The corrodibility of iron in contact with various alloys depends, as in the case of single metals, on the position of the alloy in the electrochemical series. O. Bauer and O. Vogel found that in a 1 per cent. soln. of sodium chloride, at 18°, the e.m.f. after 120 hrs. ranges from −1·5 volts with *magnesium-zinc alloys* ; −1·480 volts with *magnesium-aluminium alloys* ; −1·115 volts to −0·980 volt with *magnesium-zinc-aluminium alloys* ; −1·026 volts with *zinc-aluminium-copper alloys* ; −1·012 volts with *zinc-tin alloys* ; −0·936 volt with *zinc-aluminium alloys* ; from −0·763 to −0·577 volt with *aluminium-copper alloys* ; from −0·762 to −0·759 volt with *cast iron* ; −0·744 volt with *steel* ; −0·707 volt with *Wood's alloy*—that is, Bi : Pb : Sn : Cd as 50 : 25 : 12·5 : 12·5—percentages by weight ; −0·581 volt with 25 per cent. *nickel-steel* ; −0·483 volt with *lead-antimony alloys* ; from −0·418 to 0·401 volt with *tin-antimony-copper alloy* ; with *brass* :

Copper . . .	40·4	48·4	51·9	70·2	77·8	92·3 per cent.
E.m.f. . . .	−0·401	−0·359	−0·322	−0·236	−0·212	−0·193 volt

from −0·170 to −0·146 volt with *tin-copper alloys* ; −0·154 volt with *phosphor-bronze*—0·493 per cent. phosphorus and 5·69 per cent. of tin ; and −0·100 volt with *nickel-copper alloy* with 49·27 per cent. of copper. Observations were also made by O. Bauer, G. von Knorre, G. C. Clifford, and O. P. Watts and H. C. Knapp. W. P. Jorissen observed that the attack on iron with brass containing 33·4 per cent. of copper was less than with brass with 36·9 per cent. of copper.

In connection with the corrosion of the iron by organic acids in fruit juices preserved in "tinned cans," E. F. Kohman and N. H. Sanborn studied the electrochemical relations of tin and iron. They found that at concentrations eq. to 0·75 per cent. malic acid, tin is distinctly cathodic in acetic, malonic, and succinic acids, only slightly cathodic in malic acid, and distinctly anodic to iron in citric acid. Addition of apple pomace to acetic, malonic, and succinic acids reverses the condition and the tin becomes anodic, a further protection to iron being also induced by the presence of tin in soln., which raises the cathodic polarization on iron. In hydrochloric and sulphuric acids of conc. ranging from 0·05 to 20 per cent., tin becomes increasingly more anodic to iron with increasing conc. of acid even when the metals are not in electrical contact, and corrosion of tin is very greatly increased with metallic contact, due to galvanic action. The potential conditions are influenced chiefly by the $H^{\cdot}$-ion conc. and negligibly by the conductivity of the soln. The results agree with those of commercial practice in which the more acid fruits produce little perforation of the container, although less acid fruits—*e.g.* black cherries, in the juice of which tin is only mildly anodic to iron—cannot be canned successfully because of the hazard of corrosion. The subject was discussed by C. L. Mantell, E. Nehring, P. and E. Nehring, O. Carrasco and E. Sartori, A. Pellerin and E. Lasausse, E. Gudeman, E. F. Kohman and N. H. Sanborn, and T. N. Morris and J. M. Bryan. R. H. Lueck and H. T. Blair observed that in approximately 0·2*N*-soln. of various acids having p_H ranging from 0·81 to 2·98, iron dissolves with evolution of hydrogen but tin is unattacked. With an iron-tin couple, hydrogen is evolved but the rate of evolution is always less than that from uncoupled specimens of iron. With a citric-malic acid soln. of $p_H=2·98$ this protective action of tin on iron is exhibited when the soln. is aerated as well as when it is kept sat. with hydrogen or nitrogen. Corrosion is most rapid in the aerated soln., but in all cases it is the tin which dissolves more rapidly from the couple. Cadmium coupled with iron protects it to a similar extent, but the cadmium dissolves more rapidly than tin under the same conditions. As just indicated, the e.m.f. of cells of the type Fe | canned foods | Sn shows that, although tin is definitely cathodic to iron on open circuit, on short-circuiting, the e.m.f. falls rapidly and changes sign, the tin becoming the anode. The removal of either electrode and exposing it to air gives it a more noble potential. With similar cells using iron and cadmium electrodes, the latter is always the anode and the e.m.f. changes very little on short-circuit; using tin and cadmium, cadmium is again always anodic, but the e.m.f. falls notably on a closed circuit and recovers gradually when the circuit is opened. In a diaphragm cell containing a citric-malic acid mixture buffered to $p_H=3·5$, with the iron electrode in a soln. sat. with oxygen or hydrogen, the tin electrode always becomes the anode whether the soln. into which it dipped is kept saturated with oxygen or with hydrogen or not treated with gases at all. But with no gas passed through the soln. around the iron, the tin is always cathodic if the soln. into which it dipped is kept sat. with oxygen or with hydrogen. The addition of hydrogen dioxide to the soln. around the tin also keeps it cathodic to the iron. These results are related to the high hydrogen overvoltage of tin compared with that of iron; the tin becomes polarized and then hydrogen is more readily liberated at the iron. The abnormal tendency of canned fruits to cause the perforation of the tin container is possibly due to the presence of mild oxidizing agents which cause the microscopic areas of exposed iron to become anodic to the surrounding tin.

