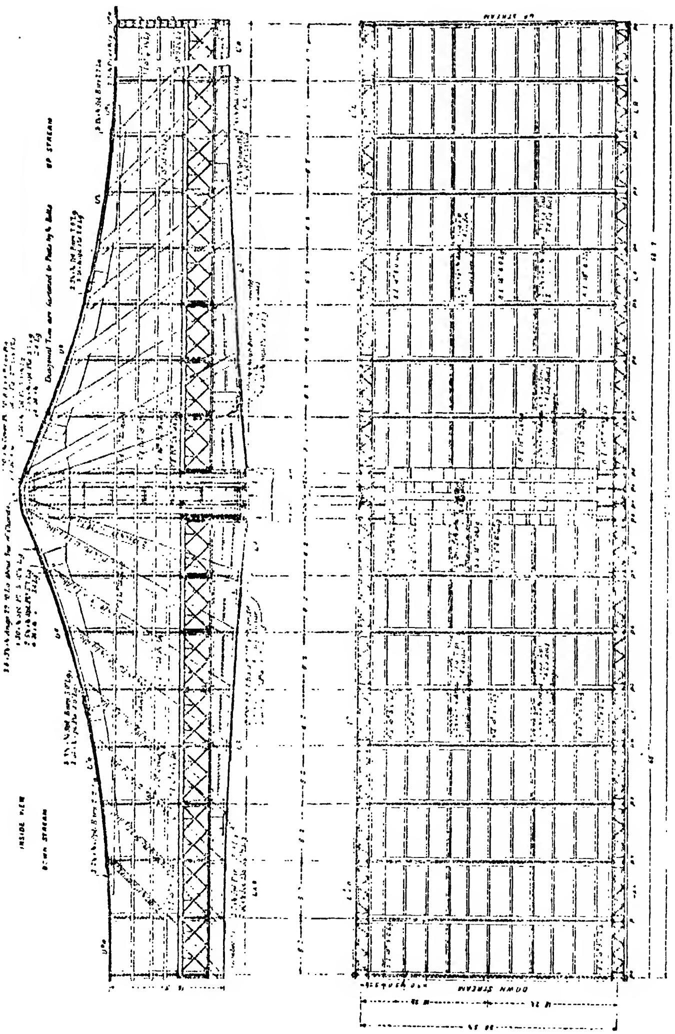

Fig. 19.—Internal View and Plan of Canal Lift Lock at Peterborough, Canada.

Canal Curves.—The formula adopted in Belgium for the increased width at curves is

$$S = \frac{A^2 + a^2}{R}.$$

Where S is the increase in bottom width to be added to the normal semi-width on the convex side of the curve, R is the radius of the curve, and A and a are the half lengths of the boats which have to pass one another. The units are all in metres, and the value of S must therefore be multiplied by 3·28 to bring it to feet. The increased width is splayed into the straight length at a distance ot 2 (A + a) from the commencemant of the curve.

Recent Tendencies in Lock Design.—The following are extracts from the conclusions passed by the International Association of Navigation Congresses at the Congress held at Venice in 1931 :—

'Concerning locks on canals and canalised rivers, a tendency has been noticed to do away with culverts for filling and emptying locks, and to assign the functions of admitting and evacuating the water to the lock-gates themselves, provided these are fitted with sluices of sufficiently large dimensions.

'In any case, when one has to deal with large volumes of water, it will be necessary to devise some special arrangement to reduce the violence of the discharge.

'As regards methods for closing locks and their working appliances, one notes still a tendency in recent years to adopt lifting gates, which present certain advantages, notably that all the moving parts are clear of water when the gate is raised, that the gate can be constructed in such a manner that it may be closed in case of a flow of water in the lock, which gives an added security ; or the lock may be utillseed to discharge water to the lower reach.

'With regard to further progress in the construction of navigation works, the adoption of lifts appears advisable only when we meet with a certain number of special circumstances combined, such as good foundations, a considerable water-height, and the impossibility of pumping the water back at a reasonable expense.

'In appropriate cases sheet piling, especially of steel, has given satisfactory and economical results in the construction of lock chamber walls, cut-off walls, and guiding walls.

'In the case of new canals intended either for navigation or for agricultural purposes (irrigation or drainage canals), as well as in that of already existing canals, one should always take into consideration the technical possibility and the economical advantages of uniting both purposes in the same canal, in the whole of its extension or in part of it.'

Twin Locks on German Canals.—The Furstenburg twin locks on the Oder-Spree Canal have a fall of 14·5 metres (47 ft. 6 ins.). When filling or emptying is to be done the water-level is equalised in both locks ; then one of the chambers is emptied into the downstream reach while the other is filled by water from the upstream reach. The four communicating culverts between the two chambers are closed, either by means of horizontal cylindrical sluice-gates with the Ardfelt system of sliding rings, in which a bell-shaped member with a cylindrical cover constitutes the means of closure, or by means of sliding cylinders on the Freund system, in which two cylinders with segmental partitions are arranged in such a way as to form side walls to the culvert when open. By rotating the cylinders through 90 degs. the partitions meet at an angle and close the passage. The sectional area of culvert is 3 sq. metres in each case.

At the Anderten twin locks on the Mittelland Canal (Hindenburg Lock), where the fall is 15 metres (49 ft.), each chamber is independent of the other, and is provided with 10 storage chambers arranged in two sets of five above one another as shown in fig. 20. The sluices are cylindrical and work in a vertical cast-iron tube passing through the successive floors of the chambers, sliding up or down to open or close.

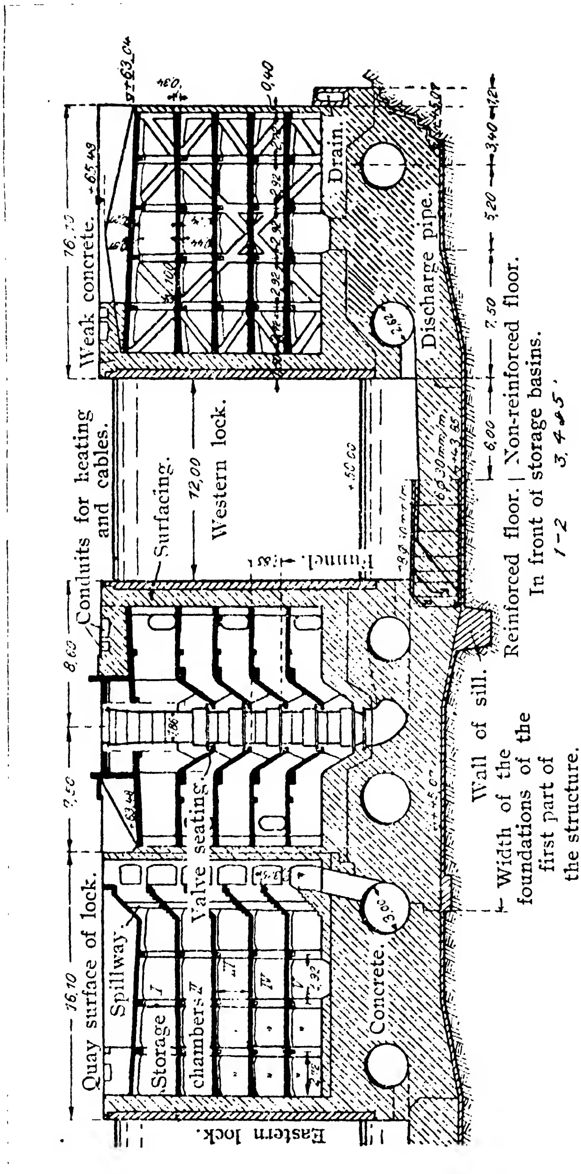
LOSS OF WATER ON CANALS.

Rankine summarises the sources of loss of water on canals as follows :

Waste of Water by leakage of the channel, repairs and evaporation *per day* = area of surface of canal × $\frac{1}{6}$ of a foot, nearly.

Current from the higher towards the lower reaches, produced by leakage at the lock gates, *per day*, from 10,000 to 20,000 cubic ft. in ordinary cases.

Lockage.—Single locks are more favourable to economy of water than flights of locks. At a single lock, single boats ascending and descending, alternately, cause less expenditure of water than equal numbers of boats in trains. On the other hand, at a flight of locks, boats in trains cause less expenditure of water than equal numbers of boats ascending and descending alternately. For this reason where a long flight of locks is unavoidable, it is usual to make it double, using one flight exclusively for ascending boats and the other exclusively for descending boats.



Section taken at 24,40 and 145,30 m. distance from the overflow wall of the upstream head.

FIG. 20.—Cross Section of the Storage Chambers of the Anderten Twin Locks on the Mittelland Canals.

East of Utica	Sandy loam	1·45
East of Rome	Sand and gravel	8·48
West of Rome	Clay loam and gravel	1·75

NOTE.—The Erie Canal has bottom widths of 52½ ft. and 42 ft. and depths of 7 ft. and 9 ft. in various portions.

Canal Bank Protection in Italy.—The sandy banks along the Candiano Canal in the province of Ravenna are strengthened with a row of reinforced concrete piling. The king piles, 10 to 16 ft. long and 8 ins. square, are driven at intervals of 10 ft. They are secured together at the top by a longitudinal runner 8 ins. by 8 ins., behind which is driven a row of sheet piling from 5½ to 6½ ft. long and 2 ins. thick. The length of the piles depends upon the nature of the ground and the depth of water, and, where necessary, further security is obtained by anchorage tie rods and bars to short piles in the rear. At points where it was possible to remove the water from the canal, or where the bottom was occasionally exposed, it was considered desirable and economical to revet the banks with a surfacing of reinforced concrete 2½ ins. thick in which the reinforcement consisted of expanded metal ·4 to 1·6-in. mesh and ·2 to ·32 lbs. per sq. ft. Where the canal bottom is not subject to erosion during floods, this revetment is continued down as far as 18 ins. above the level of the bottom, and the toe is protected by rubble. In cases of erosive action there is a concrete foundation or sill, sometimes supported by piling; and where the water level cannot be lowered sufficiently for the formation of a sill, the toe of the revetment rests against sheet piling.

TRACTION AND HAULAGE.

Means of Traction.—On ordinary small barge canals in this country, horse haulage has maintained its predominant position, but tug traction has been substituted on some of the larger systems, generally with successful results, provided the banks are sufficiently protected to withstand the wash of the tug propellers. Locomotive traction is common along the banks of continental waterways, but has not been able to establish itself on British canals where conditions are less favourable. Some craft are self-propelled, especially on larger waterways, and ship canals are, of course, navigated by vessels under their own steam. For passage through the locks of the Panama Canal electric locomotives are provided. There are 56 locomotives in service, each of which is 32 ft. long overall, has a wheelbase of 12 ft., and weighs 86,000 lbs. The gears are arranged to provide a maximum speed of 2 miles per hour on the inclines, or while towing, and 5 miles per hour when returning light. For vessels up to 350 ft. in length, four locomotives, two on each side at bow and stern, are employed. For larger vessels, six, eight and ten locomotives are assigned.

Horse Traction on a straight reach is most effective at speeds between 2½ and 3 miles per hour. Within these limits a steady pull of between 100 and 125 lbs. can be maintained, which is sufficient for loads up to 60 tons. There is the further consideration that at higher speeds the wash against the banks becomes excessive for unprotected surfaces. Where tugs or locomotives are employed some form of bank protection becomes essential.

As regards river navigation Rankine gives the following formula as a rough estimate of the effect of the current of a stream on the load which one horse is able to draw against at a walk.

Load drawn against current = load drawn in still water $\times \left(\dfrac{3\cdot6}{3\cdot6+v}\right)^2$; v being the velocity of the current in feet per second.

Cable Towage.—Lévy system, as adopted on St. Maur Canal between Paris and Joinville.—Cable weighs 2·45 lbs. per lin. ft. Set with permanent tension of five tons. Breaking strength 50 tons. Deflection due to haulage does not exceed 4 ins. Vertical supporting pulleys are 2 ft. 7½ ins. diameter, and have depth of groove of 7⅞ ins. Circuit may cover distance of 10 to 11 miles, so that two driving machines may be set 20 to 22 miles apart. For a speed of 1½ miles per hour 2 h.p. is required to draw a barge loaded with 350 tons. For a speed of 2½ miles an hour 4½ h.p. is required. Tractive force $= \dfrac{Wv^2}{2gl}$, where W = weight of boat in lbs., v = velocity in ft. per sec., g = acceleration due to gravity = 32 ft. per sec. per sec., and l = length of tow-line in feet. For a boat of 300 tons a velocity of 3 ft. per sec. and length of line of 300 ft., the tractive force = 315 lbs. Estimated cost of plant, about 12*s.* 6*d.* per lin. yd. Cost of working ranges from ½*d.* to ¼*d.* per ton per mile.

(*Report of Dr. Watson to Water Commerce Congress at Chicago*, 1893.)

Electric Traction on an elaborate scale has been installed on the Teltow Canal in Germany since 1905. The tractors run on rails on both banks. The current is continuous at 550 volts, from overhead mains, and each locomotive is driven by two 8 h.p. motors, which are sufficiently powerful to haul two 600-ton barges at a speed of 2½ miles per hour. A similar system is in use on the Douai section of the Canal d'Aire, where the tractors are of 10 h.p. In 1918, some petrol locomotives of 20–25 h.p. were introduced on the Rhine-Rhone Canal in place of horses, but though the experiment was successful the system did not come into general use on the Canal because it would have entailed considerable alteration in the permanent works.

The following advantages among others have been claimed for the use of electric tractors in place of steam tugs :—

1. Assuming that the electric lines are laid on each bank, there will be greater regularity and uniformity of speed in the service than where tugs are used, and there will be less delay in despatching cargoes at short notice and at regular intervals.

2. The banks and bottom of a canal are not so much injured by electric-towing as by tug-towing. In the latter case the peculiar disturbance to the bottom, with consequential injury to the side banks, caused by the motion of the screw, is added to the wave from the moving boats common to each mode of transport.

3. In the case of electric towing there is considerable economy of space and water in locks and lifts, because tugs and steam boats, which by reason of their machinery, have a smaller cargo-carrying capacity than barges of like dimensions, need not be taken through.

4. Electric power, when once installed along a line of waterway, can be utilised not only for traction, but also for operating locks and other works, and lighting the waterway at night, and can even, perhaps, be utilised for factories establishing themselves along the waterway.

(*Report of Royal Commission on Waterways*, 1909.)

In 1924 there was installed, on a short section of the canal from the Marne to the Rhine, a new system of electric traction known as the Chenean system. The underlying principle is the utilisation of an electric tractor, with proportional contact, travelling on an aerial cable. Owing to the light weight of the tractor (about 12 cwts.) it is possible to space the supports of the aerial cable, in general, at about 20 yards distance. The cable is of steel, 9 ins. diameter, weighing 1¾ lbs. per lineal ft. The speed of movement varies from 1 mile per hour in narrow cuttings, tunnels, etc., to 2 miles per hour and over in the open.

Tractor Boats.—In Germany small motor boats with Diesel engines of 17 to 34 h.p. were introduced a few years ago for towage between ports and loading-stations on canals. They are 8 metres in length, with a beam of 2 to 2½ metres, and are operated by one man. They can also be attached to the after-part of a vessel so as to play the part of a screw propeller.

'They are very mobile, easy to steer and have considerable tractive power. They have proved to give good service and to be economical. We are even going as far as to plan their construction on a somewhat larger scale (60 h.p.) for regular towing service on small canals. They can be advantageously used for a standard service, as auxiliary tugs, at the entrance and exit of locks' (*MM. Hoebel and Paxman, International Navigation Congress*, 1931).

Caterpillar Tractors.—Another form of towage used in Germany is that of caterpillar tractors of about 50 h.p. A winch drum for the haulage cable is arranged in front of the tractor, and as soon as the pull becomes excessive, a friction clutch automatically slackens the cable, which can also be lengthened or shortened on the drum, as required, during haulage. The cable can be lifted so as to clear craft lying alongside the canal banks by means of a mast 3 metres in height.

MECHANICAL TRACTION ON FRENCH WATERWAYS

Electric Traction.—The system consists of a rail track of metre gauge, running along one bank. The engines using the track weigh from 10 to 15 tons ; they have two driving axles and are generally equipped with a single motor, from 10 to 15 kw., supplied with power from a 600 volt D.C. trolley line. The rails are laid on wood or metal sleepers, according to the sections, and at certain points have to cross the waterways, in order, for example, to reach a bank free from other installations. The traction current is supplied by sub-stations situated along the waterway, which receive a three-phase current the tension of which can reach 31,000 volts and which in most cases transform the alternating current by means of mercury vapour rectifiers. To ensure safety of distribution every sub-station possesses an emergency equipment.

In short sections, where it is impracticable to lay a rail track, but where the importance of traffic demands electric traction, the difficulty has been surmounted by the use of electric engines on tyres and a double trolley line, the distribution being ensured as before.

Diesel Motor Traction.—Electrification is used only for heavy and medium traffic. For light traffic, engines on tyres are employed. These run along the towpath without any rails, on four wheels, each of which is used for propulsion and driving, with 5 h.p. diesel motors, having one or two cylinders to run on gas oil or fuel oil. This type of engine is used almost exclusively on non-electrified canals.

Special Forms of Traction.—Special systems of traction are used on a limited number of sections, mostly underground, which include electric tow-boats with the chain under water (St. Quentin Canal), electric tractors suspended from a mono-rail (Souterrain de Braye), and funicular cables (Mont Billy).

L. P. Alvin, 'Mechanical Traction on the French Waterways,' *Journal of Institute of Transport*, vol. 17, no. 8.

SHIP CANALS.

General Considerations.—It is desirable that the ratio of cross-sectional area of the canal to the immersed section of ships, where the traffic is commercial, should not be less than 4 to 1, and it may with advantage be much higher. In the Suez Canal it is about 7 to 1. For vessels of war, the ratio may be slightly less, as, for instance, in the Kiel Canal, where the ratio is about 3½ to 1. The limiting value is, however, dependent on the speed at which vessels are permitted to travel. In the artificial portion of the Suez Canal the speed is limited to between 6 and 7 knots, and about 8 knots represents an approximate upper limit for narrow shallow waterways. In passing through such waters vessels sink to a lower level than in the open sea on account of the displacement. Thus pilots have a rough rule that when a ship is near the bottom her 'squat' or 'sinkage' in feet may be about one-fifth of her speed in statute miles per hour.

For curves, M. Quellenec, late Consulting Engineer to the Suez Canal Commission, recommended widening the bottom, so that the longest vessel may preserve in its own direction a free space equal to 1½ times its own length between the stem and the slope of the concave side. The formula used on the canal was:

$$W = \sqrt{R^2 + (2a)^2} - (R + b)$$

where,
- W = amount of widening in feet;
- R = radius of axis in feet;
- a = length of ship in feet;
- b = ½ bottom width (on tangent) of canal in feet.

Kiel, or North Sea and Baltic Canal.—This canal, which connects the North Sea and the Baltic, was originally constructed between 1887 and 1895 at a cost of about 7,800,000*l*., including land purchase. It has a length of 61½ miles. The former dimensions have since been very considerably increased—viz. the bottom width from 72 ft. to 144½ ft., the surface width from 226 ft. to 334½ ft., the depth from about 30 ft. to 36 ft., and the cross-sectional area from about 4,500 sq. ft. to 8,868 sq. ft.

At the entrances at each end of the canal there are now twin locks of 1,083 ft. available length, by 147½ ft. clear width and 45 ft. 2 ins. sill depth at mean water level. These locks take the place of the earlier locks, which were 492 ft. long by 82 ft. wide with 32 ft. of water over sill. The new locks are constructed in concrete, and each has three pairs of caissons dividing the chambers into lengths of 725 ft. and 330 ft.

Manchester Ship Canal.—The Manchester Ship Canal was constructed between 1887 and 1893. It has a total length of 36 miles and includes four sets of locks, with an average

MANCHESTER SHIP CANAL: TYPE SECTIONS.

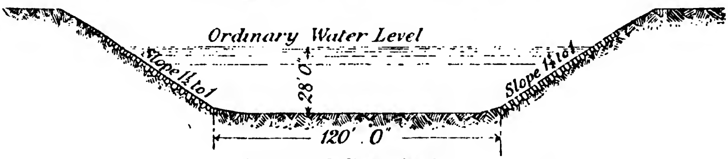

FIG. 21.—Ordinary Section.

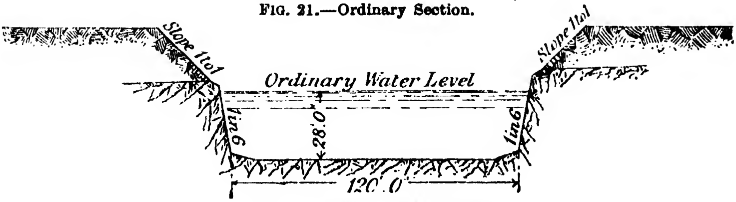

FIG. 22.—Section through Rock.

lift of 15 ft. each, about 160 acres of docks with warehouses and railway sidings, six high level bridges. seven swing bridges, and a swing aqueduct. The cost was 13,500,000*l.*, including land purchase and promotion, the actual constructional cost being about 9,000,000*l.* The capital of the company has since been increased on account of extensions and new works to 20,000,000*l.* The bottom width is 120 ft. The original depth was 26 ft., but this has now been increased to 28 ft. Deepening operations are being continued. A depth of 30 ft. has been extended from Eastham Locks as far as Stanlow Oil Dock, a distance of 4½ miles. The average annual cost of maintenance, which, before the war, was stated to be about 2,000*l.* per mile of canal, at the present time is about 5,400*l.* per mile.

Suez Canal.—The length of the Suez Canal is about 100 miles. It was opened in 1869, the cost of construction, apart from promotion, etc., having then amounted to 10.680,000*l.* It has been progressively deepened, so that the authorised maximum draught for ships in the canal has been as follows:—

From 1870 to 1890	7 m. 50 = 24 ft. 7 ins.
,, 1890 to 1902	7 m. 80 = 25 ft. 7 ins.
,, 1902 to 1906	8 m. 00 = 26 ft. 3 ins.
,, 1906 to 1908	8 m. 23 = 27 ft. 0 ins.
,, 1908 to 1914	8 m. 53 = 28 ft. 0 ins.
,, 1914 to 1915	8 m. 84 = 29 ft. 0 ins.
,, 1915 to 1920	9 m. 15 = 30 ft. 0 ins.
,, 1921 to 1924	9 m. 45 = 31 ft. 0 ins.
,, 1925 to 1929	9 m. 75 = 32 ft. 0 ins.
,, 1930 to 1935	10 m. 00 = 33 ft. 0 ins.
,, 1936	10 m. 35 = 34 ft. 0 ins.

The canal is available throughout for vessels drawing 34 ft. of water. The present depth of the canal below the mean level of L.W.S.T. is equal at least to 40 ft. or more, over the whole length; maintenance dredging is being carried to a depth of 44 ft. The width of the canal at a depth of 33 ft. is at least 196 ft. The surface width depends on the inclination of the banks, which changes with the nature of the ground through which the canal passes. This width varies normally between 400 ft. and 500 ft.

Of the total length of about 100 miles, 12 miles only are in curves, the minimum radius being 2,734 yards, and the maximum radius 8,083 yards, most curves having a radius of about 3,300 yards.

SUEZ CANAL.

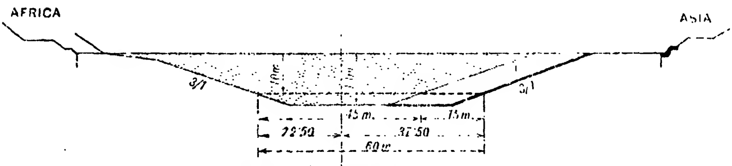

FIG. 23.—Section of Suez Canal, showing widening.

There are no locks. the canal being level throughout. At the South entrance there is a tidal range, amounting to about 5 ft. in the average at springs. The current flow does not exceed about 3½ ft. per second.

Panama Canal.—The total length of the Panama Canal, measured along its axis, is 50½ miles, but the portion actually within land area between coast lines is only 41½ miles. Of the total length, 14½ miles are at sea level, over 23½ miles in Gatun Lake, nearly 3 miles in locks of alongside approach walls, 1½ miles in Miraflores Lake, and 8 miles in the Gaillard Cut. The summit level is 85 ft. above sea level. The depth lies between 40 and 45 ft. The bottom width varies as follows: For 16 miles the canal is 1,000 ft. wide; for 4 miles, 800 ft.; for 22 miles, 500 ft.; and for 8 miles, 300 ft. wide.

There are six pairs of locks with dimensions of 1,000 ft. in serviceable length and 110 ft. in width; three of these are at Gatun, one at Pedro Miguel, and two at Miraflores. The sills are laid so as to afford a depth of 40 ft. in salt water, and 41 ft. 4 ins. in fresh water. With the exception of the lower lock in the Miraflores flight, the chambers are provided with intermediate gates, dividing them into two sections of 600 ft. and 400 ft. The range of lift of the Pedro Miguel Lock is 30½ ft. All the locks are double, i.e. with parallel chambers, so that vessels may pass in opposite directions. At the Gatun flight the lift is 85 ft. divided among the three locks; the actual operating pressure between consecutive locks is therefore nearly 60 ft.

There are 46 pairs of lock gates, constructed of mild carbon steel with yokes and pintles of vanadium steel. The height of the gates varies from 46 ft. to 82 ft. The largest gate weighs about 700 tons.

DIAGRAMMATIC SECTIONS OF PANAMA CANAL. (Not to Scale.)

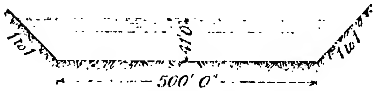

FIG. 24.—From Mindi River to Gatun Locks, and from Miraflores to Panama Bay.

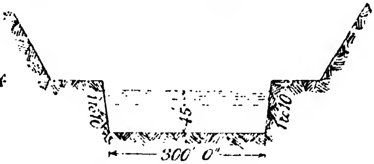

FIG. 25.—Gaillard (formerly Culebra) Cut.

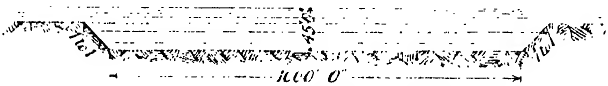

FIG. 26.—From Gatun Locks to Angle North of San Pablo.

The approximate cost of the canal, including purchase money, is 75,000,000*l*.

The following is a statement of the unit cost of excavating the Culebra (now Gaillard) Cut for the year 1912:

	Cost per cu. yd.
Transportation	\$0·1331
Drilling and blasting	·1157
Tracks	·0885
Loading by steam shovels	·0681
General expenses and supervision	·0503
Dumps	·0479
Plant, arbitrary	·0395
Drainage, structures and clearing	·0045
Total unit cost	\$0·5476

Bruges Ship Canal.—The canal connecting Bruges (Belgium) with the sea was constructed between 1896 and 1907. The works comprised an outer harbour with breakwater at Zeebrugge, and a sea-lock with a chamber 518 ft. long, 65½ ft. wide, the sill being laid at 19 ft. 8 ins. below L.W.O.S.T., giving a depth of 31 ft. 8 ins. at H.W.O.N.T. The canal proper is 6¼ miles long, 72 ft. wide at the bottom, and 229 ft. wide at water surface level. There is a depth of 26 ft. throughout, and the side slopes are about 3 to 1. Two railway and three road bridges cross the canal. At Bruges there are two basins and a lock connecting with the internal barge canal system of Belgium.

Amsterdam, or North Sea Canal.—This canal, constructed 1865–76, connected Amsterdam with the North Sea, along a route due west of 15½ miles, and supersedes in utility the Amsterdam North Sea Ship Canal, or Great North Holland Canal, made between 1819–25 which has a northerly direction, is 52 miles long, and is only suitable for vessels drawing not more than 16 ft. As originally constructed, the new canal had a depth of 23 ft. and a bottom width of 88½ ft. The entrance locks at the port of Ymuiden were two in number, the larger having an available length of 394 ft., a width of 60 ft., and a depth over sill of 26 ft. 6 ins. at ordinary low water. In 1896 a new and larger lock was provided, 737 ft. long, 81 ft. wide, and 33 ft. deep over sills. Yet again, in 1930, a third large lock was opened, at present the largest (though not the longest) in the world; it is 1,312 ft. long, 164 ft. wide, and it has a depth of 49¼ ft. of water over sills. The canal itself is in process of being deepened to 49¼ ft., and will have a bottom width of 328 ft.

The cost of the original works, including the harbour at Ymuiden, which has a sheltered area of about 250 acres enclosed by two breakwaters springing from the shore, each 1,670 yards in length, 3,940 ft. apart at the shore line and 853 ft. apart at their pierheads, was about £3,000,000. Improvement and maintenance works (including supervision) brought the total up to £5,667,000 by the end of 1910. The cost of the latest lock was about £1,600,000.

New Welland Ship Canal, Canada.—The new ship canal between Lake Erie and Lake Ontario, completed and opened in 1932, is designed to serve large-size bulk freighters of the present day which are about 600 ft. in length and draw up to 21 ft. of water. The work was begun in 1913, but was interrupted between 1917 and 1919 on account of the war. The cost has somewhat exceeded $120,000,000.

For all practical purposes of navigation the new canal is a straight line throughout. It has a length of 27·7 miles between its outermost ends at Port Weller and Port Colborne. Its present depth is 25 ft.; later this will be increased to 30 ft. Sufficient clearance is provided so that any ship passing through the lock at Sault Ste. Marie (the outlet from Lake Superior) can continue its voyage through to Lake Ontario. Later the Canadian Government expects to provide a waterway of equal dimensions from Lake Ontario down the St. Lawrence River to Montreal, whence there is ample waterway to the Gulf of St. Lawrence. There is a difference of 221 ft. in level between Lake Ontario and the river at Montreal.

The difference in level between Lake Erie and Lake Ontario is 325·5 ft. This is overcome in the new canal by 7 locks, each of which, rising 46·5 ft., has a usable length of 820 ft., a clear width of 80 ft., and a depth over sills of 30 ft. Two additional guard locks are provided, one at each end of the canal to meet high and low water differences in the level of the lakes. The guard lock at Humberstone (No. 8) is notable as being the longest lock in the world, having a length of 1,380 ft. between inner gates. Its nearest rivals are two locks on the American side at Sault Ste. Marie, which are 1,350 ft. long.

The superseded Welland Canal overcomes the difference in level between the lakes by means of 26 lifts. The locks have a usable length of 270 ft., a clear width of 45 ft., with depths over sills of 12 to 14 ft. The constructional cost of the canal was $31,031,226, and the maintenance cost to the year 1920 amounted to $9,237,961.

Moscow-Volga Canal.—The canal connecting Moscow with the river Volga and thus with the sea, which was opened in May 1937, has a length of 80 miles, the actual length of canal being nearly 68 miles and the remainder consisting of lakes and reservoirs. The canal is 150 ft. wide at the bottom and 280 ft. wide at the surface and has a minimum depth of 18 ft. The most difficult constructional feature was surmounting the elevated ridge which separated the Volga from the Moscow River—this has been achieved by a series of five locks, each providing a lift of 26½ ft. with two corresponding double chamber locks for the descent.

The **Mittel-land Canal**, in Germany, completed in 1938, is the culmination of a great scheme of internal navigation in that country, connecting the waterways of the Oder, the Elbe, the Weser and the Rhine, and placing Berlin in direct communication with the industrial region of Westphalia. The canal accommodates craft of 1,000 tons carrying capacity (29½ ft. broad and 6½ ft. draught). Among the more notable engineering features of the undertaking are the twin locks at Anderten (near Hanover) with a vertical range of 49 ft. (15 metres), see fig. 20, p. 596, and the mechanical lift at Rothensee (Magdeburg) with a vertical range of about 60 ft. (18 metres).

The **Albert Canal** in Belgium, which was put into service at the close of 1940 after ten years of constructional operations, has a length of close on 100 miles and serves to connect the industrial city of Liège with the port of Antwerp. The total fall between the extremities is 184 ft. and changes of level are negotiated by six sets of locks, five of which have a fall of 33 ft. each and the sixth one of 19 ft. The canal has a capacity for craft of 2,000 tons deadweight.

HARBOURS AND BREAKWATERS

Harbours are sheltered areas of water affording safe anchorage for ships, generally also, when discharging the functions of a port, provided with quays and facilities for landing passengers and cargo. There are many harbours where the requisite shelter is forthcoming naturally from the physical configuration of the coast line (Queenstown, Rio de Janeiro, Sydney, etc.). Where protection cannot be obtained in this way it has to be provided by means of breakwaters, as at Portland, Dover and elsewhere.

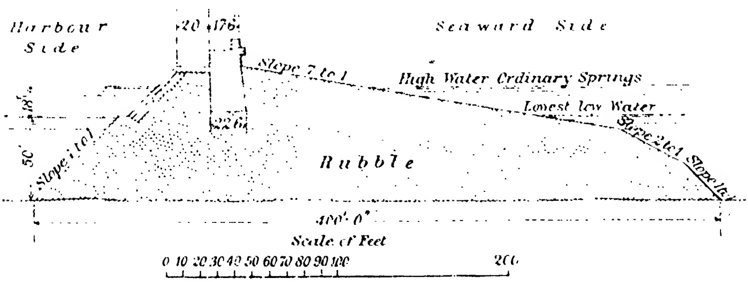

FIG. 1.—Holyhead Breakwater.

Breakwaters are of two types: (*a*) the mound of rubble stone, and (*b*) the upright wall of masonry or concrete. Frequently the types are combined. Sometimes the mound predominates and is simply capped by a slight superstructure of regular masonry, as at Algiers and Oran; in other cases it is reduced to a minimum, becoming a mere foundation layer for a wall of massive proportions, as at Ymuiden and Zeebrugge.

The relative advantages of the mound and the wall are as follows :—

1. As regards *efficiency*, the mound is not so serviceable as the wall. The undulations of the sea are transmitted through the interstices of a mass of rubble, and the harbourage area is kept more or less in a state of agitation.

2. As regards *initial cost*, the mound can be formed by unskilled labour, and where that is plentiful and stone abundant, this type of breakwater will commend itself on account of the facility with which it can be constructed. In the absence of these essential conditions, and provided the depth of water be moderate and the foundation sufficiently firm, the wall, involving a much less quantity of material, will be found preferable. Especially will this be the case where skilled labour is readily procurable at reasonable rates. Even the difficulty of a defective foundation may be overcome by one or other of several expedients without perceptibly altering the relative positions. But where the sea bottom lies at a considerable depth (40 feet or more) the superior economy of the pure wall cannot be maintained.

An interesting comparison of the estimated (pre-war) cost of four different types of breakwater, based on the conditions at Zeebrugge, Belgium, is made by MM. Bonnet and Braeckman in a paper to the Fourteenth International Congress of Navigation. The depth of the sea bed at Zeebrugge is 26 ft. 3 ins. below zero datum, and the tide rises 15 ft. above zero, giving a total depth of 41 ft. 3 ins. of water. The unit costs per lineal metre (3·28 ft.) are given as follows :—

	Francs.
(*a*) Solid wall of the Zeebrugge type. Total height 66 ft., mean thickness 23 ft.	**6,760**
(*b*) Composite breakwater with mound of unassorted rubble, the slopes being lightly covered by large natural blocks of 10 cwts. to 6 tons ; wall superstructure 33 ft. high	**7,600**
(*c*) Composite breakwater, mound having core of unassorted rubble, larger material on slopes protected on outer side by artificial blocks of 33 tons deposited haphazard	**8,700**
(*d*) Composite breakwater with base as before, but with slopes protected by artificial blocks of 31 tons laid symmetrically to inclination	**9,000**

Constructional Cost of Breakwaters.*

Valparaiso .	Composite	60 to 150	560	Concrete monoliths on rubble mound.

3. As regards the cost of *maintenance*, this is generally greater in the case of mounds than in the case of walls. A wall, provided it be properly constructed in the first instance, calls for no further attention, save for such rare and occasional damage as results from some storm of exceptional severity. The rubble mound, on the other hand, is peculiarly susceptible to wave action, and needs constant replenishment. The cost of this varies very considerably according to

* The impossibility of accurately adjusting costs and prices, where they are quoted, to the **altered and variable conditions arising has rendered it advisable to retain them on their old pre-war basis, leaving the necessary adjustments to be made as occasion may require out of war-time conditions and influences.**

situation and exposure. At Holyhead it was for many years as low as 1*s*. 3*d*. per lin. ft. per annum, but latterly there has been some extensive replenishment at considerable outlay; at Genoa, the

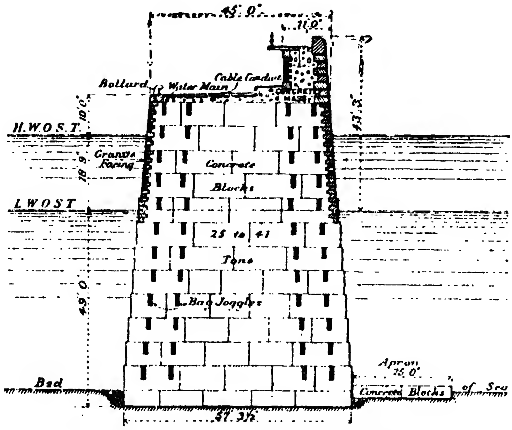

FIG. 2.—Admiralty Pier Extension, Dover.

cost is stated to be 7*s*.; at Naples, 13*s*.; while at Alderney, during a certain period, it rose as high as 45*s*. This last, however, is quite an abnormal figure, and under ordinary conditions the pre-war annual expenditure on mounds of suitable design hardly exceeded a pound a foot.

Wave Action.

Wave Action.—Wave action on breakwaters is most keenly marked between the levels of high and low water, but it extends to a depth of 30 ft., and there are instances on record of serious disturbances at even greater depths. Thus, at Peterhead, blocks weighing upwards of 41 tons have been displaced at 36½ ft. below L.W.O.S.T. But cases of this kind are exceptional.

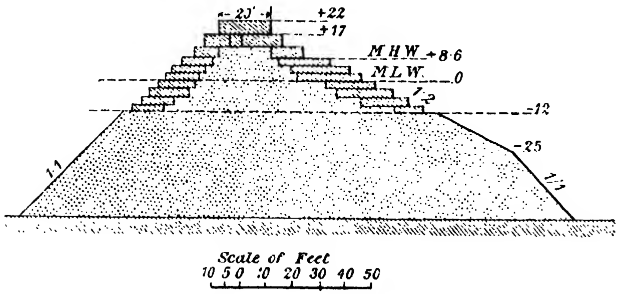

FIG. 3.—Sandy Bay (U.S.A.) Breakwater. 1902 Project.

Generally speaking, at a depth of 5 fathoms the sea is fairly quiescent and a rubble mound may be counted upon to stand therein with side slopes of from 45° to 50°.

Above this level much flatter slopes become necessary: 2, 3, 4, 5, and even 7 to 1. Unfortunately, while the equilibrium of the mound demands such gradual inclinations, they serve also to foster the disruptive action of waves, which, passing up a long seaward incline, have their oscillatory character changed into one of translation. At the summit the impact delivered is so powerful as to produce a pressure which Stevenson records as being six times as great as that against a steep wall. This inimical effect can only be counteracted by the use of huge blocks and monoliths, covering the exposed surface of the mound. The blocks, which in practice rarely weigh less than 25 or 30 tons apiece, and often considerably more, may be deposited either in courses or at random. In the former case they are generally stepped so as to conform to the general inclination. In either arrangement they should be laid as headers, pointing seaward, so as to expose the least extent of surface to wave-action and at the same time gain the utmost advantage from the moment of resistance to overturning. Hence prisms or parallelopipeds are decidedly preferable to cubes.

The *maximum pressure* exerted by waves does not appear to exceed 3½ tons per sq. ft. At Skerryvore, on the Atlantic, a pressure of from 2½ to 2¾ tons per sq. ft. has been observed; at Bell Rock, in the North Sea, 1½ ton; at Dunbar (East Lothian) 3½ tons, and at Buckie (Banffshire) 3 tons.

Composite breakwaters, in which the wall plays any important part at all, should be so designed that the *back draught* or *after-tow* of the waves cannot undermine the superstructure. To be really effective, this means that the wall should be carried down to a depth considerably below low water, and though in the past many such walls have been founded at low water level, or very slightly below it, yet the experience gained has proved that this depth is quite inadequate (the low water zone is particularly dangerous), so that of late years there has been a continual tendency towards increasing the depth of the foundation level. At Madras the wall commences at 27½ ft.; at Naples, 33 ft.; at Peterhead, 43 ft.; and at Algiers, 49 ft.*

Methods of Construction.

Methods of Construction.—Breakwaters are constructed in several ways, according to situation and type.

For Mound Breakwaters, rubble may be deposited—(*a*) from barges or scows; (*b*) by means of cranes running on temporary staging; and (*c*) from wagons passing over roads laid at or about the level of the top of the mound and extended as the work proceeds.

The first method is best adapted to sheltered situations, and affords an opportunity of depositing rubble uniformly and simultaneously over the whole site, but it is not economically practicable to carry on operations in this way at or about surface water level nor above it. Moreover, the progress of the work is very dependent on weather conditions, and there may be long periods of enforced inaction. It is to be noted in passing that irregular deposits of rubble lead to current action and scour. The second method (staging) admits of operations being carried on uniformly over the site, though not with quite the same degree of freedom as in the case of barges. But the advantages of a stable working base with infrequent interruptions and higher degree of safety and protection for workers, are very pronounced. The damage sustained by timber staging in storms and from the attacks of marine borers are drawbacks which detract from the merits of the system, though, generally speaking, the former is proportionately not a serious matter, and any evil results of the latter can be to some extent guarded against by careful inspection. The third, or low-level system of construction, by means of tipping from wagons running on tracks laid

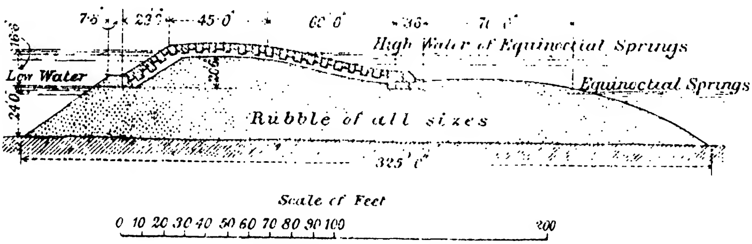

Fig. 4.—Plymouth Breakwater.

* **Even the last-named depth did not prevent the collapse of a length of 400 metres of the Mustapha Mole during an unprecedented tempest in February 1934.**

on the breakwater itself, assists in the consolidation of the work as it proceeds, and saves the cost of staging, but the area of operation is limited and there is liability to interruption during the

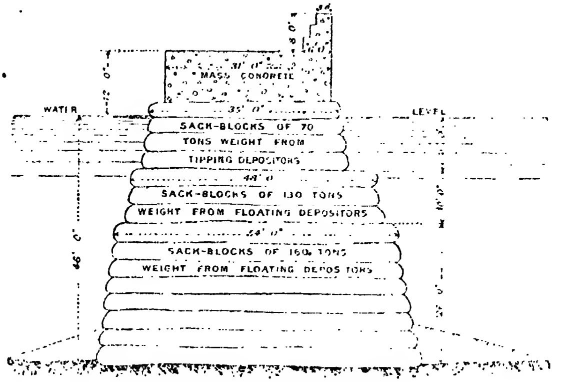

FIG. 5. - La Guayra Breakwater.

prevalence of heavy seas. It is a method more adapted to small embankments, where time also is perhaps not a matter of prime importance.

Wall-Breakwaters.

Walls are usually constructed either by means of staging, or on the low-level, end-on system; the former being generally more suitable when concrete is deposited in mass, and the latter for blockwork. The blocks, or monoliths, are deposited in place by huge revolving cranes, known as Titans, and overhead travellers, known as Goliaths. A modern Titan is a powerful cantilever crane capable of dealing with blocks of from 30 to 60 tons weight, at a working radius of as much as 100 ft. A 41-ton steam Titan used on the breakwater at South Shields had a radius of 75 ft., and was carried on 16 central-flanged wheels running on rails set to a 22 ft. gauge. The speeds of the various motions were as follows: Lifting full load, 6 ft. per min.; lifting loads up to 10 tons, 25 ft. per min.; racking full load, 20 ft. per min.; racking loads up to 10 tons, 50 ft. per min.; slewing, one revolution in 4 min. Goliaths are constructed to the same lifting capacity as Titans, and some command a lateral range of travel of 100 ft. or more, but the span is generally limited to about 50 or 60 ft. At Dover, a 42-ton steam Goliath had a range of 130 ft., a clear headway of 25 ft., and a total lift of 120 ft. The speeds of movements were: Lifting, 10 ft. per min.: crab travel, 50 ft. per min.; and main travel, 60 ft. per min.

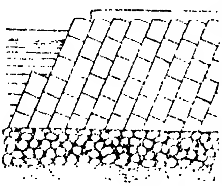

FIG. 6.—Sloping Bond.

Breakwater Construction at Genoa.