The speed of the reaction between iron and the ambient medium—say, a corrosive acid—is determined by the rate at which the film of liquid in contact with the metal is saturated, and on the rate at which the solute diffuse into the surrounding medium. This so-called *diffusion theory of dissolution* was studied by E. Bruner, L. Bruner and St. Tolloczko, W. Nernst, A. A. Noyes and W. R. Whitney, W. Palmaer, W. G. Whitman and co-workers, and R. P. Russell and co-workers.

W. R. Dunstan and J. R. Hill consider that when air and water alone fail to produce rusting, the iron has been made passive by the process of purification, and that carbon dioxide destroys the passivity and inaugurates rusting. The normal rusting process is a result of the direct action of oxygen dissolved in water upon the iron—ferrous hydroxide is first formed and this subsequently oxidizes to the ferric condition. Substances in soln. which inhibit rusting are supposed to do so by making the iron passive—*e.g.* oxidizing agents like alkali chromates, dichromates, permanganates, iodates; and potassium sodium hydroxides, etc.—and some of these substances—*e.g.* potassium dichromate—have found industrial application as anti-rusting agents.

Iron of a high degree of purity was found by H. Kreusler, A. Skrabal, A. Neuburger, J. A. N. Friend, and B. Lambert to be comparatively inactive. Industrial iron is impure, and not physically homogeneous; while natural water always contains electrolytes. Hence, local currents may be generated on the surface, and as a result the metal may be dissolved in one place and give off hydrogen in another, so that the impurities act as centres of corrosion. The oxygen dissolved in the water acts as a depolarizer for the cathodic hydrogen. M. Centnerszwer and M. Straumanis demonstrated the existence of these local currents; and F. Tödt, that the corroding surface of iron consists of local elements of active and passive metal. E. Pietsch and co-workers observed that distilled water alone does not attack homogeneous surfaces of iron, but with heterogeneous surfaces rusting commences between the grains. O. P. Watts found that a " busy rail "—that is, a rail in regular use—is electropositive to an "idle rail" and so is less liable to rust. Similarly, cold-worked metal is electropositive to the unworked metal.

In the case of iron and steel there may be many different phases—graphite, carbide, phosphide, oxide, sulphide, etc.—and the distribution of anodic and cathodic areas on the surface of the metal can be explored by the so-called *ferroxyl indicator* suggested by W. H. Walker and co-workers, and A. S. Cushman and H. A. Gardner. The soln. or jelly, containing potassium ferricyanide, and phenolphthalein, becomes blue where the iron acts as an anode, and passes into soln. as a ferrous salt, while it becomes pink where the iron acts as cathode and alkali is liberated. The test was discussed by H. S. Rawdon, W. van W. Scholten, U. R. Evans, S. Kyropoulos, J. W. Cobb, W. Blum and C. F. Thomas, and K. Pitschner. R. E. Wilson observed that the potassium ferricyanide in the indicator may act as oxidizing depolarizer when no sensible increase in the conc. of the OH′-ions occurs, and the cathode areas are then recognizable by the disappearance of the yellow colour of the ferricyanide. A. S. Cushman described the preparation of the ferroxyl indicator as follows:

> A 1·5 per cent. soln. of agar-agar is first made by dissolving a weighed quantity of powdered agar-agar in the requisite amount of water. This soln. is boiled for 1 hr., fresh water being added to replace that lost by evaporation. It is then filtered while hot, and 2 c.c. of standard phenolphthalein indicator added to every 100 c.c. of soln., after which it is brought to a perfectly neutral condition by titration with a 0·1*N*-soln. of potassium hydroxide, or hydrochloric acid, as the case may be. The addition of 7 c.c. of a 1 per cent. soln. of potassium ferricyanide to every 100 c.c. of soln. is then made, and the ferroxyl reagent while still hot is ready to use. Enough of the reagent should be poured into a dish just to cover the bottom and the dish floated in cold water until the agar-agar has jellied. A clean sample of iron is then placed on this bed of jelly and covered with the hot soln. After the final addition of agar-agar the dish should not be removed until thoroughly cooled. While the colours sometimes show up immediately, they usually require from 12 to 24 hrs. to attain their most perfect development. The mounts may be preserved for many months by keeping the surface of the agar-agar covered with alcohol.