For the construction of the extension of the Molo Principe Umberto at Genoa, the type adopted was a vertical wall of concrete blocks superimposed on a rubble mound foundation. A length of 800 metres was built to the section shown in fig. 7. It consists of four courses of monolithic concrete blocks, three of which are 12 metres in length, extending right across the wall, by 2·95 metres high by 4·50 metres wide. The lowermost block is similar, but has a length of 13·50 metres to form an enlarged base for the structure, and its upper edges are bevelled. The weight of the blocks is 350 tons in the bottom course and 300 tons in those above. Lifting and setting were done by a floating pontoon with overhanging sheers. Above the blocks, which bring the structure just above water level, is a crown or capping of mass concrete with masonry facing. In consequence of the revelation of structural weakness in the design at the foot of the parapet wall, where the sharp rectangular off-set tended to fracture under wave impact producing a complex stress of flexure and torsion in the angle, the design for the last 1,050 metres length of the breakwater was changed to the section shown in fig. 8. At the pierhead, the dimensions of the blocks were increased to 13·50 metres by 9·00 metres by 2·95 metres in height. The foundation of wall has been laid at 11·50 metres below mean sea-level and of the mound sub-structure at from 15 to 16 metres below the same datum. The cost of the breakwater complete is given as 35,000 lire per lin. metre which, if the lira be taken at its exchange value at the time, in round figures 60 to the pound sterling, represents roughly, say £590 per lin. yd.

Figs. 7 and 8.

Special Methods of Construction.

Special methods of breakwater construction include the use of bags, or sacks, of concrete, weighing from 50 to 200 tons, for deposition under water by divers, as at La Guayra: large caissons, or tanks, of reinforced concrete, with volumes of 60,000 to 70,000 cu. ft., floated out into position, sunk and filled in solid, as at Bizerta; 146 floating caissons were used in the formation of the invasion harbour at Arromanches, Normandy. The largest had a displacement of 6,544 tons and the smallest 1,672 tons; and blocks set on end, slightly tilted (15° to 20°) out of the vertical so as to form what is called 'sliced work' or *sloping bond*, the object being to allow for unequal settlement in the foundation. Small breakwaters in shallow waters are sometimes constructed of cribwork—box-shaped frames of timber in openwork with cross partitioning and ties, weighted when in position with rubble—but the system is not very durable and only suitable for comparatively sheltered situations.

Among notable breakwaters of recent date, mention should not be omitted of the very remarkable example at Valparaiso, completed in 1930, which is founded at a depth of more than 50 metres below sea level, on a bottom which consists of sand and mud. In order to reduce the cost of bringing up a mound of rubble from so great a depth, as well as to distribute the load over an adequate bearing area, the expedient was adopted of depositing a bank of sand with a base width of about 500 metres and side slopes of 5 to 1, reaching up to a level of 20 metres below the surface. Over the apex and upper part of this mound were deposited quarry waste and rubble to a level of 12 metres below the surface, at which level the wall of the breakwater was founded.

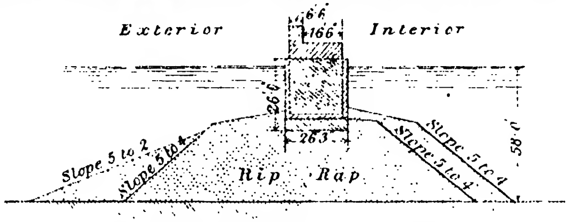

FIG. 9.—Bizerta Breakwater.

DOCKS.

Docks are enclosed repositories for shipping. Where the enclosure is not complete and there is free communication with the sea, the term *Basin*, though not universally employed, is more appropriate. Docks proper are fitted with gates or caissons, either in order to impound the water at a fairly constant level, in which case they are distinguished as *wet docks*, or to exclude the water, in which case they are known as *dry* or *graving docks*. *Floating Docks* are movable structures capable of lifting vessels out of the water and supporting them by their own displacement.

CONSTRUCTIONAL COST OF WET DOCKS.*

(Note: The variety and range of design and equipment render any very effective comparison out of the question.)

	Per acre of Water Surface.		Per acre of Water Surface.
Alexandra Dock, Hull . .	£28,900	Barry Docks	£12,950

Avonmouth Dock, Bristol .	22,600	Queen's Dock, Glasgow . .	24,450

KING GEORGE V. DOCK, LONDON.

One of the most notable docks constructed in recent years is the King George V. Dock at London, which adds 64 acres to the enclosed water area of the port. The dock has a depth of 38 ft., and the quayage aggregates approximately 10,000 ft. A section of the north, west, and east quay walls is given in fig. 13. An unusual feature on the south side of the dock, shown in fig. 14, is the provision of seven reinforced concrete jetties, each 520 ft. long and 22 ft. wide, which have been constructed at a distance of 32 ft. from the face of the main quay wall, the only shore connection being a timber foot-bridge. The arrangement is due to the fact that a preponderating portion of the goods arriving at the port is transferred to barges for conveyance to their ultimate destination up river. Ships are berthed on the outside of the jetties, and the jetty cranes can discharge goods therefrom either on to the quay for delivery to carts or railway trucks, or for sorting or temporary storage at the sheds behind, or, alternatively, into barges lying in the space between the jetties and the wall.

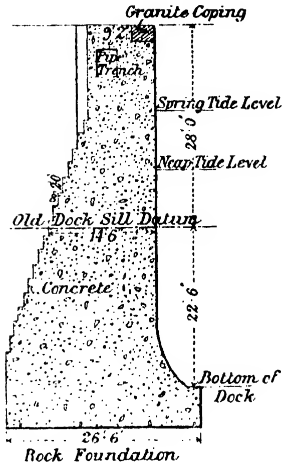

FIG. 11.—Liverpool Dock Wall.

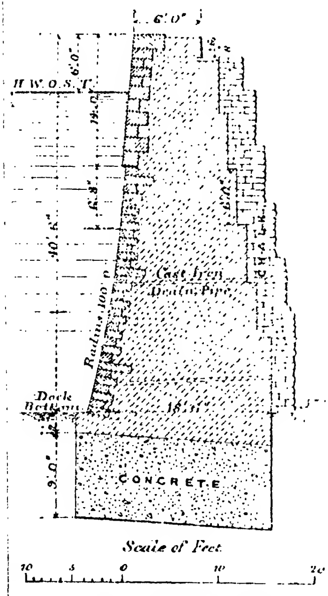

FIG. 12.—Hull Dock Wall.

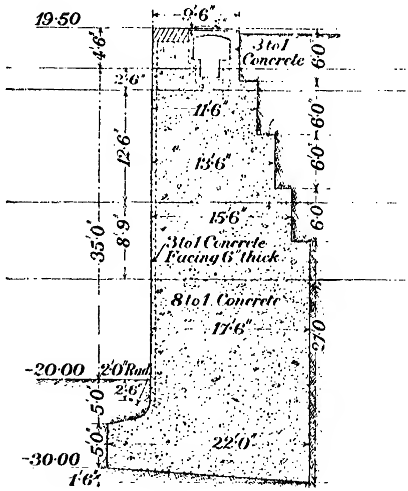

FIG. 13.—King George V. Dock, London: Section of N., E., and W. Quay Walls.

KING GEORGE V. DOCK, LONDON.

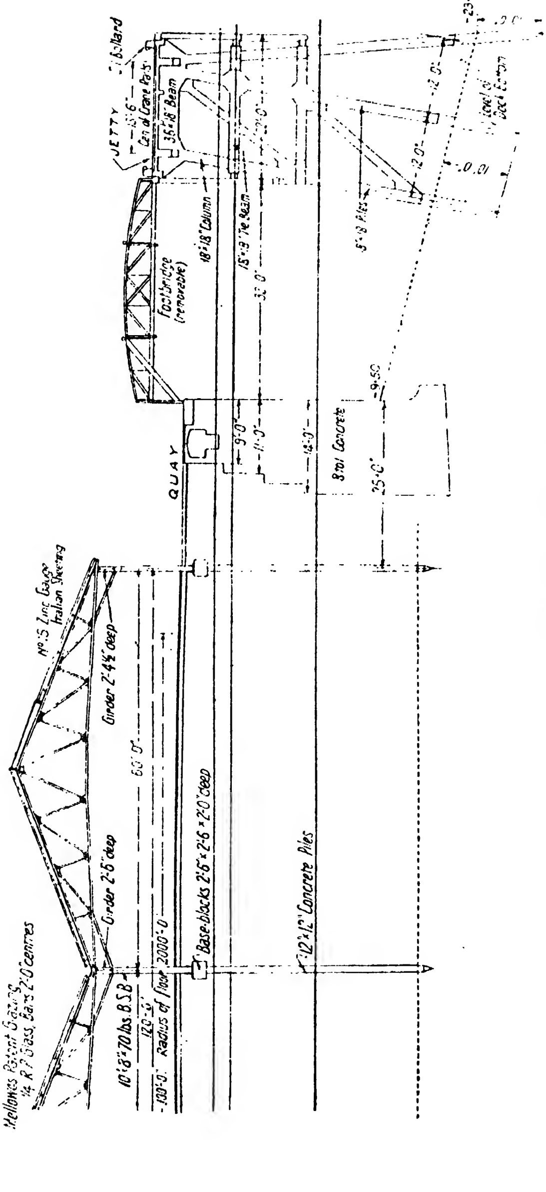

FIG. 14.—Cross-Section of South Quay.

The entrance lock from the river Thames is 800 ft. long by 100 ft. wide, with a depth of water on the sill of 45 ft. below Trinity high water. The chamber is divided into two compartments, of 550 ft. and 250 ft. respectively, by three pairs of steel lock gates, each leaf of which weighs 309 tons. By the use of a floating caisson, for which provision has been made at the inner end of the lock, the available length can be increased to 910 ft. The cost of the dock with its equipment was about 4,130,000*l*.

The Gladstone Docks, Liverpool.

Another notable example of recent dock construction is the Gladstone Dock System of the Mersey Docks and Harbour Board, opened to traffic in 1927. It consists of a vestibule, or turning, basin with two branch docks, the whole comprising a water area of 58½ acres. The vestibule dock is entered from the River Mersey by a lock of outstanding dimensions. It is 1,070 ft. in length and 130 ft. in width, divided into two compartments, with sills 20 ft. below Bay Datum, giving 48 ft. 4 ins. depth of water at H.W.O.S.T., 35 ft. at half tide level, and 22 ft. at L.W.O.S.T. Both the branch docks are 400 ft. wide; one is 1,420 ft., and the other 1,285 ft. long. They are equipped with treble storey sheds of reinforced concrete construction, providing floor areas (including the flat roofs which are designed for light loading) of 32 acres and 23 acres respectively. The system includes a graving dock, one of the largest in Europe. The length of the dock from the head to the inner caisson sill is 1,050 ft. 4 ins. The width of entrance is 120 ft. and there is a depth of water over sill of 43 ft. 6 ins. at H.W.O.S.T. This dock has the peculiarity that it can be used as a wet dock, and for that purpose it is equipped with a single storey shed on its north side.

Eastern Arm Extension of Royal Edward Dock, Avonmouth.

On May 23, 1928, H.R.H. the Prince of Wales opened a new arm or extension, 1,750 ft. long and 400 ft. wide, of the Royal Edward Dock at the port of Bristol which, with a water area of

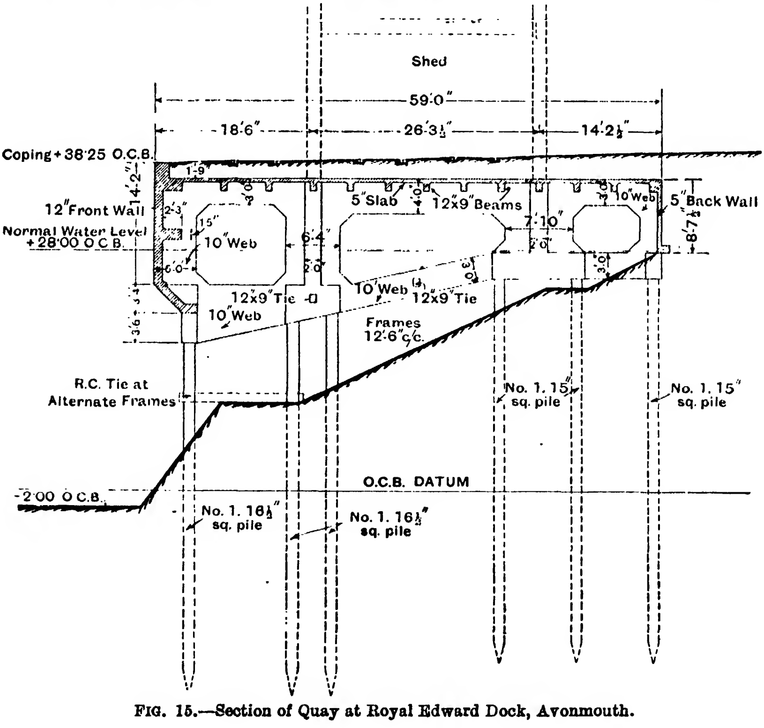

FIG. 15.—Section of Quay at Royal Edward Dock, Avonmouth.

about 17 acres, affords on each of its two main frontages three deep-water berths for large vessels, with an aggregate quayage length of 3,600 ft. The extension has been carried out on lines which, while generally applicable to wharfing, are of some novelty in dock quay construction. In place of a massive wall of the gravity type, there is a system of openwork framing and decking in reinforced concrete, supported on piles of the same material, as shown on the typical section in fig. 15. The number of piles driven amounts to over 4,500, and they are of lengths ranging from 55 to 60 ft. The main frames are set at 12 ft. 6 ins. centres, and the front spacing is made up of concrete slab and beam construction. The cost of the quay was between 70*l.* and 75*l.* per ft. run, covering the reinforced concrete work and the excavation down to the 2½ to 1 slope, within the limits of the front and back wall.

Dock Walls.

Dock Walls.—Under present-day conditions it is necessary for quay walls to possess a perpendicular, or almost perpendicular, face. Ships are now built to a square, box-like section amidships, with vertical sides inclining inwards towards the top. Unless, therefore, there is an absence of batter in the walls, vessels will be unable to lie as closely in contact with the quay coping as is desirable, and quay cranes for loading and discharging them will have to be provided with a greater outreach than is absolutely necessary, at an enhanced cost.

Dock and quay walls formerly, and still, constructed as 'gravity' retaining walls in mass concrete, occasionally faced with brickwork and generally coped with granite or other material resistive of abrasion, are, in many modern instances, designed on more slender lines with the aid of steel reinforcement, so as to dispose of the qualities of both materials to the best advantage in withstanding the thrust of the earth pressure behind. In Germany and Holland a form of quay wall in vogue is constructed from just below water level on a timber platform carried on vertical and raking piles, the wall itself being L-shaped in section, with a base much greater than the height. There are, however, many varieties of design and construction, such as the hollow caisson, cribwork, mattress work, etc., practised under different local conditions. In ground of uncertain nature, the system of well-sinking is adopted for reaching a sound foundation and the wall is built up as a series of 'monolithic' piers, with hollow compartments, which may be filled with sand, or other suitable material.

The *essential features of a 'gravity' quay wall* are weight and resistance to slip. The first is secured by using heavy material and providing ample sectional area; the second by giving a suitable bevel to the surface of the foundation so that it slopes downward from the front of the wall to the back, at the same time taking care that the maximum intensity of pressure does not exceed a certain limit, which, in the case of stiff clay, is 3 tons per sq. ft.; in the case of unconfined sand and gravel is 2 tons; and in the case of soft, uncertain ground, is 10 cwts. per sq. ft.

Stresses in Dock Walls.

Stresses in Dock Walls.—The calculation of the stresses in a dock wall is a very complex problem, involving a considerable number of elements, the exact determination of which is impracticable, so that they have largely to be based on conjecture. Briefly stated, the conditions are as follows: The wall is subjected to the overturning influence of a wedge-shaped mass of earth which represents the excess of material behind the wall lying above the plane of natural slope of the material. The pressure, of course, is intensified by any surcharge upon the surface area of the wedge. The restraining force is the weight of the wall itself, acting vertically downward, assisted to some extent by the earth backing which may rest upon offsets, if any, at the back of the wall.

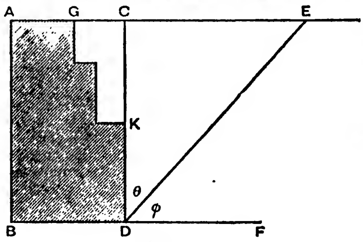

FIG. 16.

In fig. 16, let A B D K G be the outline section of a dock wall.

Let E D be the plane of natural slope of the ground behind the wall, i.e., the slope which the material would assume if left unsupported. The angle E D F will be designated ϕ and is known as the Angle of Repose.

Let the height of the wall A B be h, and w be the weight per unit volume; and let v be the weight per unit volume of the earth behind the wall.

Then the weight of the wedge of earth behind the wall, tending to overturn it, is

$$\frac{vh^2}{2} . \tan \theta .$$

In order to cover cases where the back of the wall is not vertical and where the surface of the ground is not horizontal, this expression may be written in general terms:

$$\frac{vh^2}{2} \times \text{constant.}$$

and the value of the constant, as determined by Professor Rankine in accordance with a theory which neglects any cohesion between the earth particles, is

$$\frac{1 - \sin \phi}{1 + \sin \phi}.$$

The line of action of the overturning force,

$$\frac{vh^2}{2} \cdot \frac{1 - \sin \phi}{1 + \sin \phi},$$

is taken as parallel to the surface of the ground and the point of application at one-third the height of the wall measured from the base.

The above formula, though strictly applicable only to walls with a backing of sand or granular material, in engineering practice has been applied very generally, with results that, as a rule, are 'on the safe side,' though they may in some cases be excessively so for strongly coherent earth backing, such as clay. Résal has shown (*Poussée des Terres*) that the cohesion of the material may increase the value of the angle of friction very considerably beyond the limits usually assigned to ϕ, though with pronounced variations, due to the degree of humidity of the soil. It is well known, of course, that banks of argillaceous earth will, under favourable circumstances, stand almost vertically without support for an appreciable height.

A recent paper by Prof. Frewen Jenkin on 'The Pressure on Retaining Walls' (*Min. Proc. Inst. C.E.*, vol. 234), descriptive of experiments made by him with models, gives what the author describes as a Revised Wedge Theory for sand, which is a departure from Rankine's theory. It cannot, however, be explained with sufficient brevity for notice here.

For simple practical calculations for dock walls where the quay surface is almost invariably

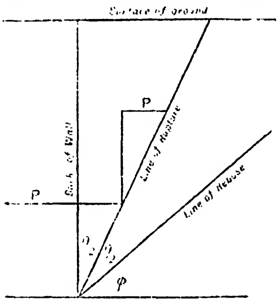

FIG. 17

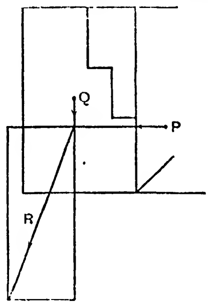

FIG. 18.

horizontal, the angle θ ($=90° - \phi$) is bisected and the value $\frac{\theta}{2}$, fig. 17, taken as representing the angle of the wedge producing maximum pressure, the other moiety being ineffective as regards overturning owing to the support it receives from the earth beneath it. The weight of the triangle $\frac{h^2}{2} \tan \frac{\theta}{2}$ is computed, and the horizontal component, P, taken of the force acting down the plane of rupture, of which $v\frac{h^2}{2} \tan \frac{\theta}{2}$ is the vertical component. This constitutes the overturning force, which may accordingly be written:

$$P = \frac{vh^2}{2} \tan^2 \frac{\theta}{2}$$

The point of application of P is again at one-third of the height of the wall.

The restraining force Q is measured by the sectional area of the wall A B D G, fig. 16, multiplied by w, together with the sectional area of the earth G K O resting on the wall, multiplied by v, the two acting vertically downwards through their common centre of gravity.

Calling the overturning force P, and the restraining force Q, fig. 18, and completing the parallelogram of forces, the resultant R will be obtained, representing in magnitude and direction the force acting at the base of the wall.

So long as the line of action of R falls within the base of the wall, there is theoretical stability, but, for practical constructional purposes, it is essential:

(1) That the line of action of R should not fall outside the middle third of the base line, and

(2) That the magnitude of R should not be sufficient to crush the base; in which connection it is to be noted that the intensity of pressure increases with the eccentricity of the resultant (i.e. its distance from the centre) and that when R passes through the limiting point of the middle third of the base, the intensity of pressure on the outer edge is just twice the mean intensity

As a rough practical rule in designing dock walls, the mean width or thickness may be made about one-third of the height. It should never be less than one-fourth. The base width may be about one-half the height, but need never be more than two-thirds.

Entrance Locks.

Entrance Locks.—During periods when the water in a dock is impounded at a higher level than that of the external water (in some cases continuously), the dock can only be entered through the medium of a lock. The size of lock chambers is governed by the dimensions of the ships making use of them, and these vary at different ports. A large vessel was the 'Normandie,' with a length over all of 1,027 ft.,† a breadth of 118 ft., and a loaded draught of 36·6 ft. The length of 1,000 ft. is, perhaps, somewhat extreme, but there are a number of vessels from 900 ft. to 950 ft. long, by 95 ft. to 100 ft. broad, and they draw from 35 ft. to 40 ft. of water when loaded to full capacity. No port can claim to be of the first rank which does not receive vessels from 500 to 600 ft. long, with 60 to 70 ft. beam and drawing 30 ft. of water.

Some examples of modern dock entrance locks are as follows:—

Name.	Port.	Length of Chamber.	Width of Entrance.	Depth of Water over Sill at H.W.