L. Aitchison observed that compact iron consists of crystals of ferrite, separated by an amorphous cement; the soln. press. of the cement must differ from that of the ferrite, so that when immersed in water, a difference of potential will be set up which must lead to corrosion. If the cement is positive to the ferrite, the cement will be corroded, and conversely. When steels are attacked by dil. acids, J. O. Arnold and A. A. Read—*vide supra,* sulphuric acid—showed that the ferrite passes into soln. while the carbides are not attacked but remain in their original form. The irregularity in the composition of a piece of iron and steel produced by segregation, etc., was discussed by R. H. Gaines, J. W. Cobb, and W. Marriott; and the pitting produced by local galvanic action due to surface impurities—traces of cinder, slag, sulphide, oxide, etc.—by C. Bach, N. Barnaby, O. Bauer, U. R. Evans, G. Gallo, B. Garre, W. W. H. Gee, E. Heyn and O. Bauer, S. Kyropoulos, V. B. Lewes, J. T. Milton and W. J. Larke, W. Palmaer, W. Parker, H. F. Richards, L. T. Richardson, A. Schleicher and G. Schultz, C. J. Smithells, R. Stumper, W. H. Walker and W. K. Lewis, G. C. and M. C. Whipple, and W. H. White—*vide infra.* As emphasized by U. R. Evans, this does not necessarily mean that impure metals have a greater tendency to corrode than purer metals.

R. Stumper found that the corrosion of iron is considerably increased when the metal is in contact with iron sulphide, and in the case of galvanic contact, the corrosion is more than twice as great. R. Mallet explained the greater corrosion of thin pieces of cast iron in sea-water by showing that thin castings cool more quickly and more irregularly than thick ones so that they are more likely to be less homogeneous. Consequently, when immersed in sea-water the number of local voltaic couples is proportionally increased, and the corrosion is thus augmented. The difference was most marked with grey, or graphitic, cast iron, and least marked with the white varieties. U. R. Evans observed that local electrolytic action may occur owing to the local abrasion of surface layers. Where the corrosion product is loose and flocculent, the abraded portion is often cathodic, and no local action occurs, but when the film is thin and highly protective, the abraded portion will be anodic, and corrosion on that part will be intensified. Similarly, local currents may be produced by the same metal, one part greased and one part not greased. G. A. Tomlinson discussed the corrosion of steel surfaces in contact.

B. Martell, and W. Denny mentioned puzzling cases of corrosion which have occurred when old iron structures have been patched up with new material. Pliny, in the first century of our era, mentioned such a case in his *Historia naturalis* (**36**. 43), for he said that the iron chain across the river Euphrates at Zeugma (Mesopotamia) was repaired by introducing new links, but the new links gathered rust under conditions where the remainder of the old links were free from rust. R. Mallet found that in sea-water, grey cast iron in contact with white cast iron corroded with the greater velocity, so that white cast iron was protected by the grey cast iron. T. Andrews found that the potential difference in volts between cast iron and wrought iron, in sea-water, is 0·030 volt in favour of cast iron for 233 days out of 300, and during that time, the cast iron was less corrodible than wrought iron ; but the potential difference varies from day to day, so that in some cases the potential difference is reversed, and he found in one case the potential difference is —0·011 volt, so that wrought iron having the higher potential was least attacked for 66 days out of 300. The adhesion of rust, and the heterogeneity of the metal are known to affect the difference of potential. E. Heyn and O. Bauer also found that the contact of steel with cast iron reduced the corrosion of steel. Hence, the contact between steel and cast iron may augment corrosion and be a source of danger. J. A. N. Friend mentioned a serious accident in the Portsmouth Dockyard owing to the abnormally rapid corrosion of wrought iron in contact with cast iron. Errors may occur in experimental work when one metal plate is placed above another in the corroding liquid, for the one plate may prevent a certain amount of oxygen diffusing to the other plate, and thus reduce corrosion independently of any galvanic action. V. B. Lewes mentioned a possible case of galvanic activity when plates of the same metal but at different temp. form couples ; and T. Andrews, *vide supra*, when plates of strained and unstrained metal are in contact—the unstrained metal is electropositive to the strained metal. The galvanic action between different kinds of iron was discussed by J. Farquharson, H. Diegel, H. S. Munroe, W. Parker, A. Ledebur, A. Sang, H. M. Howe, etc.

The galvanic activity between strained and unstrained pieces of the same iron was discussed by T. Andrews, W. M. Barr and R. W. Savidge, C. F. Burgess, U. R. Evans, C. Hambuechen, E. Heyn and O. Bauer, K. Mandi, T. W. Richards and G. E. Behr, W. Spring, W. H. Walker and C. Dill, etc.—*vide infra*. F. Osmond and J. Werth found that the cold-worked metal dissolves faster than does the unworked metal in salt soln. P. A. von Bonsdorff, C. F. Burgess, U. R. Evans, J. A. N. Friend, P. Goerens, H. Hanemann and C. Lind, W. Charpentier, E. Heyn, R. Kremann and R. Müller, D. J. McAdam, T. W. Richards and G. E. Behr, R. P. Russell and co-workers, and M. Werner made observations on this subject. According to B. Garre, the rate at which iron dissolves in dil. sulphuric acid increases directly with the number of twists to which the metal has been subjected, and the rate of dissolution of iron is greater after bending than before. H. S. Rawdon also noted that intercrystalline corrosion is favoured by high stresses. As indicated below, H. Endo observed that the loss by corrosion in dil. sulphuric acid is almost proportional to the amount of deformation by tensile stresses ; the loss also increased with torsion, and, in general, the attack is greatest where the twist is greatest ; and the loss also increases with the load of compressive stresses. J. A. N. Friend found that, as a rule, unstressed iron corrodes more quickly than iron which has been deformed by stretching, twisting, or compression—*vide infra*, corrosion fatigue. The slower the rusting of busy iron in comparison with idle iron—*e.g.* railway lines—was discussed by J. A. N. Friend, O. Bauer, and A. S. Cushman and H. A. Gardner.