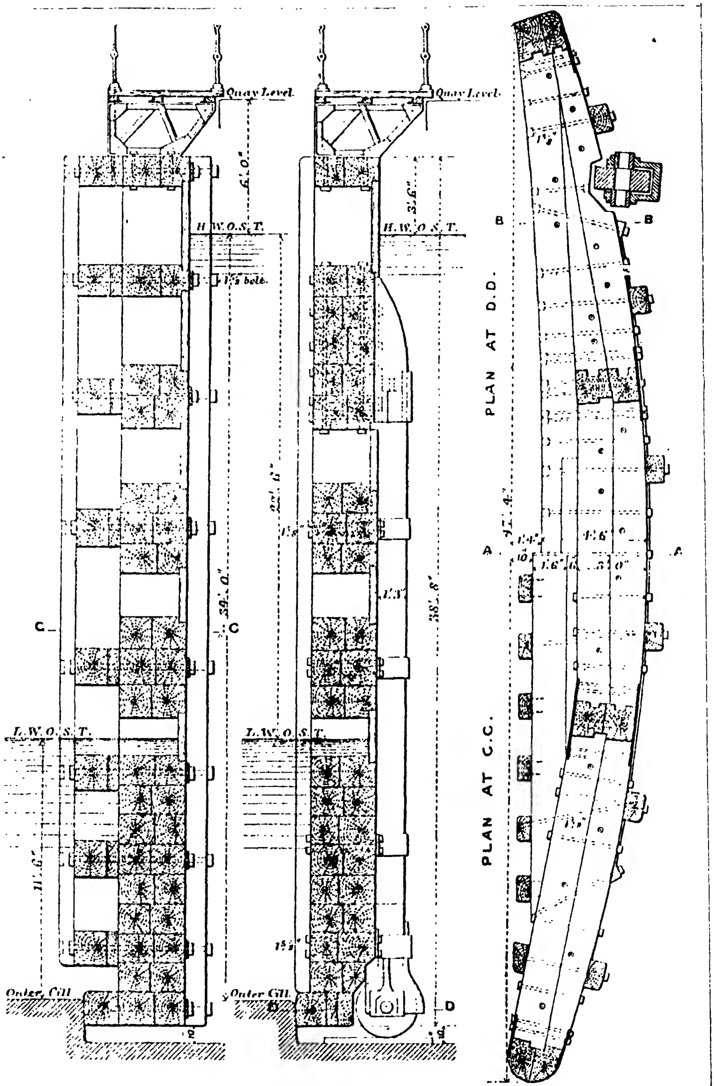
See also some prominent examples of Ship Canal Locks in Section XVI., page 599.

Dock Gates.

Dock Gates.—Where the rise and fall of the tide does not exceed about 12 ft. the inducement to provide completely enclosed areas for shipping is not great, but above that limit the necessity for impounding the dock water becomes evident on account of the inconvenience arising from rapid changes of level, frequent alteration in moorings, and chafing against the quayside.

Dock gates are either of steel or wood—in the latter case of greenheart, jarrah, or other hard, heavy, durable timber. Greenheart gates cost more than steel gates—in some cases nearly 50 per cent. more—but their natural durability is very great and the cost of maintenance practically nil. Unfortunately, they are subject to the attacks of sea organisms, and in certain ports considerable trouble has been experienced from this cause. Salt water, especially if contaminated in any way with sewage, is extremely deleterious to ironwork, and the life of a steel gate, under these circumstances, can scarcely be expected to exceed 30 years. Greenheart gates have been found in excellent condition at the end of 50 years.

* See footnote, page 606. † The length of the 'Queen Mary' is slightly less, 1,018 ft.



SECTION ON A.A. SECTION ON B.B. PLAN.

Scale of Feet

10 5 0 10 Feet

The generality of dock gates swing vertically and, consisting of two leaves which meet at an angle in the centre of the waterway, are recessed within the side walls when the passage is clear for shipping. A rather different type of gate is the 'Box' gate, which is specially adapted to conditions of site in which side recesses for ordinary double leaf gates would be inconvenient. It is a single leaf gate with a hinge or keel running horizontally across the sill, and it is lifted or lowered by means of wire ropes. When the passage is open, the gate lies in a prone position below sill level. A recent example at the entrance to a graving dock, 85 feet wide, on the river Clyde, is described in *The Engineer* of February 17, 1933. Another example at the entrance of the Dover Train Ferry Dock is described in *Min. Proc. Inst. C.E. Journal*, December 1937.

Stresses in Dock Gates.

Stresses in Dock Gates.—Dock (double-leaf) gates are maintained in equilibrium under the action of four external forces:—(1) the resultant pressure of the water against the back of the gate $= \frac{wh^2}{2}$ per lineal foot of gate, where w ($62\frac{1}{2}$ lbs. for fresh, 64 lbs. for salt water) is the weight of a cubic foot of water, and h its height behind the gate. This force acts horizontally at one-third of the height. When there is water on both faces $p = \frac{w}{2}(h^2 - h_1^2)$, and the line of action is determined by the centre of gravity of a quadrilateral representing the difference in pressure. (2) The reaction of the mitre or meeting posts of the gates acting perpendicularly to the meeting

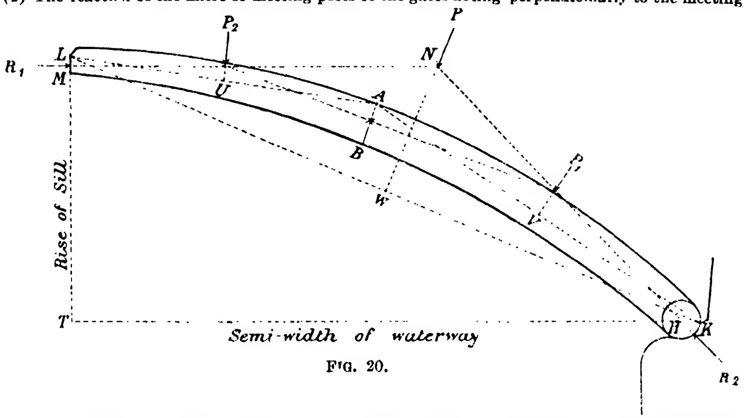


FIG. 20.

faces, and therefore also perpendicular to the centre line of the waterway. (3) The reaction of the hollow quoins passing through the heel-post of the gate and also through the point of intersection of the other two forces. (4) The reaction of the sill, which is generally neglected.

Fig. 20 represents the plan of one leaf of a pair of gates. P is the total water pressure upon the back of the leaf, assumed concentrated at its centre. R_1 is the mitre-post reaction of the adjoining leaf, taken as passing through the centre line of the abutting surfaces. R_2 is the reaction of the hollow quoin, assumed to act through the axis of the heelpost. These three forces being in equilibrium, the triangle of forces *ors* (fig. 21) can be drawn, having its sides parallel to the forces P, R_1, and R_2 respectively, and since the magnitude of P is known, the magnitudes of the other two are determined.

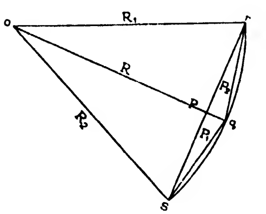

FIG. 21.

If now it be required to find the position and amount of the resultant stress across any section AB (fig. 20) of the gate, the procedure is as follows:—Join the point A to each of the extremities K, L of the water-bearing surface of the leaf; bisect these lines at U and V respectively, and draw perpendiculars to represent the total water pressure on each section. Each section is in equilibrium under the action of three forces: in one case, the water pressure, the heelpost reaction, and the stress across AB; in the second case, the water pressure, the mitre-post reaction, and also the stress acting across AB in the opposite direction. Join the points of intersection of the known forces to obtain the line of action of the resultant pressure at the section AB. Its magnitude may be determined by drawing a parallel line, qo, in the force diagram from the point o (fig. 21). By taking a series of sections in this way, it will be found that the locus of q is sensibly the arc of a circle, and therefore that, except in the case of very flat gates, the resultant pressure is so nearly constant as to be justifiably considered so without serious error.

Rise of Sill.—The 'rise of sill,' MT (fig. 20), varies in different cases from ¼ to ⅕ of the 'span of the gates' or width of waterway. The vicinity of the latter limit is the more common, especially for large cylindrical gates, where a large rise would entail a correspondingly long and deep recess in the side walls.

CAISSONS

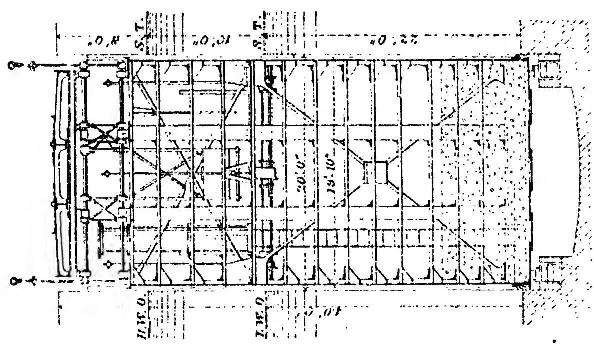

Fig. 23.—Section of Traversing Caisson.

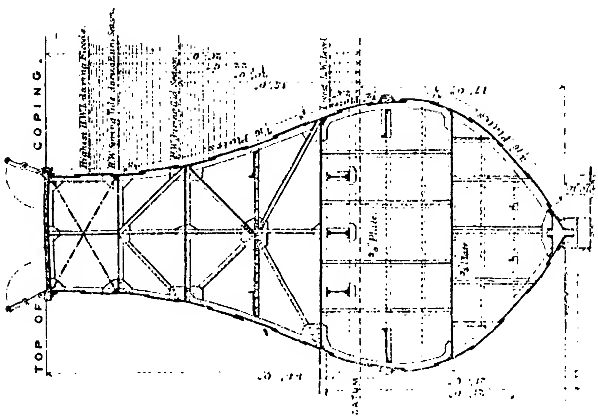

Fig. 24.—Section of Ship Caisson.

Caissons.

Caissons, which are hollow, framed structures of steel, with a platform at or about quay level, are sometimes preferred to gates for closing dock entrances, on the ground that they do not absorb the length of side walls which is required to house gates when a passage is open. Furthermore, although the first cost of a caisson is undoubtedly in most cases greater than that of a pair of gates, yet if the cost of a swing bridge for vehicular traffic, which is a necessary adjunct in the case of gates, be also taken into consideration, the advantage will be found to lie with the caisson.

Caissons are mainly of two types: traversing and floating. Traversing caissons are rectangular boxes with a rectilinear motion either sliding or rolling. When withdrawn from the passage way, they are housed in a special chamber constructed in the side wall. Floating caissons are usually ship-shaped, having more or less the form of a navigable vessel, though the curvature of the sides varies very much with the depth of water in which they have to float. Floating caissons are not easy to manage in boisterous weather and strong currents.

QUAYSIDE APPLIANCES.

Quay Cranes.

For general work, quay cranes range in lifting capacity from 1 to 3 tons. For hydraulic cranes the usual capacity is 30 to 40 cwts. It very often happens that the parcels from a ship's hold do not exceed 12 to 15 cwts., and, under these circumstances, a hydraulic crane of single and much higher power than this cannot be worked to advantage, as the consumption of pressure water is the same whether the load be infinitesimal or the maximum. Electric cranes are better adapted to variable loads, since the current consumed is directly proportional to the work done. On the other hand, the initial cost of electric cranes is some 30 to 40 per cent. more than that of hydraulic cranes, and the capital charges (interest and depreciation) are factors of considerable importance in estimating the relative economy. Electric cranes are now commonly installed at leading ports with 3 tons maximum capacity.

Crane Types.—Quay cranes are generally movable and include several types.

(*a*) The ordinary crane, with a wheel gauge of 10 to 15 ft. running at quay level.

(*b*) The portal crane, with an arched base spanning one or more lines of railway sidings and admitting of the passage of rolling stock beneath the crane.

(*c*) The semi-portal crane, like an inverted L, with one leg or support running on a rail at quay level, and the back support carried by a rail at a higher level on an adjacent shed structure, the object being the same as in the case of the portal crane.

(*d*) The roof crane, carried entirely on the roof of the shed or warehouse.

Types (*a*) and (*d*) are adapted to cases where there are no sidings, and type (*d*) where the shed is situated close to the edge of the quay.

The *cycle of operations* of a quay crane consists of lifting from a hold, slewing, depositing, and returning unloaded, and should, in ordinary cases, where the range of lift does not exceed 50 or 60 ft., be performed in about one minute. A good average under favourable conditions would be 50 cycles per hour; but spread over any lengthy period, this rate could hardly be maintained, for reasons entirely unconnected with the crane.

Speeds of Quay Cranes.—The ordinary speeds of 30 to 35 cwts. quay crane machinery are as follows:—

Lifting, full load	250 ft. to 300 ft. per min.
Lifting, light	350 ft. to 400 ft. per min.
Lowering, full load	400 ft. per min.
Lowering, light	150 ft. per min.
Slewing	one revolution in 25 or 30 seconds.

Luffing Cranes.—It is an important consideration in modern quayside work that cranes should have considerable outreach. Not only is it necessary for them to plumb the hatchways of vessels moored alongside, but in many cases it is desirable to command a barge or lighter beyond. This involves an outreach of 50 to 60 ft. from the face of the quay for even vessels of moderate beam, and entails a luffing or derricking movement of the jib. In view of the obstruction to radial movement caused by ships' yards and stays, the luffing of the crane jib has of recent years become

* See footnote, page 606.

an important feature of crane design. Formerly, the load was unavoidably raised during the inward travel of the jib with a correspondingly unnecessary expenditure of energy and time. This has now been obviated by the introduction of compensating luffing gear by means of which the load is carried at a uniform level throughout its range of travel.

Compound Cranes.—Quay cranes have generally a radial action, and though the luffing gear provides a rectilinear motion, the movement of goods is mainly along a more or less circular path. The joint effect is to afford considerable scope for the deposit of goods on the quay in contradistinction to cranes of the transporter type, which can only function along a straight line and often only deposit at a single point. Such cranes, however, have an advantage in being able in certain cases to transmit their loads within a transit shed and so under cover. At Hamburg, a combined type of quay crane has been introduced with the usual radial jib on a rotating platform above, while below, within the framework of the pedestal, there are one or two crabs travelling on horizontal tracks at right angles to the quay front. The aggregate power of these cranes is considerable, reaching to as much as 6, and even 9, tons.

Fixed Quay Cranes.—Fixed quay cranes are provided for dealing with special loads of considerable calibre. The powers provided are generally 5, 7, 10, 12, 15, and 25 tons, with appliances at first-class ports ranging up to 150 or 200 tons. The rates of lifting are correspondingly slower; about 150 ft. per min. for 5-ton cranes, 30 ft. per min. for 25-ton cranes, and 20 ft. per min. for 50-ton cranes.

Burtoning.

General cargo is mainly, and in fact almost universally, handled at North American ports by a system known as Burtoning, which is the same in principle as the Union Purchase used at English ports in conjunction with ships' gear. At American ports, the sheds are equipped with cargo masts, generally prolongations of the shed front columns, rising to a height of 80 ft. or so above the quay level and supporting a longitudinal girder, or rail, running the full length of the shed. To this rail, at any selected point, a pulley may be attached, worked with a line, one extremity of which is joined, with a similar line from a pulley at the extremity of a ship's boom, to the hook carrying the load. Two winches are required for operating: one for each line. The ship's winch and line serve to lift the load from the ship's hold to deck level; the shed winch then takes charge, and by means of the shed line draws the load overside to the quay, where it is lowered to the ground.

Floating Cranes.

Floating Cranes.—For the heaviest lifts, floating cranes are often preferred. It is a convenience to bring the crane to the ship rather than *vice versâ*. Against this must be set the greater initial and working cost of a floating crane. Floating cranes are provided at most first-class ports of lifting power ranging from 25 to 100 or 150 tons. A floating crane recently built for a Japanese port has a working load of 200 tons at 105 ft. radius, 100 tons at 150 ft. radius, and 30 tons at 160 ft. radius. The heaviest lifts are performed at the rate of 5 ft. per minute. A revolution takes 6 to 8 minutes.

A floating crane of 200 tons capacity is among the plant of the Mersey Docks and Harbour Board. It is an electrically-driven, derricking, and revolving crane, 154 ft. in length, 88 ft. in breadth, and 16 ft. in depth. The hoisting speeds vary from 6 ft. per min. for loads of 200 tons, to 20 ft. per min. for loads of 60 tons. The highest point of the jib at its highest position is 246 ft. above the water-line, with a maximum radius for loads of 60 tons amounting to 183 ft., and for loads of 200 tons, to 110 ft. The vessel is named the *Mammoth*; in conjunction with its outreach it is claimed to possess the largest lifting capacity of any existing floating crane. There are, however, two floating cranes of 250 tons capacity at the Panama Canal.

Even for relatively small power lifts (5 tons or less) floating cranes are employed with advantage at some French ports where the conditions are favourable for their use. The length of the crane pontoons are about 60 ft., a convenient dimension from the point of view of manœuvring; the width increases (to prevent transverse oscillation) from 17 to 31 ft. in proportion as the power of the cranes increases from 1½ to 5 tons and the outreach from 25 to 50 ft. The height of the jib pulley varies from 53 to 65 ft. above water level.

(See also CRANES, Section XXXVIII, Part I.)

Transporters.

Transporters.—Where loads are uniform, can be readily handled, and have to be transmitted some distance, a transporter offers considerable facilities for dealing with them at high speeds, ranging up to 1,200 or 1,500 ft. per minute. Quayside transporters have generally to be furnished with hinged cantilever ends capable of being raised when out of action. The travelling motion is not necessarily rectilinear, curved tracks being employed where necessary.

Coaling Appliances.

Shipment of Coal.—Coal is shipped in a variety of ways. The simplest method is that practised on the north-east coast, where the altitude of the banks of the rivers Tyne and Wear enables discharge to be made direct from wagon into steamer by means of 'staiths,' which are wharves or jetties provided with shoots inclined downwards towards the holds. Apart from this, the appliances used at low-level quays comprise the hoist and tip and the coaling crane, as also the belt conveyor travelling up an incline, which is perhaps most developed in the United States.

The belt conveyor requires a layout on the quay, which is not always practicable or convenient in congested areas such as prevail at English docks. The hoist raises the wagon to the requisite height and tips it at an angle of 45° or 50°, so that the contents pass into a shoot. The crane lifts the wagon bodily, slings it over the ship's hatchway and there empties it. The protection of coal from breakage is of such importance that in nearly all cases where coal is tipped from a considerable height, anti-breakage appliances are provided to deposit the first few loads at the bottom of the hold.

Coal wagons in this country are commonly built to contain 10, 12, 15 or 20 tons of coal, and the gross weight ranges from 15 to 30 tons. To this must be added from 6 to 9 tons for the cradle or platform. Consequently the lifting capacity of a coaling appliance will range between 20 and 40 tons according to the class of wagon dealt with. In certain special cases, as at Goole Docks, provision is made to lift a gross load of 50 or 60 tons, of which up to 40 tons is coal. The coal is brought along the Aire and Calder Canal in tanks, which are floated under the hoists.

In America the size of coaling wagons is very much greater and varies from 40 tons upwards to 100 or 120 tons. At British ports attempts are now being made to secure the general adoption of larger-sized wagons (20 tons capacity) than has hitherto been the practice.

The rate of coaling by an ordinary crane or hoist is from 300 to 450 tons and may even reach 600 tons per hour, but it is largely governed by the rate of trimming operations in the hold. The lifting and lowering of the wagons is done at speeds of between 100 and 180 ft. per minute and slewing at about one revolution per minute.

The belt conveyor consists either of a continuous rubber belt or of articulated steel plates. Of the two, the rubber belt has shown itself to be more convenient and more durable than the steel plating, the wear on which is considerable. Rubber belts are run at rates up to 600 or 700 ft. per minute, and they discharge the coal in a continuous stream. The belt is fed by means of a hopper recessed in the quay, into which the coal wagons are emptied. Installations in this country are of moderate proportions, the width of the belt running up to about 48 ins., but in the United States very much larger installations have been effected with belts of 60 ins. diameter. These belts travel up inclined ways to the summit of movable towers, whence the coal is passed on to a transverse belt discharging into the ship. Considerable expedition has been gained by the use of the mechanical trimmer, which is a short, rapidly rotating belt at the foot of the vertical shoot leading into the hold. The speed of the trimmer belt ranges up to 2,000 ft. per minute, and the acquired velocity projects the coal forward into all parts of the hold to distances up to 40 or 50 ft.

Ship's Bunkering.—The foregoing appliances are in vogue in connection with shipping coal cargoes. For the more moderate requirements of ships' bunkers, the loading appliance has generally to be brought to the ship's side, so as to proceed simultaneously with cargo discharging or loading operations. A good deal of bunkering is done by hand, with such primitive assistance as is afforded by baskets, ropes, pulley blocks, and winches, but the rate of coaling under such conditions is very slow and relatively costly—perhaps 2 tons per man per hour. There are a number of special floating machines provided at important ports for doing the work more expeditiously. A typical example, and one of the most modern designs, is the Sulsted Elevator, built for the company of that name by Spencers (Melksham) Limited, and at work in the port of London. It is capable of handling 300 tons of coal per hour, but such a rate is manifestly only practicable under favourable circumstances; it could not be maintained with trimming operations going on.

Coal Discharge.—For the importation of coal, as also of ore, the grab is perhaps the appliance most commonly in use in this country, as also on a much more gigantic scale at the Lake Ports of North America. As used at English ports, the capacity of the grab runs up to 6 tons, with a total combined load, including the grab itself, of about 12 tons. At the Lake Ports of North America the standard type is a grab capable of taking a load of 12 tons, and the largest can take 17 tons. There is a 'bucket' for clearing up the holds at the close of operations, which when outspread has a span of 24 ft. between the bucket lips.

Grain Elevators.

Grain Elevators.—Grain is handled either by the bucket elevator and conveyor, or by the pneumatic elevator or suction apparatus. The latter has the advantage that the pipes, being flexible, can easily be taken to the furthermost parts of a ship's interior, and that no restrictions are imposed by variations in freeboard and depth of hold. The bucket elevator, though cheaper to construct and requiring less power, is hampered in working by the necessity of ploughing and trimming a preponderant portion of the grain—often as much as 80 per cent.—to the elevator leg. A special gang of competent men is required for the purpose, and this, of course, increases the cost of handling.

It is impracticable to do trimming with a ship's winch at a higher average rate than about 80 tons per hour. Beyond this limit the pneumatic machine becomes more effective, and pneumatic elevators can be constructed so as to give outputs of between two and three hundred tons per hour. In practice something like 200 tons per hour is quite a normal rate.

Pneumatic plants are now commonly in use in warehouses and mills for handling granular material. One of the great advantages is freedom from dust which is a desideratum in handling foodstuffs and other material which must be kept clean.

An objection urged against the suction apparatus is that the surface friction of the pipes tends to injure some of the more delicate classes of grain, such as malting barley, but this drawback, for all practical purposes, has been eliminated of late years by the easing of bends and the removal of all internal projections in the pipes. In any case it should not be overlooked that the cutting and driving action of the buckets of a bucket elevator cannot be without some similar attritional effect.

Bucket elevators are either housed at the quayside or are mounted on barges, in both cases being fitted with derrick supports and suspension gear to enable them to be projected forward and set into the ship's hatchway. Elevator speeds generally range between 200 and 400 ft. per minute, but may be as high as 600 ft. per minute. Band or belt conveyors run at 300 to 600 ft. per minute, but for light grain, such as oats, the speed should not exceed 500 ft. per minute.

The development of the pneumatic operation of handling grain has been very marked in recent years. The slow-speed horizontal reciprocating steam-driven suction pumps have been largely superseded by quick-acting vertical pumps driven by internal combustion engines which are coupled direct to the pumps. A further development is the introduction of a multi-stage air exhauster, also driven in many cases by an internal combustion engine through speeding-up gear. This type is perhaps coming mostly into favour, especially where electric power is available.

Timber Appliances.

Timber, as received at ports, is generally divided into the categories of hard wood and soft wood, the former comprising logs of greenheart, teak, oak, etc., and the latter consisting chiefly of deals, battens, and boards of pine and spruce. Logs are handled overside by crane and either floated to timber ponds or conveyed on trollies to storage sites. In Liverpool a special arrangement of tandem axles is employed to which the logs are underslung.

Cargoes of deals may consist of from 150,000 to 300,000 pieces of various sizes and marks. This renders the use of apparatus of the conveyor type difficult and unsuitable, although such appliances have been successfully installed in certain cases. Generally speaking, cargoes of this class are best dealt with by steam cranes of moderate capacity (30 cwts. to 2 tons) which, arranged to run at right angles to the quay front, convey their loads to an adjacent storage ground at speeds up to 600 ft. per minute. The lifting speed is about 160 ft. per minute, and the slewing speed about 1½ to 2 revolutions per minute.

There is an appliance in use at American ports as well as at sawmills and lumber yards which has proved very serviceable for handling timber. It is known as the Ross carrier, and is a framed motor-driven carriage, standing about 9 or 10 ft. high, the driver's seat being at the top. The framework is of arched or pierced pedestal type, so that the carriage can run astraddle of the load to be lifted, which is placed on 'bolsters,' or cross-bearers, on the ground. Suspended from the carriage chassis are two adjustable side frames with angle iron clips which can be lowered, brought under the bolsters, and then raised to a height of a foot or so to give the necessary clearance for travelling. The carrier transports its load at a speed of 12 to 15 miles per hour. The load to be carried may be 3 ft. wide, 4 ft. high, and of any ordinary length of deals; the carrier frames being about 12 ft. long, the deals project back and front. The carrier can also be used for logs and timber in baulk within the same limits of width and height. The carrying capacity is 10,000 lbs. The appliance is used in connection with a sorting table, known as the Ross break-down rig or drop table, which receives the parcel of deals from the carrier and drops, thereby releasing the deals from the bolster and placing them on a series of chains which serve to break down the load, so that it can be spread over the table and sorted to grade and size.

GRAVING AND FLOATING DOCKS.

A modern graving dock is an excavated chamber with a floor, two sides and an end wall, all of these being usually constructed of concrete, which may, in certain cases, be faced with brickwork, granite or other material. A few of the older graving docks are to be found with wooden floors over a concrete or masonry base. The remaining end of the chamber is the entrance, and is closed, as occasion requires, either by a single gate, or a pair of gates, or again by a caisson, which may be either of the sliding, rolling or floating type. When a single gate is used, it is of the 'Box' type, hinged at the sill and falling flat into a recess below the sill, when open (see page 619). Double gates are pivoted, or hinged, into the side quoins of the entrance, and move in a vertical position through the arc of a circle.

Suitable culverts are provided for emptying and filling the dock. After the entry of a ship, the entrance is closed and the water is pumped from within the dock, though, in certain cases, where graving docks are entered direct from a river or open waterway where tidal conditions prevail, the operation may be assisted, and sometimes be altogether effected, by the fall of the tide.

The floating dock is an open-ended, hollow structure of steel which, in order to receive a vessel, is sunk to the requisite depth, by allowing its interior chambers to fill with water. When the vessel has been berthed, this water is pumped out, the dock rises bodily and so lifts the vessel above the water-level.

It is not altogether easy to make an effective comparison of the respective merits of graving and floating docks, on account of the wide divergence in the conditions to which each structure is specially applicable, and, although there are strong and convinced advocates for the general superiority of one or other of the two systems, a brief summary of the most salient considerations will show that it is scarcely justifiable to decide conclusively in favour of either. Floating docks are very widely adopted in Germany and Holland and at various other Continental ports: in Great Britain there are more graving docks than floating docks.

A graving dock requires a good foundation at a reasonable depth and a disposition of site which frequently involves the appropriation of a considerable area of valuable land.

A floating dock requires a sheltered position with an adequate depth of water which, if not obtainable naturally, will have to be gained by dredging. The depth of water to be provided for a floating dock must be sufficient to cover the draught of the ship, the depth of the pontoons and the requisite clearances of a foot or so between keel and blocks and between pontoon and bed.

As a typical example, the Wellington Harbour (N.Z.) floating dock, of 17,000 tons lifting power, has a draught over keel blocks of 26 ft., and requires a depth of water of 46 ft in which to work when a ship of the maximum draught has to be lifted. Where there is tidal variation, if ships of the maximum draught are to be docked at low water, the site may require some dredging to give the necessary depth of water under these conditions, but when the range of tide is very considerable it is not always considered necessary to make provision for docking ships of maximum draught at lowest tide level.

In sites where the foundation is defective, the depth of excavation required for the floor of a graving dock may easily equal the depth of the floating dock pontoons, and the difficulties and expense in these cases are just as pronounced.

The utility of a graving dock is measured by the linear dimensions of the largest vessel which it can accommodate. The weight of the vessel is relatively a matter of little or no importance.

On the other hand, the utility of a floating dock is gauged by its maximum lifting capacity and is independent of the exact size of the vessel. Floating docks can, and often do, take vessels several feet in excess of their own length and, in the case of one-sided docks, in excess of their own width.

The size of the entrance of a graving dock is influenced by the cost of the gates, or caisson, to be used for closing it, and by the greatest width that can safely withstand the pressure of water. In floating docks these considerations do not enter into account.

Broadly speaking, apart from the physical conditions of the site, it may be said that for ships needing long and heavy repairs, the graving dock has certain advantages, while for the execution of light repairs, painting and hull inspection, such as form the major part of the work done in a dry dock, the floating dock affords quicker and more convenient service. Both classes of work, however, can be carried out in either type of dock with equal success.

Relative Costs of Graving and Floating Docks.*

Initial Cost.—The initial cost of a number of concrete and stone graving docks, including pumping and general equipment, measured in terms of their serviceable dimensions (*i.e.* internal length by breadth of entrance by depth of water over blocks or sill), has varied in the past from 1*s.* 3*d.* to 3*s.* 6*d.* per cubic foot.

The cost of floating docks is usually measured in terms of their lifting power, and varies inversely as the size of the dock; it has ranged from about 14*l.* per ton for a dock which would take small coasting ships to about 6*l.* per ton for one to take large Atlantic liners.

As regards time of construction, a graving dock of any importance could hardly be completed within less than eighteen months or even a couple of years, whereas a floating dock could be ready in half the time. The floating dock could, moreover, be constructed in any convenient locality and transported to its destination at some additional expense for towage and insurance. Many floating docks for the colonies are constructed in home shipyards.

Durability and Upkeep.—A stone or concrete graving dock is practically indestructible, and the only charge brought against it, in this respect, is that of outlasting its utility and becoming obsolete. This is, no doubt, true in regard to the class of vessel for which it is constructed; but, on the other hand, when the growth of shipping has left the graving dock too small for the larger vessels, it is still utilisable for those of smaller size. With the exception of the expenditure on the gates or caisson, which close the entrance, there is practically no maintenance outlay. It is all probably covered by an allowance of $\frac{1}{5}$ per cent. per annum.

The life of a floating dock, considered as an iron or steel structure constantly afloat, will vary with its situation, some waters being more destructive than others. It may be fairly reckoned at from 40 to 50 years, and there is no reason why, with reasonable care and attention, the longer period should not be exceeded. The annual cost of maintenance estimated from several existing examples lies between 1 and 1½ per cent. of the capital outlay. Any cost of dredging required to keep the berth clear of mud deposits must be added to this allowance.

Working Cost.—The amount of pumping to be done in the case of a graving dock generally greatly exceeds that in the case of a floating dock—it may be as much as 3 or 4 times. In a floating dock only so much work is required to be done as is necessary to raise the vessel and the deck of the pontoon above water level. The graving dock chamber, on the other hand, has always to be completely pumped out, no matter what may be the size of the vessel occupying it, and the smaller the vessel the greater the quantity of water to be pumped.

Small graving docks on the banks of a tidal river, in cases where time is unimportant, may be emptied of water by natural means. These cases are exceptional.

But even in the larger docks the cost of pumping is small in comparison with the capital charges. For one hundred dockings a year they probably do not amount to more than 10 or 12 per cent. of the whole annual expenditure.

* See footnote, page 606. The figures quoted are for comparative purposes only. They are not applicable strictly to present conditions.

Again, the pumps being only intermittently employed, one pumping station may be made to serve two graving docks, whereas each floating dock requires its own installation.

As regards general adaptability, floating docks have the advantage, already pointed out, of mobility, and they may be transferred from one port to another, whenever the circumstances require. This has already been done on several occasions to meet altered trade conditions, or for purposes of war.

A floating dock can be trimmed to take a vessel having a list which conceivably might interfere with its passage through a graving dock entrance with vertical sides. This operation was frequently performed during the war.

The mobility of a floating dock is not free from certain drawbacks. The dock may founder or be wrecked. The movement of floating docks is, however, very infrequent. It happens occasionally that a dock is constructed at a British shipyard for towage to a foreign destination.

All these varying considerations point to the conclusion that there is scope for both graving and floating docks, and that each may be employed to better advantage than the other under some particular set of local conditions.

SOME OF THE LARGEST FLOATING DOCKS IN THE WORLD.

Location.	Lifting Capacity.	Length.	Inside Width.	Depth of Water over Keel Blocks.	Owners.
	Tons.	Ft.	Ft.	Ft.	
*Southampton	60,000	960	130½	38	Southern Railway Co.
Singapore	50,000	855	126½	40	British Admiralty.
Rotterdam	46,000	695	142	35	Wilton's Eng. & Slipway Co.
Hamburg	46,000	575	123	33	Blohm & Voss.
Malta	65,000	962	140	38	British Admiralty.

THE SOUTHAMPTON FLOATING DOCK.

The following particulars are extracted from a paper read before the Institution of Civil Engineers in January 1925, by Dr. E. H. Salmon (*Min. Proc. Inst. C.E.*, vol. 219):

Weights and Lifting Power.—The total net estimated weight of the dock in its final form was 18,990 tons, made up as follows:

	Tons.
Steelwork in hull, including mooring-booms	16,482
4½ per cent. for rivets	741
Joint bolts	17
Machinery	404
Fittings	736
Timber	407
Cranes, crane-rails, and collecting gear	183
Stores and spare gear	50
Proportion of weight of brow and moorings carried by dock	33
	19,053
Less half-weight of mooring-booms	63
Total	18,990

The above weight does not include any allowance for overweight and extras. From measured displacements of the finished dock its actual weight was found to be 19,330 tons. The displacement of the pontoon at Southampton (density of water = 35·09 cubic feet per ton) is 81,840 tons. At the conclusion of the test made to determine the lifting power of the dock, 1,530 tons of water remained in the pontoon. The true lifting power of the dock, therefore, is 81,840 — 19,330 — 1,530 = 60,980 tons.

Cost.—The original contract price for the dock delivered at Southampton was £375,000. The corresponding price of the steelwork in the hull comes to £17 per ton; the machinery, about £120 per ton; the fittings, about £32 per ton; and the timber, £22 per ton. A number of extra fittings over and above the original contract have been added, somewhat increasing the total cost of the finished structure. The above figures include the dock proper and mooring booms, but not the shore work, nor the preparation of the site.

* Information as to the post-war existence of this and others is lacking.

PARTICULARS OF SINGAPORE FLOATING DOCK.

(*Built* (1928) *by Swan, Hunter, & Wigham Richardson, Ltd., Wallsend-on-Tyne, for the British Admiralty for service at Singapore.*)

Lifting capacity	50,000 tons
Length	855 ft.
Breadth outside	172 ,,
Clear width between fenders	126 ft. 6 ins.
Height of side walls and pontoon	75 ft.
,, walls from pontoon deck	50 ,,
Steel weight, including joint bolts, castings, etc. . . .	21,750 tons
Number of rivets	3,500,000

Pumping capacity: 30,000 tons per hour, viz.:

Three pumps, each expelling 6,000 tons of water per hour.
Two ,, ,, ,, 4,000 ,, ,, ,,
Two ,, ,, ,, 2,000 ,, ,, ,,

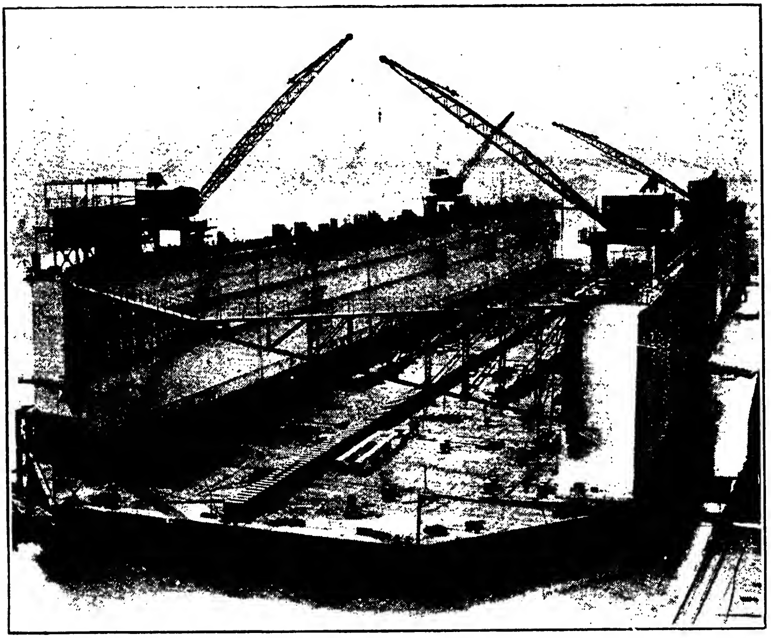

FIG. 25.—Singapore Floating Dock.

The pumps are of centrifugal type and driven by electric power. They can work at full capacity except when there is less than approximately 4 ft. of water in the tanks.

There are also four wash-down and fire-extinguishing pumps, each with a capacity of 75 tons per hour.

Electrical equipment:

(*a*) 1,000 volt, 3-phase, alternating current system for main generation and pumping.
(*b*) 220 volt, 2-wire, direct current system for auxiliary generation, lighting and power.
(*c*) 20 volt, 2-wire, direct current system for valve control in docking operations.
(*d*) Complete telephone system with central exchange.
(*e*) Provision for supplying ships in dock with electrical energy for lighting and power.
(*f*) Provision for supplying submarines in dock with electrical energy for charging large storage batteries, etc.

A view of the dock lying alongside the builder's yard is shown in fig. 25.

Notes on Floating Docks.

(Contributed by Swan, Hunter, & Wigham Richardson, Ltd.)

The development of different types of floating docks in this country is largely due to Messrs. Clark and Standfield, Westminster, who have designed docks of almost every kind, and for service in many parts of the world.

Floating docks may be conveniently divided into two classes: (*a*) those which are not self-docking, or 'box docks,' and (*b*) those which can be self-docked.

(*a*) The *box dock* is double sided and of └ ┘ section. It has two side walls, and is the only form of modern floating dock which cannot be divided into more than one part for the purpose of self-docking. The two side walls and the bottom pontoon are one permanent structure. Box docks of great size have been built: for instance, the British Admiralty floating dock of 33,000 tons lifting capacity built at the Wallsend Shipyard and stationed at the River Medway.

(*b*) By a 'self-docking' type is meant a dock divided into sections any one of which can be lifted on the remainder of the dock for painting or repairs. The following are some of the various types of self-docking docks: the *Bolted-Sectional*, the *Sectional Pontoon* or *Rennie*, the *Off-Shore*, the *Sectional Box*, the *Multi-Sectional*, and the *Depositing*.

The *Bolted Sectional Dock* combines the advantages of the great longitudinal strength of the '*Box*' type with facility for self-docking. This type is usually built in three sections of approximately equal lengths, the two end sections being stepped to form landings when carrying out a self-docking operation.

Fig. 26 shows, firstly, the whole dock assembled; secondly, the centre section lifted by the two end ones; and thirdly, one of the end sections lifted by the centre and other end section. Examples of this type of dock may be seen at Rotterdam, at Sténia in the Bosphorus, and at Walsh Island, N.S.W. (See fig. 31, page 631.)

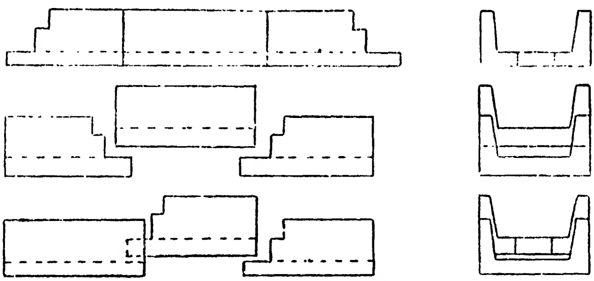

Fig. 26.—Bolted Sectional Floating Dock.

The Sectional Pontoon Dock (also called 'the Rennie Dock,' after its inventor), consists of a number of separate pontoons lying transversely to the length of the dock. Upon these pontoons and bolted to them rest two continuous side walls. The length of each pontoon, i.e. on the keel line, is such that when detached from the rest of the dock it can be passed end-wise between the walls of the latter and so lifted in the same manner as a ship. Each pontoon can be successively dealt with in the same manner. Fig. 27 shows first the whole dock assembled and then

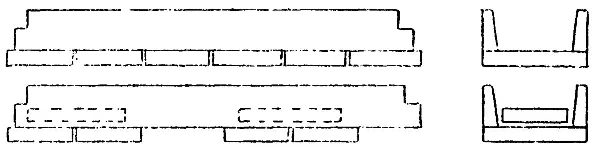

Fig. 27.—Sectional Pontoon Floating Dock.

two of the pontoons lifted by the remainder of the dock. This *Sectional Pontoon* type is very suitable for vessels of moderate dimensions, and owing to its form can easily be constructed in places where docks of other types could not be completed. The separate pontoons not being very large in size can be easily erected and launched, after which the walls can be built upon them.

Examples of this type of dock were built at Wallsend-on-Tyne for the Government of Southern Nigeria, and for service at Saratov on the River Volga.

The Off-Shore Dock is an ingenious design patented by Messrs. Clark & Standfield in 1884; a well-known example of it was built at Wallsend-on-Tyne for a ship-repairing establishment at Sunderland, and there is another good example of it also constructed by Messrs. Swan, Hunter, and Wigham Richardson, Ltd., at Penarth, near Cardiff. The off-shore dock (fig. 28), of which the end elevation is 'L' shaped, is very easily handled. The side wall is connected to the shore by booms or girders hinged at each end. When the dock is sunk to receive a vessel the

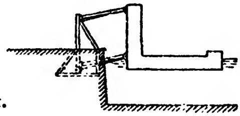

FIG. 28.—Off-shore Floating Dock.

latter can enter the dock from either end or may be warped in sideways. It is then rapidly centred by telescopic side shores and supported underneath by mechanical bilge-shores. This type of dock is divided into two sections, and as it has only one wall one-half of the dock can be lifted, so to speak, in the lap of the other. Fig. 30 on this page illustrates the self-docking operation.

The *Sectional Box Dock* (fig. 29) was originated by Messrs. Clark & Standfield, Westminster. It combines the advantage of ease and simplicity in self-docking possessed by the Sectional Pontoon dock, with the strength of the solid or *Box* dock. The dock is divided, like the ordinary sectional dock, into sections of such a length that any one section can be turned round 90 degrees and docked on the rest of the dock. In the Sectional Box dock, however, the sections are all

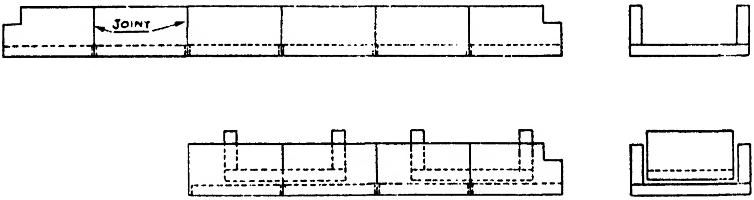

FIG. 29.—Sectional Box Dock.

joined together by a strong, rigid joint of a similar type to that used in the bolted sectional docks running round the whole profile of the dock. The 60,000-ton dock at Southampton, designed by Messrs. Clark & Standfield, the British Admiralty 50,000-ton dock at Singapore (fig. 25, p. 628), and the Wellington Harbour Dock (17,000 tons), New Zealand, both built by Swan, Hunter & Wigham Richardson, are notable examples of this type.

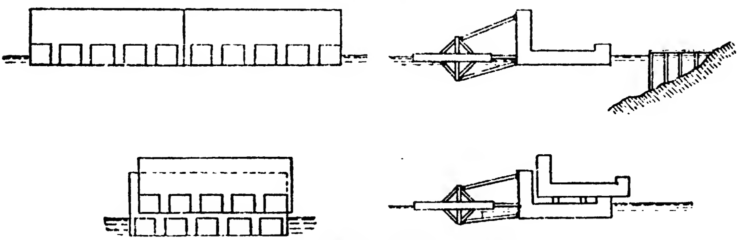

FIG. 30.—Depositing Floating Dock.

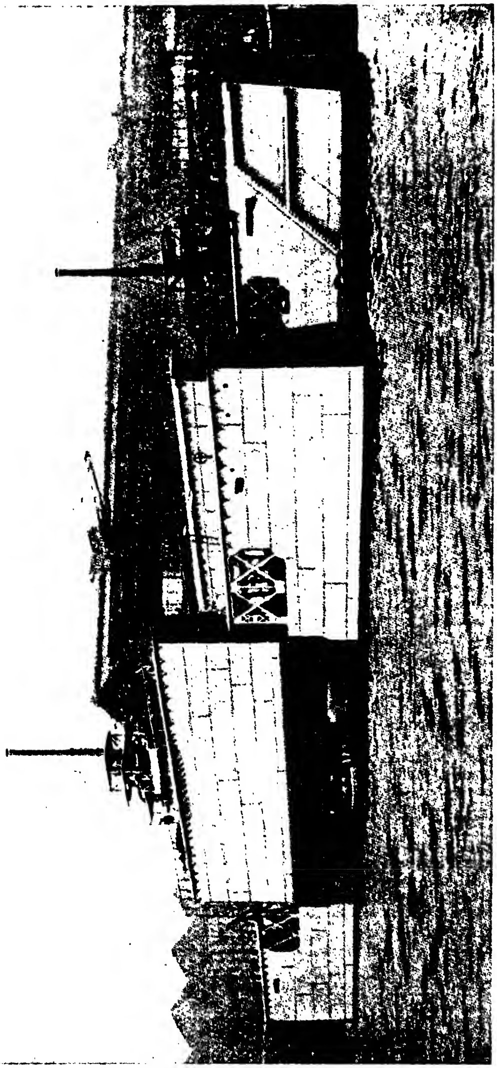
The *Multi-Sectional Dock* is a modification of the Sectional Dock type. In small docks it is not necessary to connect the bottom plating right across the width of the pontoon. The joints at the sections only occur, therefore, round the profile of the side wall, the spaces between the pontoons being decked over to form a continuous platform.