A. C. Brown,[13] O. Brown, and J. Aston and co-workers observed that iron coated with freshly-formed rust, which has had no chance to dry, is always anodic to the bare metal, so that the rust promotes electrolytic effects equal to or surpassing those factors generally considered to be of marked importance. There is sometimes a reversal of the current between anodic rust and the cathodic metal. The change in the polarity of freshly-formed wet rust is attributed to unpreventable local action on relatively large electrode surfaces. Dry rust tends to reverse its initial cathodic character and to behave like fresh wet rust after varying periods of immersion. The reversal of the polarity in the drying of wet rust is attributed to a change in the degree of hydration, to the adsorption of gases from the atmosphere, or to the formation of an oxide or other compound of iron in contact with the metal surface. The effect of rust on the surface of the metal was discussed by J. Aston, O. Bauer, E. L. Chappell, U. R. Evans, J. A. N. Friend, F. Goudrian, E. Heyn, O. Kröhnke, R. Kremann and R. Müller, E. Maass and E. Liebreich, E. A. and L. T. Richardson, W. D. Richardson, A. Schleicher and G. Schultz, G. C. Schmidt, J. Spennrath, J. Stapenhorst, W. A. Tilden, W. H. Walker, G. C. and M. C. Whipple, and H. Wölbling. L. H. Callender showed that a boundary film solid, liquid, or gas—tends to form on a metal whenever the film has a higher potential than the metal itself. E. L. Chappell, and T. Fujihara discussed the rôle of rust-films in the corrosion of metals. According to G. A. Tomlinson, the rusting which occurs when the two pieces of steel have been rubbed together is not due to the crushing of the surfaces of contact and so producing minute particles of powder which oxidize rapidly, but he considers that the phenomenon is a result of molecular cohesion produced by pressure.

J. Aston showed that the reason wet rust promotes further rusting is not due to its acting as a cathode, but rather because it acts as a diaphragm the same as the interposition of wet cloth, or filter paper between two metals. J. Aston said:

> The underlying feature appears to be the relative access of oxygen to the surface of the electrodes. The electrolyte (moisture) must reach both; then that to which oxygen has the more free access becomes the cathode, and the other is the anode. If two bare iron electrodes are separated by a partition of porous earthenware, parchment, etc., either may be made the cathode by bubbling air into this compartment, and not into the other. Wet rust or similar coating upon one electrode plays the rôle of a diaphragm permeable to the moisture, but preventing or slowing down the oxygen penetration. Anodic soln. of the underlying iron results, with oxidation and precipitation as greenish ferrous hydroxide. This colloid, migrating outwards under the directive influence of the current, is in turn oxidized to ferric hydroxide nearer to the exposed surface of the rusted anode. The effect of rust and oxygen is well illustrated by local rusting of an iron sheet which has air bubbling up one strip or zone. Contrary to general expectation, the zone supplied with air remains clear, whilst the adjoining parts are anodic and become coated with rust.

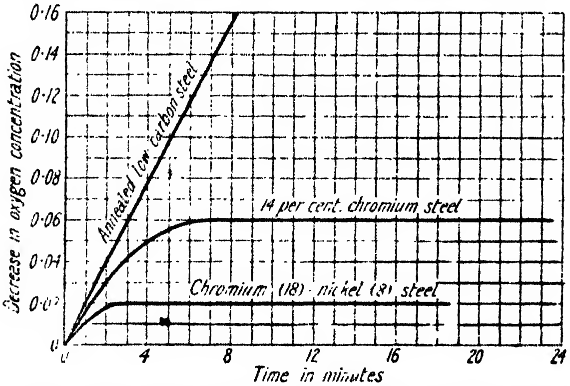

FIG. 363.—Initial Rates of Corrosion of Ordinary and Alloy Steels.

According to H. O. Forrest and co-workers, the corrosion of iron and other metals in, say, aerated water is attended by the formation of more or less protective films of hydrated oxide on the surface of the metal. The metals which are usually considered to resist corrosion, like ordinary iron and steel, are initially attacked in a similar manner, but so-called resistors of corrosion form a very resistant and protective surface film. The differences in the resistance of, say, ordinary mild steel and stainless steel is attributed solely to differences in the physical and mechanical properties of the films. Fig. 363 represents the rates of attack of these steels expressed in terms of the rates at which oxygen is consumed in c.c. per sq. dm. Corrosion starts in all cases but ends very quickly as the protective film is formed. This is shown by the flattenings of the curve corresponding with zero corrosion. The curve for the low-carbon steels begins to flatten after a longer period of time, but the film is here not so resistant as in the case of the two alloy steels.

In 1830, E. Marianini found that momentary currents can be produced between two zinc electrodes immersed in water, simply by lifting one of them into the air and replacing it; and E. Warburg, and W. Kistiakowsky showed that an electrical current may be generated by variations in the conc. of the oxygen in the soln., and by variations in the conc. of the salts in soln. in contact with different parts of the metal. U. R. Evans made a special study of the electrical currents set up by the **differential aeration** of metals. In what he called the key experiment, a cell was made with two sheets of the same iron as electrodes; one of which was placed in a porous cell of parchment; the electrolyte was 0·5N-KCl; the electrodes were connected with a milliammeter. Air was bubbled against the iron plate in the outer compartment. The milliammeter then showed that the aerated electrode was the positive pole or cathode, and the unaerated electrode was the negative pole or anode; the current was provided by the consumption of metal from the unaerated electrode, since the unaerated electrode loses more weight than the aerated electrode. If the current be tapped from a plate of metal immersed vertically in a soln. of potassium chloride exposed to air, a current flows between the upper aerated zone at the top, and the unaerated portion below. The general results indicate that the corrosion of metals like iron, zinc, and lead by a soln. of a salt like sodium chloride is an electrochemical process; for it involves (i) the production of an electric current; (ii) the production of a soluble metal salt—ferrous chloride—at the anodic or unaerated places; (iii) the production of sodium hydroxide at the cathodic or aerated places; and (iv) the precipitation of an insoluble hydroxide—*e.g.* ferrous hydroxide—where the products from the cathodic and anodic zones meet. The white ferrous hydroxide darkens rapidly, and it may appear green on the lower surface and brown on the upper surface. This is illustrated by U. R. Evans' study of the corrosion of a dry horizontal sheet of polished iron by a drop of a soln. of sodium chloride resting on it. After some minutes, a precipitate of ferrous hydroxide begins to appear, not at the edge, but in a circle running round the drop a short way within the margin—Fig. 364. The precipitate is at first white, and after a time it becomes brown, and extends as a membrane until it passes over the top of the drop. A sample of liquid taken from the clear outer ring is strongly alkaline, and free from iron salts, while a sample abstracted from the interior, by means of a fine capillary tube, contains ferrous chloride but no free alkali. Oxygen is more easily renewed at the edge than near the centre of the drop, so that metal under the outer rim of the drop acts as cathode and alkali hydroxide is formed, whereas in the interior unaerated portion the metal suffers anodic attack and ferrous chloride is formed. Along the surface of contact of the alkali hydroxide and ferrous chloride soln., a ring of white ferrous hydroxide is formed, which by further oxidation changes to rust-brown hydrated ferric oxide. Corrosion occurs only in the central portion of the drop. Hence, U. R. Evans concluded that corrosion is likely to persist most readily in places where oxygen has least access, provided the inaccessible places are not far removed from places to which oxygen can freely penetrate. He illustrated the principle of differential aeration by the

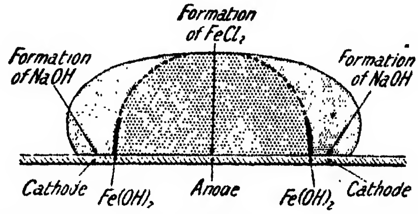

FIG. 364.—Vertical Section illustrating the Corrosion of Iron by a Drop of a Solution of Sodium Chloride.

case of a minute cavity in a plate of metal immersed horizontally just below the surface of a soln. of sodium chloride. Oxygen will not be so quickly supplied to the liquid within the cavity as it is to liquid over the plane surface of the metal. Hence, the metal about the cavity becomes anodic, and the aerated portion outside becomes cathodic. The phenomena occurring in the case of the drop are repeated under another guise—Fig. 365. The general result is that the corrosion is concentrated upon a small anodic area within the cavity, and pitting results. The drop method of studying corrosion was employed by U. R. Evans, T. Fujihara, and T. S. Fuller; and the principle of differential aeration was discussed by E. Maass and E. Liebreich, E. Herzog and G. Chaudron, F. Tödt, E. Liebreich, D. W. Smith and R. F. Mehl, and H. Cassel and T. Erdey-Gruz.

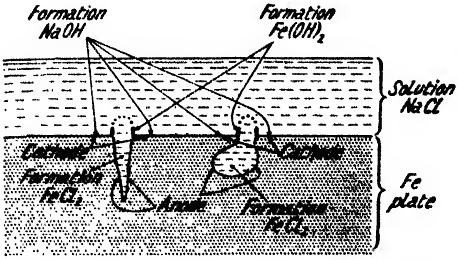

FIG. 365.—Vertical Section illustrating the Formation of a Couple of Pits in Iron immersed in a Solution of Sodium Chloride.