Floating Dock.

Fig. 31.—Bolted-Sectional Dock.

(Built by *Swan, Hunter, & Wigham Richardson, Ltd.*, Wallsend-on-Tyne, England.)

Self-docking operation; centre section lifted by the two end-sections.

The *Depositing Dock* was designed as early as 1877, by Messrs. Clark & Standfield. In section it is 'L' shaped. The single side wall is continuous, but the bottom pontoon is made up of a series of 'fingers' with spaces between them (fig. 30). The necessary stability is given to the dock by means of parallel booms hinged at each end and connected to a floating outrigger. This type of dock can not only dock vessels, but owing to the peculiar construction of the bottom pontoon is enabled to deposit them on a gridiron formed by groups of piles. There are spaces between each set of piles of such a width as to admit the 'fingers' of the dock. The dock carrying a ship is pushed forward so that the 'fingers' are engaged between the piles and then on sinking the dock the ship is left upon the gridiron. The wall of the dock is divided into two equal lengths, either of which can be docked by the other as in the case of the off-shore type.

Depositing docks at Kobe and Barcelona have been used for the purpose of lifting large, hollow ferro-concrete blocks for harbour construction. These were built upon the depositing grids, lifted off by the dock, and finally floated off so that they could be towed to their final position and sunk there. In the case of the Kobe dock, some of these monoliths were 120 ft. long by 41 ft. high, and weighed as much as 2,200 tons. In this way the difficulty of launching such large masses was avoided and much expense saved.

DREDGING.

Modern dredging appliances may be summarised under two classes, each with several subdivisions.

Class I.—Digging dredgers, comprising (*a*) the ladder, or elevator, dredger, with a continuous band of buckets; (*b*) the dipper dredger, with a single bucket at the extremity of a long arm, or lever; and (*c*) the grab or grapple dredger, with a drop bucket suspended at the end of a chain.

Class II.—Suction or hydraulic dredgers, comprising (*a*) the sand pump; and (*b*) the suction cutter dredger.

Rock cutters are not dredgers, but constitute an auxiliary class which will be treated separately.

Ladder Dredgers.

Ladder Dredgers, or Elevator Dredgers (sometimes in Europe called bucket dredgers), are characterised by high power and great serviceability under nearly any conditions. They are adaptable to the removal of every variety of material except the harder kinds of rock. The principle upon which they are constructed is that of an endless chain of buckets travelling in an elliptical path about two pivots, or tumblers, set one at each extremity of an inclined plane. The buckets excavate material at the lower tumbler and discharge it into a shoot while passing over the upper tumbler.

Single Ladder v. *Double Ladder Dredgers.*—Dredgers of the ladder type have either one or two ladders. In single ladder dredgers, the ladder is situated along the centre line of the vessel; in the other case, the ladders are placed at each side.

Single ladder dredgers are most in favour for ordinary operations. In machines of the same power, they have the advantage of few working parts and of less working friction. As seagoing craft, they possess a more convenient outline, and their lesser width enables them to pass through narrower waterways and lock chambers. But they cannot work so closely to a quay wall as side ladder dredgers, and if any breakdown occurs in the chain of buckets, the whole dredger is thrown out of action, whereas, with the double ladder dredger, this is not necessarily the case.

Capacity of Ladder Dredgers.—The capacity of the buckets of ladder dredgers ranges from 5 to 54 cubic ft., but, generally speaking, about 35 cubic ft. is looked upon as the maximum size consistent with convenient utility. A moderately sized dredger, with buckets of 20 to 25 cubic ft. capacity, travelling at speeds from 15 to 20 ft. per minute, and working in water of depths up to 50 ft., may be expected to raise from 400 to 500 tons of stiff clay per hour; in suitable material, such as ballast and gravel, the rate obtained may be as high as 1,000 tons per hour. The most powerful dredgers can double this performance.

Examples of Ladder Dredgers.—The following particulars relate to the 'Corozal,' a Hopper dredger, built in 1911 for the U.S. Government, for work on the Panama Canal:—

Dimensions.	Ft.
Length on load water-line	239
„ between perpendiculars	259
„ over all	268¾
Breadth moulded	45
Depth moulded	19½
Draught fully loaded	15½

Propelling speed: 10 knots.

Dredging capacity: 1,200 cubic yds. of mud and sand per hour.

Buckets: Two sets; one of 54 cubic ft. capacity for soft material and one of 35 cubic ft. for stiff clay.

Maximum dredging depth: 50 ft.

The 'Silurus,' built by W. Simons & Co., Ltd., Renfrew, is a twin-screw bucket hopper dredger of the following dimension:—

		Ft.
Length between perpendiculars		260
Breadth moulded		46
Depth moulded		2
Propelling speed	$8\frac{1}{2}$ knots.	
Dredging capacity	2,200 tons per hour.	
Buckets, two sets	one of 42 cu. ft. and one of 22 cu. ft.	
Maximum dredging depth	50 ft.	
Hopper capacity	1,500 tons.	

Both the foregoing vessels are of the hopper dredger type, that is to say, the buckets discharge into a hopper in the interior of the dredger. The following are two examples of dredgers loading into barges alongside. They are of recent construction by Ferguson Bros., Ltd., of Port Glasgow.

(1) Double side-ladder barge-loading dredger, 'Bulldog':—

	Ft.
Length between perpendiculars	156
Breadth moulded	43
Depth moulded	$12\frac{3}{4}$
Draught loaded	$8\frac{1}{2}$

Dredging capacity: 1,200 tons per hour of loose material, such as sand or ballast.
Buckets: Two sets, each of 15 cu. ft.
Maximum dredging depth: 50 ft.

(2) Central ladder dredger, 'Persevere':—

	Ft.
Length between perpendiculars	190
Breadth moulded	36
Depth moulded	$11\frac{1}{2}$
Draught loaded	7

Dredging capacity: 1,000 tons per hour.
Buckets: 30 cu. ft. capacity.
Maximum dredging depth: 50 ft.

Neither of the above vessels is self-propelling.

Utility of Ladder Dredgers.—Although the serviceability of ladder dredges does not extend to the removal of hard rock, yet they are capable of scraping away the surface of the softer varieties of sandstone and chalk, and, for this purpose, the bucket edges are sometimes fitted with spikes or tines. A ladder dredger works admirably in marl and stiff clay, and no difficulty even is found in dealing with heavy boulders which are frequently encountered in clays of glacial formation. The buckets of a first class dredger will readily lift stones weighing from 30 cwts. to 2 or even 3 tons apiece, bringing them up to the surface and within the range of a deck crane. As illustrative of the character of the material dealt with in many cases, the following particulars may be cited, relating to twelve months' work on the river Tees. A quantity of 417,963 cubic yds. was dredged at a cost of 22,432*l.*, equivalent to about 1*s.* $6\frac{3}{4}$*d.* per cubic yd. About two-thirds of this was hard, boulder clay and there were removed therefrom 1,651 stones, varying in weight from 5 cwts. to 4 tons apiece, of which 1,523 were raised by the dredgers unaided by divers; and, in addition, there were 19 tree trunks, ranging in length from 10 ft. to 20 ft., 16 tree roots and stumps, and 107 miscellaneous obstructions.

Dipper Dredgers.

Dipper Dredgers.—The dipper dredger is an American type, and though to be found in certain ports has not yet become popularised to any extent in Europe. It is mainly employed on the great lakes of the Northern Continent of America, and on river beds and channels when the working depth does not generally exceed 20 ft. or so, and where space for manœuvring is somewhat restricted. This is accountable for by the fact that the dredger is not manipulated by chain moorings, as in the case of the ladder dredger, but is maintained in position by vertical spuds, of posts, which pass down through the vessel to the bottom of the channel, and are raised and lowered as occasion may require. The dipper arm itself assists in manœuvring, being allowed to remain on the bottom while the position of the spuds is changed.

Capacity of Dipper Dredgers.—The single bucket, or scoop, at the end of the lever arm has a capacity ranging from 1 to 12 or 15 cubic yds. The bucket is operated in a curved upward sweep by suitable gearing, on the same principle as a steam navvy or land excavator. The speed of a good dipper dredger in sheltered inland waters is from 30 to 40 seconds per dipper load, and on the sea coast from 40 to 50 seconds. For hard material, the bucket, as in the case of the ladder dredger, is fitted with teeth.

Examples of Dipper Dredgers.—The following particulars relate to a very large dredger, the 'Onondaga,' which worked in New York Harbour :—

Length of hull	140 ft.
Breadth ,,	50 ft.
Depth ,,	15 ft.
Capacity of dipper bucket	12 cubic yds.
Dredging depth	50 ft.

Size of dipper arm : 80 ft. long by 36 ins. square.
Spuds : Four timbers, 80 ft. long by 5 ft. square.
The dipper arm and spuds are both of Oregon fir.
Engines : Double cylinder, condensing.
Cylinders : 20·5 ins. diameter by 24 ins. stroke.

Particulars of a dipper dredger made for Japan, by Lobnitz & Co., Ltd.

Length of hull	120 ft.
Moulded breadth	47 ft.
Moulded depth	12 ft.
Mean draught	7 ft.
Dipper capacity	8 cub. yd.
Maximum dredging depth	50 ft.
Normal reach from centre when dumping	64 ft.
Clear height of dump above water	15 ft.
Number of dips per hour, average	50
Output per hour free soil	400 cub. yd.

Two dipper dredgers, the 'Gamboa' and the 'Paraiso,' each with buckets of 15 cub. yds. capacity, were built by the Bucyrus Co. in 1914 for work on the Panama Canal.

These dredgers have a displacement of about 1,500 tons, and the hulls, which are of steel, have an over-all length of 136 ft., a width of 44 ft., and a depth at bow of 15½ ft. and at stern of 13½ ft. Each dredger has two dipper buckets, the larger, of 15 cub. yds. capacity, for soft material, and the smaller, of 10 cub. yds. capacity, for harder material. The buckets, of ¾-in. plate, have lips of manganese steel, 2 ins. thick, which are 50 ins. deep at the centre, reduced to 9½ ins. at the back edges. They have no teeth. The handles are of Oregon fir, 72 ft. long.

The rate of working is said to average 6,000 cub. yds. per day each, in two 8-hour shifts.

A dipper dredger at work in Bombay Harbour has a bucket capacity of 6 cub. yds., dredges to a depth of 40 ft., and is capable of lifting boulders of over 12 tons weight.

Comparison of Dipper Dredger with Ladder Dredger.—Compared with the ladder dredger the dipper dredger is not quite so serviceable a machine for all-round purposes, and, for the more intractable kinds of material, it has been demonstrated that the former is more efficient than the latter. Thus, in excavating a channel in indurated clay in the St. Lawrence River, dipper dredgers of the most powerful design failed and were replaced by a ladder dredger which completed the work in a satisfactory manner.

The Grab or Grapple Dredger.

The Grab or Grapple Dredger has a bucket which consists of two or more curved plates, or jaws capable of opening and closing under the action of suitable gear. The grab is suspended from the jib head of a crane which does the requisite raising and lowering. The working is actually done very largely under the influence of gravity, the bucket being allowed to fall with open jaws under its own weight and to bury itself in the ground, where the jaws are closed and the bucket with its contents is then withdrawn. The principle of the grab is simple, but there are many complex adaptations in practice. Thus, the appliance may be worked by one or by two chains, each of which arrangements admits of several variations, so that there are quite a number of different machines on the market, each possessing special characteristics and advantages.

Comparison of Single and Double Chain Grabs.—The drawback of a double-chain grab is that it cannot be fitted to an ordinary crane; but, on the other hand, it has less intricate and less delicate mechanism, and, consequently, does not run the same risk of getting out of order. With two chains, moreover, there is less likelihood of the bucket being lost through fracture of the hauling gear. There is the further consideration that in many, if not most, single-chain grabs, the full height of lift has to be made before the grab can be opened in order to discharge its contents. Double-chain grabs can discharge at any stage of the lift. This advantage is shared by a few of the single-chain systems. Its importance lies in the fact that the grab might close upon some immovable object below water, and therefore necessitate the sending down of a diver, unless the jaws can be opened mechanically in that position.

Utility of Grab Dredgers.—The grab is not a suitable appliance for extensive operations. It is best adapted to dealing with material in confined and awkward situations inaccessible to other types of dredger. It is thus excellently suited for the removal of mud and silt in the vicinity of dock entrances and passages. Silt is generally of so impalpable a character that any disturbance of the water in which it lies causes it to rise in suspension, and renders it difficult of removal. The grab proves a most effective appliance for dealing with this soft material, entrapping it with the least admixture of water and the least alteration in consistency. Moreover, the grab is an extremely convenient implement for picking up miscellaneous articles which find their way to the bottom of docks; logs of hard wood, rails, coal, bales of hay and wool, barrels of nails and cement, hoop iron, etc.

Capacity of Grab Dredgers.—Grabs are constructed of a capacity up to 10 cubic yards, but for general purposes the most useful size lies between 70 and 120 cubic ft. They work very successfully in water up to 50 or 60 ft. in depth, at a speed of about one dip per minute, raising in this way from 150 to 250 cubic yds. per hour.

Examples of Grab Dredgers.—Several excellent examples of this class of dredger are constantly at work in the Liverpool docks. The grabs are mounted on barges of 1,100 to 1,400 tons hopper capacity. There are four 5-ton or 7-ton cranes of 16 ft. and 19 ft. radius respectively on each barge, each actuating a grab of 70 or 115 cubic ft. capacity. The principal dimensions of the vessels are:—

1,100 ton barges	200 ft. long by 35 ft. beam by 15½ ft. deep.
1,400 ton barges	225 ft. long by 38½ ft. beam by 16 ft. deep.

The speed of the barges is about 11 knots.

Bag and Spoon Dredging.—This notice of dredging appliances would be incomplete without some reference to a very rudimentary form of apparatus still practised in restricted areas and where operations are on a small scale. This apparatus consists of a strong leather bag of a capacity of from one-half to one cubic yard attached to a steel rim at the end of a stout spar, or pole, from 20 ft. to 35 ft. long. The bag is kept at the bottom by means of the pole, while it is drawn along the surface by a line attached to the rim. The operation is performed by manual labour, and about half a dozen men are required to man a barge for the purpose. The quantity raised and loaded into the barge will range from 60 to 100 cubic yds. per day. The appliance is really only suitable for dealing with mud in timber ponds and in canals.

Suction or Hydraulic Dredgers.

Suction or Hydraulic Dredgers.—Turning now to the second class of dredging plant, the suction or hydraulic type may be described as consisting essentially of a continuous pipe, or tube, through which material is drawn up by suction from the bottom and discharged either into a hopper or through a long pipe line to a depositing site some distance away. The first application of the principle was to the removal of sand—hence the name Sand Pump—but it has since had a much wider application. As regards sand, the method proved extremely effective from the first, the light granular nature of the substance lending itself admirably to easy incorporation with the body of water flowing into the pump intake. Such difficulty as has been experienced has been merely in regard to securing the deposition of the sand within the hopper, the tendency being for a large proportion to flow out over the sides with the escaping water. Considerable reduction in this unremunerative pumping has been made by giving the effluent stream as long a distance to travel as possible and providing the channel with adjustable coamings.

Sand Pump Dredgers.

Sand Pump Dredgers.—For the purposes of suction dredgers, centrifugal pumps are universally employed, and of these, those with a single inlet have an advantage over pumps with a double inlet, in that there is less concussion and interference with the flow. A double inlet pump, on the other hand, disposes of any question of balancing, which has to be met in a single inlet pump by thrust bearings. The most efficient peripheral speed is stated by the Mississippi River Commission to be about 50 ft. per second. The form of the nozzle of the intake pipe materially influences the percentage of sand raised, which may be anything up to 50.

Examples of Sand Pump Dredgers.—The largest sand pump dredger in existence at the present day is the 'Leviathan' of the Mersey Docks and Harbour Board. Her dimensions are 465 ft. 9 ins. long between perpendiculars, by 69 ft. wide by 30 ft. 7 ins. deep moulded. She is fitted with four suction pumps, each of 42 ins. diameter, and is capable of filling herself with 10,000 tons of clean sand in 50 minutes from a maximum depth of 70 ft. The speed of the vessel is 10 knots. On arrival at the depositing ground, she discharges herself in 10 minutes through large cylinders extending from valve openings, 5 ft. 6 ins. diameter, in the bottom of each hopper to deck level. These valves have a lift of 4 ft. and are operated by hydraulic rams. At work on the bar and entrance channel of the Mersey, the Leviathan pumps up over 12 million tons of sand per annum.

The following particulars relate to the 'Blesbok,' the largest vessel of its type so far constructed by Lobnitz & Co., Ltd. It was supplied to the South African Railways and Harbours Administration.

Length between perpendiculars	304 ft.
Breadth, moulded	54 ft.
Depth	23 ft.
Maximum dredging depth	70 ft.
Speed	11 knots

Loading capacity: 2,600 cu. yds. of sand in 45 minutes and able to pump out the same load through a discharge pipe 2,500 ft. long in well under 60 minutes (*vide* 'The Engineer,' May 19, 1939). Triple expansion engines with cylinders 18 in., 31 in., and 51 in. × 30 in. stroke, develop 3,000 h.p. at 120 r.p.m. with steam pressure at 200 lbs. per sq. in.

Particulars of a number of other types of suction dredgers are given in the table on p. 637.

Suction Cutter Dredgers.

Suction Cutter Dredgers.—The success attending the introduction of the sand pump led to an investigation of the possibility of dealing with less tractable material by the same means. Water jets for loosening and disintegrating hard and compact strata were added, and some satisfactory results being obtained, the further step of introducing rotary cutters was taken. There was found to be little difficulty in treating in this way earth of a marly or brittle nature, easily resolvable into disconnected particles. Trouble, however, was experienced in dealing with clay and tenacious material, which clogged the cutters and choked the intake. Eventually this was overcome by the evolution of cutter blades of a suitable form and pitch.

Capacity of Suction Cutter Dredgers.—Suction cutter dredgers are now constructed capable of removing over 1,000 cub. yds. of stiff clay per hour. In material usually dealt with by bucket dredgers, the cutter suction and discharging dredger 'Lord Willingdon' at Cochin dredged and discharged, through 4,500 ft. of pipe line, 1,500 cub. yds. per hour over an extended period, and on occasion this output has been considerably exceeded.

Use of the Pipe Line.—The use of the pipe line for discharging purposes is becoming very general, especially in cases where it is practicable to use the dredged material for filling and embankment purposes. These lines are often of great length. A dredger working at Oakland, California, U.S.A., has successfully delivered material through 6,170 lineal ft. of 20-in. diameter pipe. Diameters reach as high as 42 ins. when altogether afloat, and 30 ins. to 36 ins. when partly ashore. In calm water thin sheet tubing will suffice, but in exposed situations long lengths of solidly built sections must be provided. The carrying capacity of a 36-in. pipe with 80 per cent. of solid matter conveyed at a rate of 10 ft. per second would be 7,400 cubic yds. per hour. Sand causes considerable wear and abrasion of the piping and requires a high percentage of water with greater velocity to keep it in suspension. Clay, from its unctuous nature, exercises far less frictional resistance and is sometimes rendered sufficiently fluid by 10 per cent. of water. A velocity of 7 ft. per second for clay and mud, and 10 ft. per second for sand, has been found to give good results.

Compound Dredgers.

Compound Dredgers.—A compound type of dredger has recently been introduced fitted with both the suction, or suction cutter, apparatus and a bucket ladder. This enables the dredger to be applied to a wide variety of material in the most effective manner. The bucket ladder is generally placed in the centre well and the suction apparatus at the sides of the vessel, but in some cases the suction pipe is also centrally situated.

Example of Compound Dredgers.—The dredger 'La Loire,' built for service on the river of that name, is a twin screw combined bucket and suction dredger with cutter gear and pipe line shore delivery. Her dimensions are 173 ft. 10 ins. in length by 32 ft. beam by 14 ft. deep. She is fitted with two centrifugal suction and force pumps, capable of raising material from a depth of 25 ft. and of driving it ashore through floating delivery pipes about 30 ft. long and 24 ins.

From Brochure on Dredger 'Chien She,' by Dr. Herbert Chatley. With addition from 'Dredging Machinery,' paper in *Journal of Inst. C.E.*, April 1945.

diameter. The suction pipe is 26 ins. diameter and works, together with the bucket ladder, in a centre well.

The cutter has a diameter of 6 ft. 10 ins. and is driven at 12 revolutions per minute, the engine running at 140 revolutions.

The bucket ladder enables the dredger to work to a depth of 52 ft. 6 ins. The buckets have a capacity of 27½ cubic ft. They are driven at a speed of 16 buckets per minute with the engine running at 170 revolutions.

Both suction and bucket apparatus enable the dredger to excavate her own flotation in advance.

The machinery consists of two complete sets of direct acting, triple expansion surface condensing, reversible propelling engines, each arranged to drive a centrifugal pump as well as the bucket dredging gear. Each set of engines indicates about 450 h.p. when running at 170 revolutions per minute. The cylinders are 13 ins., 21 ins., and 33½ ins. by 18 ins. stroke.

The cutter gear is driven by means of belting from a separate engine of 200 h.p., which also serves for a centrifugal pump delivering spoil from the buckets into the upper part of the shoot.

For the purpose of working the bucket dredging apparatus the suction pipes and cutter gear are dismounted, but in deepening the bed of the river Loire the latter proved so effective that over 13 million cubic yds. of alluvial material have been removed without recourse to the bucket apparatus.

Hopper Service.

When dredged material has to be removed some distance to a depositing ground it is excavated by the dredger into its own hopper, or into hopper barges ranged alongside.

A combined hopper dredger costs less in initial expenditure and subsequent upkeep than a separate dredger and hopper of corresponding capacity, and it occupies less valuable space in a crowded waterway.

On the other hand, it involves the discontinuity of dredging operations and the frequent getting out and taking in of moorings. This latter consideration is of importance more to dredgers of the bucket ladder type.

On the whole, it is found expedient on undertakings of considerable magnitude, and in cases where the depositing ground is several miles distant from the dredging site, to maintain a fleet of hopper barges in attendance on bucket ladder dredgers. Suction dredgers, when they do not discharge through a pipeline, more commonly are compound vessels with self-contained hoppers.