A. Payen noted the localized oxidation at what he called oxidized points. The corrosion of iron is thus due to the formation of local *oxygen concentration cells*. The amount of corrosion depends on the supply of the corroding agent to the cathodic areas where it acts as a depolarizer, but the metal is attacked in the anodic areas. At the cathodic surface, $6H'+1\cdot5O_2=3H_2O+6\oplus$; at the anodic surface, $2Fe+4OH'=2Fe(OH)_2+4\ominus$; and in the corrosion product, $2Fe(OH)_2+2HO'=2Fe(OH)_3+2\ominus$, the resultant reaction being $3H_2O+1\cdot5O_2+2Fe=2Fe(OH)_3$. The theory was discussed by R. E. Wilson, J. Aston, R. J. McKay, W. G. Whitman and co-workers, and F. N. Speller. The localized forms of corrosion known as pitting and perforation are usually the most serious forms of corrosion. Many pounds of iron might be lost by a boiler through uniform surface corrosion without any particular harm, but a small proportion lost by pitting might perforate the plate; or, as A. S. Cushman expresses it, just as a chain is no stronger than its weakest link, so also a piece of iron in service may be ruined and discarded even if more than 99 per cent. of its mass and surface is still in good condition. The subject was discussed by J. R. Baylis, C. Benedicks, S. C. Britton and U. R. Evans, E. Englesson, U. R. Evans and C. W. Borgmann, J. A. N. Friend, G. N. Huntley, E. Liebreich, G. Mehrtens, J. Mitchell, E. Pietsch and E. Josephy, G. Schikorr, E. H. Schulz, A. Thiel and W. Ernst, W. Thomson, F. Tödt, G. C. and M. C. Whipple, A. Winstanley, and F. Wurtzemberger. D. F. Calhane and A. L. Gammage found that a small proportion of iron in nickel plates forms with nickel a series of galvanic couples, and these after long exposure to the atmosphere cause rusting.

J. T. Milton and W. J. Larke,[14] and S. Rachwal noted that iron with a heterogeneous structure is more prone to corrosion than when the structure is more homogeneous. C. Frémont and F. Osmond discussed corrosion along Hartmann's and Luder's lines—*vide supra*. The *annealing* of cold-worked iron makes it less corrodible, and, according to E. Heyn and O. Bauer, the influence is perceptible even when the metal has been heated to 100°. The subject was discussed by H. Altpeter, M. Delbart, P. Goerens, H. Hanemann and C. Lind, and J. H. Whiteley and co-workers. C. Chappell found that *quenched steel* is more corrodible than steel which has been quenched and then annealed, and that the effect depends on the temp. of corrosion; J. Driesen observed a maximum between 350° and 400°, and a minimum between 100° and 200°. The subject was discussed by V. Duffek, H. Endo, W. Köster, and S. Whyte.

Observations on *the effect of grain-size* on the corrosion of metals are often complicated by the simultaneous presence of other factors, so that the evidence is sometimes conflicting. P. T. Bruhl, and S. W. Smith considered that a small grain-size favoured the attack. J. P. Sparrow, S. Whyte, W. H. J. Vernon, and N. S. Kurnakoff and A. N. Achnasaroff said that a fine structure resists attack better than does a coarse structure; R. J. Anderson and co-workers, and G. D. Bengough and R. May added that whilst the effect of the grain-size is small, corrosion is less with a small grain-size than with a large one; and J. H. Whiteley and A. F. Hallimond could detect no difference in the reaction curves of annealed iron having widely different grain-size with nitric acid. Observations on the subject were made by H. Hanemann and C. Lind, W. R. Fleming, R. G. Guthrie, C. Irresberger, G. Rittler, A. Schleicher, G. Schleicher, G. Schumann, and S. Whyte. Some of the results of C. Chappell with sea-water for 116 days are summarized in Fig. 366—*vide infra*. The preferential corrosion between the crystals—*intercrystalline corrosion*—was studied by H. S. Rawdon, D. Hanson, and J. A. Jones. L. Aitchison concluded that *the twinning of the crystals* is likely to hasten the corrosion of any metal showing a tendency to be attacked.

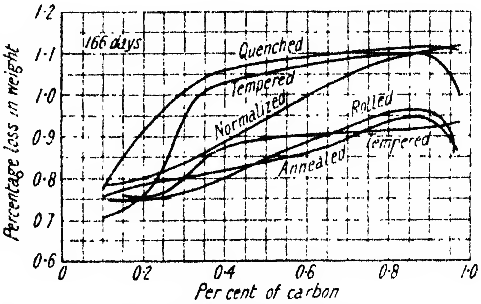

FIG. 366.—The Effect of Heat-treatment on the Corrosion of Iron.

K. Arndt[15] showed that the physical condition of the exposed surface is an important factor affecting its corrodibility. R. Pflücker emphasized the favourable influence of polishing on the resistance to rusting; and U. R. Evans, the unfavourable influence of surface abrasion. A highly polished surface is less liable to corrode than a rough-filed, more or less porous mass. The latter will rust under conditions where the former will remain bright, because moisture may condense in the interstices of the rough surface, and evaporate slowly. So also are the coarser grained varieties of cast iron more corrodible than the finer grained varieties. The interstices between the strands of a wire cable behave as pores, and allowing condensed water to lodge therein greatly accelerate the speed of corrosion, so that, as M. T. Murray showed, a cable may appear outwardly sound and strong, and be internally rotten. O. Bauer discussed the influence of blobs and pores in the metal on rusting; and H. S. Rawdon, etc.—*vide supra*—the intercrystalline corrosion of metals. Observations on the influence of surface conditions on corrosion were made by L. Aitchison, G. D. Bengough and co-workers, L. H. Callender, U. R. Evans, C. E. Fawsitt, W. Fraenkel and G. Tammann, B. Garre, P. Goerens, H. Hauschild, E. Liebreich, E. Liebreich and F. Spitzer, L. R. Luce, E. Newbery, W. Rosenhain and co-workers, G. M. Schwab and E. Pietsch, G. Tammann, H. S. Taylor, W. H. J. Vernon, and G. Walpert; the intercrystalline corrosion of metals was studied by H. S. Rawdon; and observations on the surface phenomena, by U. R. Evans, H. Euler, W. H. Hatfield, I. Langmuir, C. Marangoni and P. Stefanelli, D. Ruff, B. D. Saklatwalla, and G. A. Tomlinson. The favourable effect of the skin produced during the casting of the metal in resisting the corrosion of cast iron was noted by H. G. Haase; and the unfavourable influence of spheroids of cementite in the rim, by R. G. Guthrie. J. Wulff found that the form of the test-piece has an influence on the corrosion; and A. M. Portevin found that the attack is dependent on the curvature of the surface.

The **porosity of metals** has been long recognized. In 1620, Francis Bacon, in his *Novum organum* (London, 2. 45, 1620), demonstrated the porosity of lead by compressing water in a hermetically sealed vessel until "the water, impatient of further pressure, exuded through the solid lead like a fine dew"; and in 1667, the Accademia del Cimento reported, in the *Saggi di naturali esperienze* (Firenze, 1667), a similar result with gold. At the beginning of last century, F. Clement placed a turned and bored cylinder of cast iron within a copper cylinder and filled the intervening space with molten tin. On cooling, some of the tin had squeezed through the cast iron, and appeared like a fine, filamentous wool lining the interior. E. H. Amagat observed a similar result with mercury—*vide* iron amalgams. P. W. Bridgman found that when mercury is pressed on to the surface of steel, some mercury penetrated the pores of the steel, and made it rotten, owing to the formation of an iron amalgam (*q.v.*). J. Smithson observed that tin could be forced by pressure through cast iron. The penetration occurred only when the strain was expansive and thus tended to open the pores; a compressive strain, such as that caused by pressing on the outside of a steel ball, closed the pores and prevented penetration. During the ocean survey, by the officers of the United States Navy, it was observed that thick, hollow, glass balls, sunk to great depths in the ocean for an hour or two, became more or less filled with water. No cracks or breakages could be detected microscopically, and the inference made was that water had been forced by the enormous ocean press.—5 to 6 tons per sq. in.—through the pores of the glass. This will prove to be a very important fact if it be confirmed. A. Jouve has also observed the permeation of sulphuric acid in the pores of vessels of cast iron with a high proportion of silicon; whilst G. Tammann and H. Bredemeier forced by press. a soln. of dye into the interior of specimens of metal; and M. Juncker proposed to reduce the corrodibility of cast iron by forcing under press. linseed oil into its pores. Observations on the porosity of metals were also made by J. Dewrance, U. R. Evans, J. A. N. Friend, W. H. Perkins, E. Piwowarsky and H. Esser, and W. M. Thornton—*vide supra*, the sp. gr. of iron. B. Garre discussed the pores formed when the metal is twisted or bent.

The capillary channels, discussed by L. Guillet and co-workers, are thought to follow the edges of the original crystal grains—*vide infra*, surface oxidation. U. R. Evans considered that the corrosion in capillaries is also due to differential aeration, and not to capillary action assumed by L. McCulloch. In cast metals, therefore, as pointed out by U. R. Evans, the corrosion in cavities will tend to dig downwards into the metal and enlarge the cavities, producing pitting, sponginess, and penetration; while in worked metals, corrosion will tend to pass below the surface layer in a direct parallel to the surface, enlarging the original capillary channels, causing the surface layer to peel off in flakes, or rise in blisters, or split into flakes and appear rotten. As observed by C. Chappell, and others—*vide supra*—cavities are also likely to occur where the iron contains inclusions of slag, scoria, etc., so that corrosion is often found to penetrate deeply around the edges of inclusions, and to follow slag lines in the metal. W. H. J. Vernon emphasized the effect of atm. dust in favouring the corrosion of iron exposed to the atmosphere. Unfiltered air produced rusting under conditions where polished plates remained bright in air filtered through cotton-wool. Here, the speck of dust may lead to the retention of a film of moisture between the grain of dust and the underlying metal, and the conditions will then be established for the anodic corrosion described by U. R. Evans. When the rust is produced as a precipitate, well away from the metal, and afterwards settles on the metal, it forms a flocculent layer with no great adhesive power; and, as E. L. Chappell showed, when the whole surface is completely covered, it will act as a protector by hindering the diffusion of oxygen to the metal.