Capacity of Hopper Barges.—Barges are constructed capable of receiving from 500 to 1,000 cubic yds. of dredged material (say 650 to 1,350 tons) and of making journeys to sea and back at speeds of 10 to 11 knots.

Example of Hopper Barge.—A typical barge of 800 tons capacity has a length of about 190 ft., breadth 30 ft. and depth 14 ft. The engines are triple expansion, surface condensing, with cylinders 16½ ins., 26 ins. and 43 ins. diameter by 27 ins. stroke, which at 110 revolutions per minute develop 820 i.h.p. and give a speed of 10 knots, steam being supplied at 180 lbs. per sq. in. from marine multitubular boilers.

Cost of Dredging Plant.*

The following figures may be useful as approximate indications of the cost of dredging plant which must, of course, vary from time to time with fluctuations in the price of material and the engagements of the shipbuilding yards.

Ladder Dredgers.—A 5 cubic ft. bucket, single ladder dredger, capable of raising 150 tons of soft material per hour from a depth of 40 ft., has cost in round figures 7,000*l.*

A 15 cubic ft. bucket, single ladder dredger, capable of raising 400 cubic yds. of sand, gravel and clay per hour from a depth of 45 ft., has cost about 27,000*l.* and was constructed in six months.

A one cubic yd. bucket, single ladder dredger, capable of raising 750 cubic yds. of ballast per hour from a depth of 55 ft., has cost about 43,000*l.*, and was built in nine months.

Dipper Dredgers.—A one to two yard dipper dredger costs from $8,000 to $12,000; say 1,600*l.* to 2,400*l.* The hull is of timber, about 60 ft. long by 25 ft. wide, with a draught of 3 ft.

A 3½ to 4 cubic yd. machine dredging to a depth of 30 to 35 ft., would cost about $80,000 to $90,000, say 16,000*l.* to 18,000*l.*

A 10 cubic yd. machine dredging to a depth of 35 ft. would cost about $130,000 to $140,000, say 26,000*l.* to 28,000*l.*

---

* See footnote, page 606.

Grab Dredgers.—A twin-screw hopper dredger, with a hopper capacity of 1,200 tons, and fitted with 5 hydraulic grab cranes each of 5 tons bucket capacity, working to a depth of 47 ft., has cost about 35,000*l.*

Suction Dredgers.—A suction hopper dredger with a hopper capacity of 70,000 cubic ft., capable of raising 3,500 to 4,000 tons of sand per hour from a depth of 70 ft., has cost about 75,000*l.* A 2,000 ton suction hopper dredger would cost about 50,000*l.*

Compound Dredgers.—A sea-going hopper dredger, fitted with both ladder buckets (18 cubic ft.) and suction pumps, and capable of dredging by the former means 400 cubic yds. per hour, and by the latter means 650 cubic yds. per hour, from a depth of 50 ft., has cost about 53,000*l.*

Hopper Barges.—A steam hopper barge of 800 cubic yds. capacity, with a speed of 11 knots costs from 18,000*l.* to 20,000*l.*

Cost of Dredging Operations.*

Conditions and circumstances vary with each locality, so that it is difficult to give reliable figures for general guidance. Sand pump dredging has been done for as little as 1*d.* per cubic yd. or even less, and grab dredging from 2*d.* to 6*d.*, but a very great deal depends on the distance the spoil has to be carried. In bucket dredging, either by ladder or dipper, the range of cost is considerable, depending in addition, as it does, on the kind of material dealt with. The following are a few collected records from various sources:—

Bombay Harbour and Docks.

Total Maintenance Dredging during Five Years, 1920–1925.†

Costs exclusive of Interest and Depreciation on Dredging Plant.

Port Natal.—The following particulars (extracted from a paper by Mr. William Brown on 'Recent Progress in Dredging Machinery'; vide *Min. Proc. Inst. C.E.*, vol. cciii.) relate to the performances of the four principal dredgers at Port Natal, Durban, within a period of several years ended December 31, 1914. The costs include all charges for working, maintenance, insurance, depreciation and interest on capital. The price of coal consumed by the dredgers was low, and seldom exceeded 8*s.* per ton. The three large vessels (Labrus, Cetus, and Nautilus) each employed fourteen Europeans, eighteen Kaffirs, and eleven Indians, or a total complement of

* See footnote, page 606.

† Extract from paper on 'Maintenance Dredging in Bombay Harbour and Docks,' by E. L. Everatt, *Min. Proc. Inst. C.E.*

forty-three hands, at an annual cost of about 3,850*l.* per vessel. 'With the possible exception of Liverpool, no port hampered by sandbars has made such progress in comparatively recent years as Durban.'

PARTICULARS AND WORKING COST OF SEA-GOING PUMP DREDGING PLANT AT PORT NATAL.

Name of Dredger.	Year Built.	Tonnage. Net.	Tonnage. Gross.	Hoppr. Capacity (Tons of Sand).	Pumping Speed (Tons of Sand per hour). Contract.	Pumping Speed (Tons of Sand per hour). Record.	Average Spoil handled per ann. (Tons).	Average number of days worked per ann.	Cost per ton handled. (*d.*)	Remarks.
Labrus .	1911	1,215	2,097	2,000	2,000	2,000	719,500	244	6·806	Worked exclusively in stiff clay, being fitted with patent clay cutter. All spoil dredged re-pumped ashore from ship's hoppers for land reclamation.
Cetus .	1905	1,327	2,414	3,000	3,000	7,430	2,151,000	232	2·227	Largely employed for bar work. Spoil mostly coarse loose sand and fine stone, all dumped at sea, two miles from harbour entrance.
Nautilus	1903	1,050	2,034	2,500	3,000	7,894	1,466,000	217	3·109	Employed chiefly on maintenance and deepening of harbour bed and channels. Material mostly fine sand, with occasional admixture of loose clay and mud, all deposited at sea two miles from harbour entrance.
Snipe .	1903	180	265	200	300	310	358,000	256	3·201	Used for clearing up wharf and quay berthage, cutting and maintaining boat channels, occasional reclamation, etc. Spoil deposited within harbour.

Panama Canal.—During 1910 the sea-going suction dredgers 'Culebra' and 'Caribbean' removed 6,083,902 cubic yds. at a cost of 3·7*d.* per cubic yd. The ladder dredger 'Marmot' removed 1,372,665 cubic yds. at 7·82*d.*, and dredger No. 5 removed 560,622 cubic yds. at 13·65*d.* per cubic yd. The small 5 cubic yd. dipper dredgers 'Cardenas' and 'Mindi' removed 1,013,485 cubic yds. at 27·89*d.* per cubic yd. and the 20-in pipe-line suction dredgers, Nos. 82 and 85, dealt with 2,472,822 cubic yds. at a cost of 14*d.* per cubic yd. During a period of twelve months ended May, 1916, the dipper dredgers 'Gamboa' and 'Paraiso' each removed over 2,900,000 cubic yds., at costs varying from 2·25*d.* to 5·45*d.* per cubic yd., including operation and maintenance.

Mississippi River.—In 1907 three pipe-line suction-cutter dredgers dredged 1,279,000 cubic yds. at 4·12*d.* per cubic yd. including the cost of idle time. In 1908 the same dredgers accounted for 989,000 cubic yds. at 5¼*d.* per cubic yd.

New York Harbour.—In 1909, the sea-going suction dredgers 'Manhattan,' 'Atlantic,' 'Raritan,' and 'Navesink,' removed 10,786,638 cubic yds. at a total cost of $424,734 (say 85,000*l.*) or at the rate of 1·97*d.* per cubic yd. made up as follows: Dredging, 1·785*d.*; surveys and examinations, ·125*d.*; contingencies and supervision, ·06*d.* The 'Delaware' removed 1,675,562 cubic yds. at a total cost of 2·39*d.* per cubic yd.

River Thames.—The contract cost of removing hard material (ballast and clay) by ladder dredger from the Thames below London Bridge has ranged at various times before the war from 1*s.* 4*d.* to 2*s.* 6*d.* per cubic yd. largely dependent on the distance the material had to be conveyed. Some work has been carried out departmentally, including all establishment and capital charges, at a figure as low as 7½*d.* per cubic yd. This was for a quantity of about one million cubic yards, and the distance conveyed was about 30 miles.

River Mersey.—At the bar and in the entrance channels of the Mersey nearly 15 million cubic yds. of sand were removed annually at a pre-war cost of ·6*d.* per cubic yd. exclusive of interest and depreciation on the plant.

Siam Irrigation Canals.—The following particulars of the working expenses of a 2½-cu. yd. dipper dredger, employed on the Siamese Irrigation Service, are given by Lobnitz & Co., Ltd.:—

'During the year 1920, working nine hours per day, the total quantity dredged was 312,130 cu. yds., measured in place, or an average of 26,010 cu. yds. per month. The best month in that year was October, with 43,700 cu. yds. at a total cost of 1·95 pence per cu. yd., and the average cost per cu. yd. for the year was 2·87 pence, including labour, fuel, supplies, repairs, and every expense except interest and depreciation. The fuel used was oil, and represented about half the total operating cost. The quantity used was about one ton per day.

'While larger outputs have been made for short periods and under more favourable conditions, this record is notable chiefly for steady running for a long period without appreciable delays or expense on account of the machinery, and this in a tropical country remote from base of supplies. The cost of repairs was 4·3 per cent. of the total cost, and consisted mainly in the replacement of some wire ropes.'

SUBAQUEOUS ROCK REMOVAL.

The removal of hard rock under water is generally effected by one or other of two means: (*a*) by drilling and blasting; and (*b*) by the use of the chisel or rock breaker. In both cases a dredger is subsequently required for the purpose of clearing the débris from the site.

Drilling and Blasting.

Drilling and Blasting.—The first is the older method and remains still a most effective means of dealing with rock of adamantine hardness in huge solid masses, such, for instance, as reefs of granite and other igneous rock, and for the harder varieties of limestone.

The holes are drilled by suitable plant at distances apart dependent upon the nature of the rock and the quantity to be removed. In very extensive operations chambers may be formed for the reception of powerful charges.

Two classes of drill are generally available for boring purposes: (*a*) diamond drills and (*b*) jumper drills. The former are hollow rods, fitted with a head or crown of diamonds, costing from 50*l.* to 60*l.*, and driven at from 200 to 300 revolutions per minute. The latter are bars or shafts of steel, furnished with bits, preferably of circular form, which are worked by percussion at the rate of from 20 to 30 blows per minute.

The blasting material is usually dynamite, or any of the numerous compounds of nitro-glycerine to be found on the market.

The following are brief notes on the methods employed in several instances.

Blyth Harbour.—The rock at Blyth harbour is sandstone of the hardness of basalt in places, and the work was done by six drills lifted by steam power and guided by hand. The distance between the shot-holes was 5 ft. in one direction and 6 ft. 2 ins. in the other. The blasting material, bellite, was lowered in canisters through the drilling tubes and fired by fuses and detonators, the holes being tamped with small gravel. The cost of drilling and blasting came to 3*s.* per cubic yd. of rock *in situ*, adding to which 2*s.* 6*d.*, the cost of dredging, and 8·2*d.* for interest and depreciation on the dredger, the total amounts to 6*s.* 2·2*d.* per cubic yd. The average quantity of rock drilled and blasted per week by one barge was 488 cubic yards. The system was afterwards abandoned in favour of the rock-cutter.

Black Rock Harbour, Buffalo, U.S.A.—Here the rock formation is a very hard limestone containing veins of flint. The blasting material was dynamite and, for a quantity of 14,450 cubic yds., the holes were drilled to an average depth of 9 ft. 9 ins. The cost of drilling and blasting only, including an allowance for interest and depreciation of 2 per cent. per month on 8,000*l.* (the value of the plant), came to 2*s*. per cubic yd. On the other hand, a smaller quantity of 333 cubic yds. with holes drilled only to 3 ft. 6 ins. deep cost 23*s*. 2*d*. per cubic yd.

The drill boat employed on this work was a steel hull, 137 ft. by 33 ft., divided into 20 water-tight compartments. It was equipped with five drill frames located along one of the gunwales each with a travel of 25 ft. on longitudinal tracks. Each frame was fitted with an Ingersoll-Rand drill 2½ ins. in diameter, with 4-in. bits, having a vertical range of 21 ft. without changing the drill bars. Each frame was also provided with an engine for hoisting the drills, two davits for handling drill steels and charging pipes and a pipe which was driven, whenever required, through loose material to the rock to prevent the drill holes from clogging. A 250 h.p. boiler supplied steam to the drills, spud engines and capstans.

Detroit River.—On three sections of the Detroit River, where the blasting material was dynamite and the holes ranged from 5 ft. to 8 ft. in average depth, the total cost is stated to have been 3*s*. 4*d*., 4*s*. 4*d*., and 4*s*. 1*d*. per cubic yd., respectively, of useful material, or about half the rates for the whole quantity removed. The holes were spaced 5 ft. apart, and the total number drilled was 94,691 at a cost of about 52,000*l*. It is not apparent that this figure includes any allowance for interest and depreciation.

Fremantle Harbour, Western Australia.—On account of the shallowness of the water, the work of drilling at Fremantle Harbour could be carried on from light wooden stages resting on four-footed trestles. In a couple of days it was possible to erect 20,000 square ft. of this staging, which carried 120 to 160 men drilling with regularity in 20 ft. or more of water. The holes were from 8 ft. to 12 ft. apart, and the charges consisted of 12 to 15 lbs. of dynamite or gelignite. One ton of explosive accounted for 5,600 cubic yds. of rock blasted. The cost of drilling and blasting 1,503.099 cubic yds. was 238,345*l*., equivalent to 3*s*. 2*d*. per cubic yd.

Fårösund, Sweden.—The cost of a navigable channel dredged in limestone at the island of Gothland in the Baltic Sea, completed in 1934, was as follows: mass dynamited, 42,000 cubic m. *in situ*; metres drilled, 31,342; mass dredged, 40,000 cubic m. *in situ*; total cost of dynamiting, 5·93 swedish crowns per cubic m.; cost of dredging, 5·85 swedish crowns per cubic m. —Report by Capt. L. Lawski to Sixteenth Navigation Congress.

Rock Breakers or Chisels.

Rock breakers, or chisels, are steel rams weighing from 15 to 20 tons, with pointed ends of hard chrome steel which are detachable for renewal. The appliance is suspended from a frame, or tripod, mounted on a barge, and is worked by a winch. A drop of from 6 ft. to 10 ft. is generally sufficient to produce disintegration. Blows can be repeated with advantage until a depth of 3 ft. is reached, with holes spaced about 3 ft. to 4 ft. apart (about eight blows will give the required penetration), when it becomes desirable to dredge the broken material before proceeding further. A net depth of 2½ ft. over the site will probably thereby be obtained. It is found that the average result in hard rock is 2 cubic ft. per blow and that about 150 blows can be given per hour. This is equivalent in uninterrupted working to about 10 cubic yds. per hour for a single-cutter machine; about 50 per cent. more will be achieved by a double cutter. In moderately hard rock the output will be greater, as about 250 to 300 blows can be given per minute. About 200 cubic yds. may be reckoned a good day's work.

There are several types of cutter, but perhaps the Lobnitz rockbreaker is that which is best known. The following are some instances of its employment. It may be added that some of the latest examples of this type of cutter have been fitted with an under-water sleeve, to afford more accurate guidance for the ram or chisel.

Suez Canal.—On the Suez Canal, where the rock consisted of limestone, calcareous agglomerate, and tufa, gypsum and alabaster, 132 blows were delivered per hour of effective working, or 83 blows per hour of whole time, allowing for interruptions from passing ships and stoppages for repairs. The average thickness of rock shattered was 2 ft. 7½ ins., and each cubic yd. of rock required a mean of 5·4 blows. The cost, exclusive of dredging but covering everything else except general charges, varied from 2¼*d*. to 7*s*. 6½*d*. per cubic yd.

Blyth Harbour.—At Blyth in hard sandstone of the coal measures, a ram of 15 tons weight, falling through a distance of 8 ft., penetrated the rock to a depth of 3 ft. on an average of 8 or 9 blows. The holes were spaced 4½ ft. apart. The plant comprised two Lobnitz rock-breakers, each consisting of a steel barge carrying sheer legs, from which the rams, 40 ft. to 50 ft. long and 17 ins. to 19 ins. diameter, were suspended. The cost of one rockbreaker was about 6,800*l*. The quantity broken per week by a single machine working night and day was 908 cubic yds., at a cost (including wages, coal, stores, repairs and insurance) of 46*l*. 11*s*. 3*d*., equivalent to 12·3*d*. per cubic yd. Adding 6½ per cent. for interest and depreciation on plant, the total cost was 14·5*d*. per cubic yd. The cost of subsequently dredging the loose material (including capital charges) was 2*s*. 9·1*d*. per cubic yd., making 3*s*. 11·6*d*. per cubic yd. in all.

Black Rock Harbour, Buffalo, U.S.A.—The cost of working two Lobnitz machines at Black Rock Harbour in hard limestone rock was 2*s*. 9½*d*. per cubic yd. for a quantity of 52,500 cubic yds. This does not cover the cost of dredging.

Panama Canal.—On the Panama Canal, a Lobnitz cutter worked mounted on a barge 100 ft. long by 28 ft. beam by 8 ft. deep. The extreme variation in the tides necessitated the use of 3 rams, weighing 15, 16 and 19½ tons respectively. The holes were spaced 4 ft. apart, and 3 ft. of penetration was made in each case. From records during 1910–11 the work done was an average of 16·2 cubic yds. per hour of actual working time, or 11 cubic yds. per hour of total time, at an average cost of 3*s*. 4*d*. per cubic yd.

Value of the method of Drilling and Blasting as Compared with the use of Rock Breaker.—While drilling and blasting is most commonly adopted for hard rock in large masses, it does not necessarily follow that the cutter always gives better results in soft rock. In some cases it is found that the cutter has a tendency to stick in the hole which it makes, and for that reason the extent of penetration should be carefully limited. On the other hand, the cutter offers less interruption to the passage of ships close to the area of operations, and it can be used in positions where blasting is inadmissible. Moreover, the rock is broken to a more uniform and more convenient size, which facilitates the action of dredging. The cost of the work done by the cutter is generally, though not invariably, less than the cost by the alternative method.

Firth of Forth.—The breaking of fine-grained granite, known locally as Whinstone, at an average depth of 43½ ft. below water-level, cost in 1923–25, about 34*s*. per cubic yd. of rock *in situ*, including repairs and replacement of plant. The total cost of breaking up and removing the broken rock varied considerably, but, for the hardest granite, worked out at about 56*s*. per cubic yd. *in situ* for the most difficult and toughest part of the work.—Report by N. G. Gedye to Sixteenth Navigation Congress.

DIVING.

Though naked diving is still practised in some parts of the world—*e.g.*, in the Greek Sponge Fisheries and on certain pearling grounds in the East—this primitive method, which has been responsible for much physical suffering and a high rate of mortality, has for many years been giving way steadily to the safer and more comfortable diving dress.

The methods of diving with apparatus in general use to-day are (1) the diving bell, and (2) the flexible closed dress originally designed in 1837 by Augustus Siebe, his principle still being in universal use. The air supply is (*a*) by pump worked manually or by electric or oil motor; (*b*) by air compressor, belt or power-driven, in connection with air reservoirs, for use in case of breakdown of the compressor; and (*c*) by banks of large cylinders of compressed air at pressures of from 2,000 to 3,000 lbs. per square inch, with reducing valves and air control panel. In all cases, care must be taken that the air sent down to the diver is clean and free from oil-vapour and other impurities.

In recent years, as a result of research and practical experiment, much progress has been made as regards depth to which the diver, equipped with the flexible dress, can work in safety, as is evidenced by the following tables compiled by Siebe Gorman & Co., Ltd., after the work of the Admiralty Deep Diving Committee of which Sir Leonard Hill, F.R.S., and Sir Robert Davis, were members. These tables include decompression times for the diver's ascent after work at various depths for different periods.

Compressed air illness—or caisson disease, or 'bends,' as it is variously called—is caused by too sudden release of the excess of nitrogen in the blood and tissues; it is absolutely essential, therefore, to decompress in accordance with the tables. It will be seen that the breathing of oxygen at certain stages during the return to normal atmospheric pressure greatly reduces the decompression period.

For decompressing from the greater depths, divers of the Royal Navy use Sir Robert H. Davis's submersible decompression chamber which is lowered to the diver's first stopping place where he enters the chamber through a door in the bottom which is closed by an attendant; the chamber is then hauled to the deck of the diving vessel where the diver is decompressed in comfort and under observation. Thus he is saved the tedium and discomfort and cold of decompressing in stages on the shot-rope as by the old system.

Another form of diving dress which has been tried at different periods is a metal armour with articulated legs and arms. While this dress has proved satisfactory in protecting the diver from the external pressure of water (the air within the dress is at normal atmospheric pressure), it allows him so little mobility that it has proved of less practical value than the steel observation chamber. In proof of this, work on the 'Egypt' treasure-recovery operations was first started with the metal armour, but had to give way to the observation chamber. The occupant of the chamber was in telephonic communication with the salvage vessel, and gave directions for the placing of explosive charges, and the working of grabs for removal of the blasted debris and the treasure itself.

In both the metal armour and the observation chamber, oxygen supplies and CO_2 absorbing apparatus are carried as the air purifying media.

Various forms of self-contained diving apparatus have been finding favour in many cases, particularly for use in ships, etc. All these are a development of the first practicable apparatus of the kind, as designed by H. A. Fleuss in 1878. The latest improved forms are adapted to the ordinary diving dress and helmet, and to several modified forms of dress. It is also used in the Davis Submarine Escape Apparatus.

For further information on the subjects of 'Diving' and breathing in poisonous atmospheres, see Sir Robert H. Davis's books 'Deep Diving and Submarine Operations' and 'Breathing in Irrespirable Atmospheres,' in which the subjects are dealt with fully.

The following table indicates the ordinary time limits in deep water, stoppages in ascent, and approximate air supply :—

Depth.		Pressure, Lbs. per Sq. In.	Time under Water from Surface to Beginning of Ascent	Stoppages in Minutes at different Depths.			Total Time of Ascent, Minutes.	No. of Cylinders needed.	Revolutions of Pump per min.
Feet.	Fathoms.			30 ft.	20 ft.	10 ft.

FLOATING LANDING STAGES.

The opening of the Tilbury Floating Landing Stage in May 1930 brought into prominence the value of these facilities for passenger traffic at ports where there is an appreciable range of tide.

The Tilbury Landing Stage has a length of 1,142 ft., a width of 80 ft., and is secured to the left bank of the River Thames by means of four hinged steel booms and heavy mooring cables. It comprises a Jarrah timber deck carried on steel girders resting across sixty-three floating pontoons which rise and fall with the tide through a range of about 20 ft. At each end are two massive dolphins of timber pilework.

The Liverpool Landing Stage near the mouth of the River Mersey has been in service for many years. It is 2,534 ft. long by 80 ft. wide and has ten bridges connecting it with the shore, while, in addition, a floating approach bridge 550 ft. long, also carried on pontoons, provides an easy incline for vehicular traffic at all stages of the tide, which during springs attains a range of 30 ft.

Passenger landing stages for overseas traffic are provided with facilities for the handling and examination of baggage, waiting rooms, shelters, and other accommodation according to circumstances.

CHANNEL DEMARCATION.

(Contributed by J. P. Bowen, C.B.E., B.Sc., M.I.C.E., Engineer-in-Chief, Trinity House.)

Entrance channels to ports are outlined by buoys and lighted beacons on the river banks. Important changes in direction are also indicated by lightships and harbour entrances by minor lights.

Uniform System of Buoyage.

The general Lighthouse Authorities of the United Kingdom have adopted the following uniform system of buoyage.

Conical Buoys (those with pointed tops) denote the starboard hand, or that side which would be on the right hand of a mariner, either going with the main stream of flood tide, or entering a harbour, river or estuary from seaward.

Can Buoys (those with flat tops) denote the port hand, being the side on the left hand of the mariner under the circumstances described.

Spherical Buoys, with domed tops, mark the ends of middle grounds.

Pillar Buoys, having a tall central structure on a broad base, mark special positions.

Colour.—Starboard-hand buoys are always to be painted in one colour only ; port-hand buoys are to be painted another characteristic colour, either single or particolour. Spherical buoys are to be distinguished by white horizontal stripes. Wreck buoys are to be coloured green with the word 'wreck' in white letters across.

Types of Buoys.

Buoy Construction.—Buoys are generally hollow structures of steel or iron plating, at least ¼ in. thick. They should be constructed in two watertight sections to prevent sinking in case of penetration of one part.

The size and weight of buoys is as follows :—

		Diam. Ft.	Weight. Tons.
Trinity House Day Mark Buoys	First class	12	1
	Second class	10	2½
	Third class	8	1¾
	Fourth class	6	¾
	Fifth class	5	
Gas Buoys		10	4 to 9.

Gas buoys, in which gas is stored under pressure, should be made of welded iron or mild steel, not riveted, as under high pressures the riveted joints tend to leak and are not satisfactory.

Buoys carrying independent gas cylinders can be of either welded or riveted construction.

Buoy Moorings.—Mooring chains for large diameter and heavy buoys are about 1¼ ins. diameter, attached to sinkers weighing about 50 cwt. For buoys weighing 3 to 4 tons the chains are usually 1⅜ ins. diameter with 40 cwt. sinkers. For smaller buoys the chain is proportionately reduced. The length of a mooring chain is usually about 2 to 2½ times the depth of the water in which the buoy is laid.

Bell Buoys are provided with a bell from 3 to 6 cwts. in weight struck under the action of the sea by pendant clappers, or by a hammer actuated by carbonic acid gas.

Whistling Buoys emit a sound by means of air imprisoned in a long central tube during the period of rising in a swell and expelled through a whistle during the period of falling. The tube descends into the water to a considerable depth—about 15 to 20 ft.

Luminous Buoys.

Luminous Buoys are lighted by means of either oil gas, Blau gas, or acetylene. On account of the high pressure required for compact storage, coal gas is unsuitable for use as a naked flame, the luminosity of the gas being rapidly reduced by pressure. The ratio of calorific value is approximately as follows :—Coal gas, 5 ; oil gas, 10 ; Blau gas and acetylene, 14.

Oil gas, as manufactured on the *Pintsch* system, is produced at a cost of about 30*s.* per 1,000 cubic feet, about 75 cubic feet of gas being obtained from one gallon of oil. The average burner of a fixed light consumes about 0·75 cubic feet per hour. The gas is stored under pressure, generally of about 90 to 105 lbs. per sq. in., but reaching up to 150 lbs. A reservoir of 380 cubic feet in a buoy of 10 ft. diameter, charged to 75 lb. pressure would hold a sufficient supply of gas to maintain a 25-litre burner showing equal periods of light and darkness for about four months.

Blau gas is derived from the decomposition at a lower temperature of the raw or residuary products from which ordinary oil gas is extracted, and is richer than the latter in heavy carbides of hydrogen. It is liquefied for storage in bottles. Before use, the gas requires to be expanded in an intermediate receiver. The cost of production of Blau gas is considerably higher than that of oil gas, but the cost of transport is much less, and the increased heat of the flame gives an increase of 30 per cent. over oil gas to the intrinsic brilliancy of the mantle and the intensity of the lens.

Acetylene, a gaseous compound of hydrogen and carbon, is produced by the access of water to calcium carbide. From 1 lb. of commercial calcium carbide can be produced about 4½ cubic feet of acetylene.

Acetylene gas produced as above is not chemically pure, and gives rise to deposit on the burners, but this difficulty can be overcome by the addition of a suitable purifier between the gas-generating chamber and the burner. Unattended lights working on this system will run for six months, or even a year, without recharging.

Dissolved Acetylene.—The compression of acetylene for storage purposes is generally illegal, on account of the liability of the gas, so stored, to explode. On the other hand, compressed acetylene in what is known as the dissolved form is perfectly safe, and cylinders of dissolved acetylene, prepared in accordance with official regulations, are classed by the Home Office as non-explosive. Acetylene in this form is now most commonly used both for buoys and unattended lights, because of its convenient storage and transportation.

The solvent commonly employed is acetone, which is a liquid hydro-carbon, possessing the property of absorbing about 25 times its own volume of acetylene at atmospheric pressure, and multiples of this to correspond with the number of atmospheres to which compression is carried.

The steel cylinders for the reception of the dissolved acetylene are first completely filled with a substance having a porosity of 80 per cent., which is then caused to absorb as much acetone as would occupy 40 per cent. of the volume of the cylinder. The actual gas capacity of the cylinder is thus 40 per cent. of 25, or 10 volumes per atmosphere of pressure.

Dissolved acetylene cylinders should not be discharged below the atmosphere gauge pressure, because the rate at which the acetone is carried off by the gas greatly increases as the pressure approaches zero. Acetone vapour has no detrimental effect upon the consumption of the gas in the burner. It is generally found necessary to make up the quantity of acetone, after five to ten refillings of the cylinder with acetylene.

Economies in the consumption of dissolved acetylene have been effected by the introduction of mechanism for emitting flashing or occulting lights invented by Mr. Gustav Dalen and others whereby a wide range of intermittent light signals can be produced automatically.

To the same scientist is attributable the *Sun-valve*, or, more correctly, the *Light-valve*, which is a mechanical device sensitive to light and actuated entirely by the alternation of daylight and darkness. It opens the gas supply at nightfall and closes it at daybreak with perfect regularity, resulting in a saving of some 25 to 40 per cent. of the gas, according to climate, as compared with a constantly burning light. The use of the instrument is generally restricted to shore lights, or lights of considerable magnitude.

Mr. Dalen has further produced complete automatic apparatus for mixing in correct and constant proportions the dissolved acetylene and air and for burning the compound in conjunction with incandescent mantles, either as a constant or intermittent light. This apparatus, by reason of its nature, is more applicable to lights of considerable power, superior to those generally fitted to buoys.

Lenses.—Lenses are usually of 150 to 300 mm. (6 to 12 ins.) diameter. The candle power of lanterns fitted with an oil-gas burner with incandescent mantle or a 25-litre acetylene burner and 200 mm. diameter lens, is about 200 candles, and with 300 mm. lenses about 300 candles.

The elevation of a luminous buoy given in fig. 32 (the Gas Accumulator Co. (United Kingdom), Ltd.) has been selected as an example of buoy design with an unusually varied range of application. It has been designed primarily for use as a spare or wreck-marking buoy.

The lantern, which can be of any size up to that carrying a 300-mm. lens, is mounted upon a trestle superstructure. In this way it is possible to place any one of the three conventional types of daymark in position, namely, can, cone, or spherical, without in any way interfering with the light apparatus. The lantern carries a special type of flashing mechanism which is so designed that any one of three characters can be exhibited at will by simply turning a valve on the burner stem. The characters are single, double, or triple flashing.

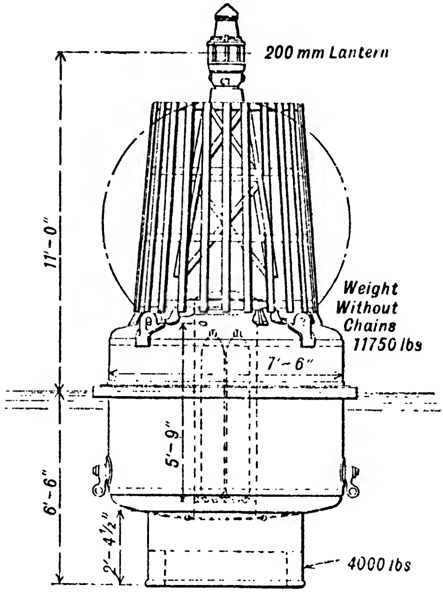

FIG. 32.—Luminous Buoy.

Two accumulators are the minimum number with which the buoy may be equipped and retain its calculated stability, but, if necessary, the number can be increased to four, and the unattended service period can be as much as twelve months.

The candle-power depends upon the size of lens and burner used. With a 300-mm. lantern and 15-litre burner this would amount to 180 s.c.p. The coloration of the light can be varied at will by the insertion of suitably tinted glass shades inside the lens and surrounding the flame. Further reference to the use of acetylene lighting will be found on page 651.

Lightships.

Lightships afford a more powerful light than luminous buoys, and the focal plane is at much higher level—generally about 35 to 40 ft. above the water surface. They are more costly both in first outlay and maintenance, and are usually manned by a crew, though this is not essential in all cases.

Small lightships, without constant attendance, are stationed on the coast of this country and of France. A vessel of this type is about 40 ft. long, 12 ft. beam, and 8 ft. deep, fitted with a storeholder containing 2,500 cubic ft. of gas, which is sufficient to maintain a light for 3 months. Many unattended light vessels in all parts of the world are equipped with dissolved acetylene lights and run without recharging for six or twelve months.

Larger vessels, with crews, range from 60 to 150 ft. in length, from 20 to 30 ft. in breadth, and from 10 to 20 ft. in depth, the draught being from 7 to 10 ft.

Lenses vary from 250 mm. to 500 mm. focal length and the candle-power from 2,000 to 500,000. Catoptric reflectors with a candle-power of 4,000 are used in the oldest types of light-vessels. Some modern light-vessels are being equipped with electric light, and fig. 33 shows a typical example of the flashing optic and pendulum revolved by an electric motor. The illuminant is an incandescent electric filament lamp and the lens is of small Third Order size (375 mm. focal length). The whole of the optical apparatus is swung on gimbals, so tha the beam is kept practically horizontal, and is entirely of Trinity House design.

Third "	500		

The Eddystone Lighthouse.

The type of foundations and general construction of rock lighthouses is well exemplified by the new Eddystone Lighthouse. In this structure the tendency of the curvilinear outline of Smeaton's and of other similar sea-towers that have succeeded it, to elevate the centre of force of each wave-stroke on the structure, induced Sir James Douglas to adopt a cylindrical base, from which base, at a level of 2½ feet above high-water spring-tides, the curved shaft of the tower commences. The difference in the rise of heavy seas on the two structures during stormy weather is remarkable. The cylindrical base has the further advantage of affording a convenient landing platform, thus adding considerably to the opportunities of relieving the lighthouse.

The base is 44 feet in diameter by 22 feet in height. The tower is a concave elliptic frustum, the generating curve having a semi-transverse axis of 173 feet, and a semi-conjugate axis of 37 feet. With the exception of the space occupied by the fresh-water tanks, the tower is solid for 25 ft. 6 ins. above high-water spring-tide level. At the top of the solid portion the wall is 8 ft. 6 ins. in thickness, diminishing to 2 ft. 3 ins. in the thinnest part of the service-room. All the stones are dovetailed both horizontally and vertically. The system consists in having a raised dovetailed band 3 inches in height on the top bed and on end joint of each stone. A corresponding dovetailed recess is cut in the bottom bed and end joint of the adjoining stones, with just sufficient clearance for the raised band to enter it freely in setting. From experiments made with blocks put together in this manner with Portland cement, it is found that the work is so homogeneous as to be as nearly as possible as strong as the solid granite.

Each stone of the foundation-courses (figs. 34, 35) is sunk to a depth of not less, at any part, than 1 foot below the surface of the surrounding rock, and is further secured by two Muntz metal bolts, 1½ inch in diameter, passing through the stone, and 9 inches into the rock below, the top and bottom of each bolt being fox-wedged.

The masonry consists of 2,171 stones, containing 62,133 cubic feet of granite, or 4,688 tons.

Cost of Construction of Various Lighthouses.

Name of Structure.	Total Cost.			Cubic Feet.	Cost per Cubic Foot.		
	£	s.	d.		£	s.	d.

Different Descriptions of Lights.

(1) *Fixed.*—The light being continuously visible.

(2) *Occulting.*—A light regularly eclipsed in which the duration of light is greater than the duration of darkness.

(3) *Group occulting.*—An occulting light with two or more occultations in quick succession.

(4) *Flashing.*—A light regularly eclipsed in which the duration of light is shorter than the duration of darkness.

(5) *Group Flashing.*—A flashing light with two or more flashes in quick succession.

(6) *Alternating Light.*—A light in which successive occultations or flashes are alternate colours, usually white and red.

BASE OF EDDYSTONE LIGHTHOUSE.

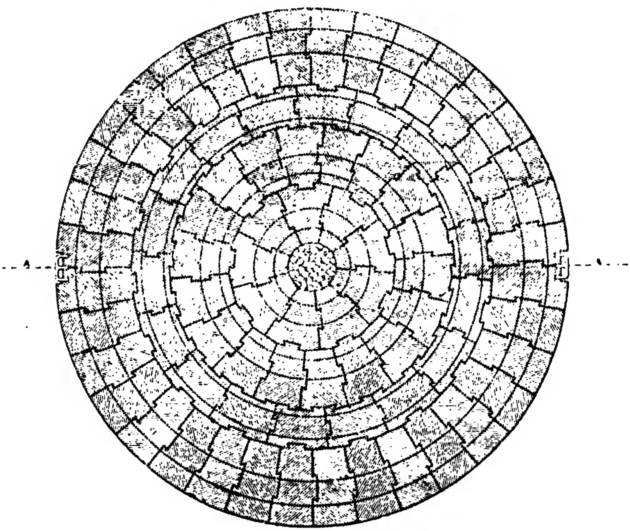

FIG. 35.

Distance visible from Lighthouses.

The following Table shows the distance of the horizon visible from towers of the heights given. In it the necessary correction has been made for refraction :—

H. Heights in Feet.	λ. Lengths in English Miles.	H. Heights in Feet.	λ. Lengths in English Miles.	H. Heights in Feet.	λ. Lengths in English Miles.
5	2·958	80	11·832	250	20·916
20	5·916	90	12·549	300	22·912
30	7·245	100	13·228	350	24·748
40	8·366	120	14·490	400	26·457
50	9·354	140	15·652	600	32·403
60	10·246	150	17·201	800	37·416
70	11·067	200	18·708	1,000	41·833

Optical Apparatus.

The essential part of a lighthouse is the optical apparatus, which is formed of glass lenses and reflecting prisms in order to concentrate the light from the burner in the required direction. The optical apparatus of a fixed light concentrates the rays in the vertical plane only, and sends out a zone of light which illuminates the horizon over the whole 360° or any less angle which may be required. That of a flashing light concentrates the rays in both the vertical and horizontal planes, and thus throws out a series of beams, the number varying with the character which the light is required to give. The whole apparatus is revolved, and by this means the beams sweep round the horizon and appear as flashes at definite intervals to the mariner.

Large lights are supported on a mercury float whereby friction of movement is reduced to a minimum ; ball bearings are satisfactory for lights up to small third order. The former enables the largest type of optical apparatus, the weight of which runs up to 10 tons, to be rotated, with the minimum friction.

It is usual to arrange the optical system so that the flashes have a minimum duration of 0·2 second ; it has been found that a shorter duration is not sufficient for the mariner to detect the flash in hazy weather. Fig. 36 illustrates an optical apparatus of 700 mm. focal distance and 500,000 candle-power, mounted on a mercury float pedestal, and also the lantern which protects it. The lens is shown with a system of prisms outside, to throw upwards a beam of 11,000 candles for the use of aircraft.

Large glass catoptric mirrors with a single light source as developed by Mr. Stevenson for the Poward Lighthouse on the Clyde, are now employed at certain lighthouses.

Sources of Lighthouse Illumination.

Where an electric supply is not available paraffin oil and dissolved acetylene gas are the most suitable and economic illuminants.

Oil and gas lights, when shown through similar lenses, are equally affected by atmospheric variations. The electric light is absorbed more largely by haze and fog, but in all weathers and at all distances its penetration has proved superior.

The luminary now in general use at large lighthouses is the petroleum vapour burner, to which paraffin oil is supplied under pressure, and is vaporised in a retort beneath the burner, being afterwards consumed in an incandescent mantle. The sizes of mantle usually employed vary from 35 mm. to 110 mm. in diameter with intensities up to 3,500 candles.

A modern burner of this type is the ' Hood ' petroleum vapour burner designed by the late engineer-in-chief to the Trinity House ; the mantle employed is of the autoform type, with an intrinsic brightness of 325 candles per sq. in. The burner is in five sizes, 25 mm., 35 mm., 50 mm., 75 mm., and 100 mm., with total intensities of 400, 660, 1,150, 2,200, and 3,300 candles, and consumptions of 0·50, 0·75, 1·25, 2·25, and 3·25 pints of oil per hour, respectively.

At the Eddystone, which is a biform light having superimposed lenses and burners, the resultant beam with a 35 mm. ' Hood ' burner in each tier, is nearly 600,000 candles and the consumption 700 gallons per annum.

The development in high-powered electric incandescent filament lamps has made possible their use for lighthouse illumination. Lamps up to 10 kw. are now employed and, combined with automatic apparatus, effect economy in maintenance by the reduction of personnel.

For minor lighthouses and portlights at the entrances to harbours, etc., the illuminant is sometimes a capillary wick lamp having one or more wicks, which can be left without attention for a single night. A distinctive character is given to such lights by means of revolving screens driven by a simple clockwork mechanism which will run for a night without rewinding ; the screen occults the light at regular intervals. For the entrance to harbours where range is not a great consideration the light may be coloured red or green. Where electricity is available electric lamps are employed and a small motor used for revolving the screens. Sometimes an electric flashing mechanism is used to give the character.

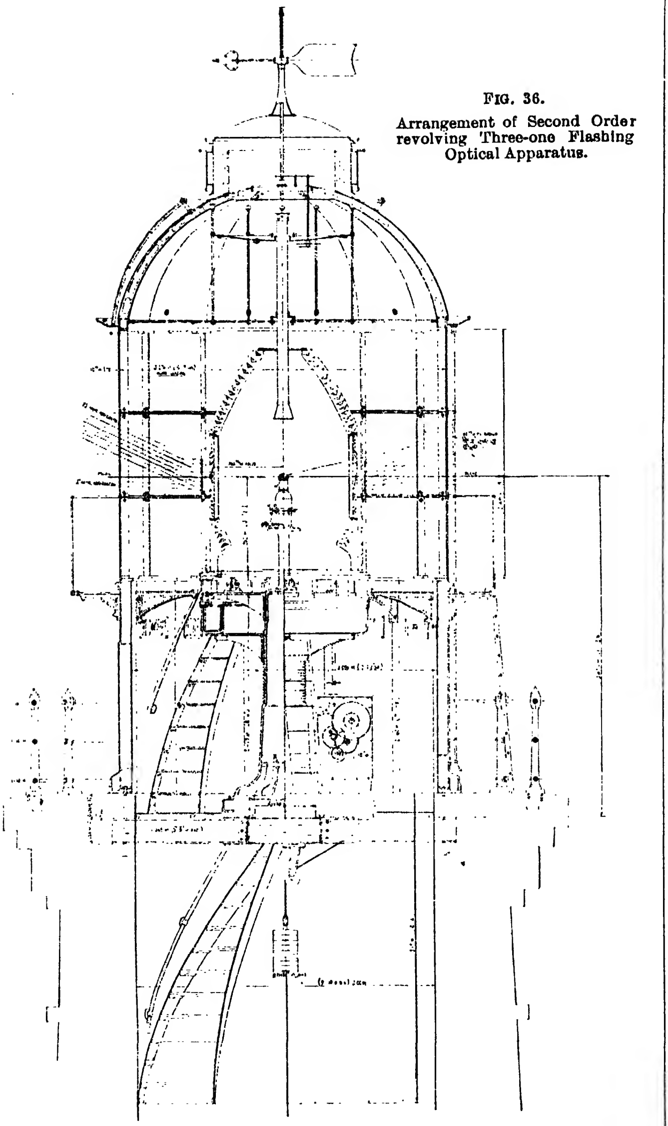

FIG. 36.

Arrangement of Second Order revolving Three-one Flashing Optical Apparatus.

Many lights are now left unattended for long periods, and the illuminant is generally compressed oil-gas, stored in receivers, or acetylene gas, manufactured in generators on the spot or on the dissolved acetylene principle; or electricity.

BAS SERANI LIGHTHOUSE, MOMBASA.

The following description of a modernised lighting equipment has been furnished by the Gas Accumulator Co. (United Kingdom), Ltd.:—

The lighthouse was originally equipped with an oil-burning, clock-driven rotating lens installation attended by light keepers.

In 1928 it was converted by the company, the light source being a 500 watt electric lamp mounted in a catadioptric section of a drum lens having an arc of illumination of 180°. The focal distance of the lens is 300 mm.

Electric current is derived from the town lighting mains, at a pressure of 240 volts, the supply being 50 periods, single-phase.

In order to render the apparatus automatic in operation and cover lamp filament and supply current failures a burner changer mechanism is installed as shown in fig. 38, p. 655. Two electric lamps are fitted, one being in the focal points of the lens, the other being carried on an arm at 120° to it; a third arm, again at 120°, carries an acetylene burner, the whole being arranged to rotate about a vertical axis. Should the filament of the lamp in service break, the cessation of the flow of filament current is utilised to operate a release gear, whereby the second bulb is brought into the focus and the defective one removed. As the new lamp comes into position, it lights up and thereby stops the action of the changing mechanism.

Should a failure of the electric supply occur due to a breakdown at the power station or for any other reason, the acetylene burner is automatically brought into focus. On renewal of the electric supply an electric lamp is replaced at the focus.