The effect of oxygen in corrosion has been treated from one point of view in connection with the action of aerated water; and the subject has been also discussed by W. D. Bancroft, J. M. Bryan, G. Chaudron, G. L. Cox and B. E. Roetheli, W. H. Creutzfeldt, W. R. Dunstan and J. R. Hill, H. Endo and S. Kanazawa, U. R. Evans and co-workers, H. O. Forrest and co-workers, E. C. Groesbeck and L. J. Waldron, J. C. Hudson, K. Inamura, B. Lambert and J. C. Thomson, A. R. Lee, A. L. McAulay and F. P. Bowden, J. McBride, T. N. Morris, C. Moureau and C. Dufraisse, E. Naumann, G. Paris, W. S. Patterson, J. G. A. Rhodin,

W. D. Richardson, B. E. Roetheli and co-workers, J. Rothe and F. W. Hindrichsen, G. Schikorr, C. F. Schönbein, F. N. Speller, G. Tammann and W. Köster, F. Tödt, W. H. J. Vernon, W. H. Walker, W. K. Weller, W. G. Whitman and R. P. Russell, W. R. Whitney, and H. Wölbling—*vide infra.* G. Paris, E. Naumann, and J. W. Cobb and G. Dougill attributed the extensive rusting in hot-water-pipe systems to the oxygen dissolved in the water. W. A. Bradbury found that the corrosive effects of water are due to the dissolved air and carbon dioxide, and that magnesium chloride alone, usually represented as acting $MgCl_2+Fe+2H_2O=Mg(OH)_2FeCl_2+H_2$, does not so act at atm. press. when cold or hot. The prevention of the corrosion of hot-water pipes by de-aeration of the water was discussed by F. N. Speller, C. R. Texter, J. R. Baylis, O. Kröhnke, and F. Meyer.

When a plate is immersed horizontally below the surface of a soln. of sodium chloride, lines, spots and rings of the hydrated oxide appear on the surface; these are formed about the openings of the pores; in time, the centres of the rings fill in, humps of hydrated oxide extend over the pore openings, and the flocculent rust spreads irregularly until the whole surface is covered. The blanket of hydrated oxide shields the metal from oxygen, and the whole surface will become anodic, but the corrosion will be slow, since the presence of oxygen is not needed at the anodic portions, yet access of oxygen is necessary at the cathodic areas. If the blanket of hydrated oxide is removed from part of the surface by movements of the liquid, slow corrosion will continue over the blanketed portion. On the lower surface of the plate the removal of the hydrated oxide may occur by sedimentation, so that blanketing does not occur, and corrosion continues in the pores. With plates placed vertically in the liquid, there is the tendency of the hydrated oxide to spread downwards from each pit, and the fact that the upper portions are more accessible to oxygen than the lower portions. The lower, less aerated part is therefore anodic to the upper, aerated portion. The lower portion is therefore corroded first, while the upper portion, near the level of the soln., remains clear. The corrosion may begin in pits or cavities, forming what A. Payen called *les tubercules ferrugineaux*, and extending downwards, developing into streamers, or, as A. Payen called them, *les formes vermiculaires*. F. H. Rhodes and E. B. Johnson found that in the case of a municipal gas-holder, the attack occurred along a horizontal zone between 4 in. and 3 ft. below the level of the sealing water. There was no evidence of attack at or just below the water-level. In this case the reducing action of the coal-gas may have helped to lessen the oxygen concentration of the parts below the surface of the water. In some cases, the aerated, cathodic zone may resist corrosion for a time, even when the distribution of the oxygen has become uniform; and U. R. Evans attributed this to the formation of a film of oxide which is more protective than a film formed by exposure to dry air. This film of oxide may become thick enough to give interference tints.

According to J. R. Baylis, tuberculous deposits form an impervious coating where soluble iron from the interior comes into contact with dissolved oxygen. If the water has $p_H=8\cdot5$ the iron forms an impervious coating of crystalline iron oxide in a few months. Pits are often found under tubercles, and negative ions, such as sulphate and chloride ions, are concentrated in these: the overlying tubercles may contain over 1 per cent. of these salts. A. L. McAulay and F. P. Bowden measured the potential between metal and liquid at different parts of a surface both during corrosion, and afterwards when removed from the liquid. The value on the cathodic zone varied slightly from that on the anodic zone. Using $0\cdot1N$-NaCl, against a normal calomel electrode, the anodic portion near the bottom had a potential of $-0\cdot520$ volt, and near the water-line of the cathodic portion, $-0\cdot380$ volt.

Iron is less quickly attacked by distilled water than it is by a soln. of potassium chloride, sulphate, or nitrate; and with water, the direct product of anodic corrosion is ferrous hydroxide, which is sparingly soluble in water. The corrosion of the metal by a drop of distilled water follows very much the course of that illustrated by Fig. 364; but with water distinctly alkaline, where the solubility of ferrous hydroxide is greatly reduced, U. R. Evans showed that an insoluble, protective film will be produced which will grow until the potential of the parts inaccessible to oxygen approaches the value of the aerated part, the current will cease to flow, and corrosion will cease. This agrees with the general observation that iron immersed in alkaline liquids containing oxygen usually remains bright, and passive.

Some factors influencing the rate of corrosion.—Although in the local anodic corrosion of iron, access of oxygen where the actual corrosion occurs is not necessary, yet oxygen must be present at the cathode portions to act as depolarizer. Hence, considering the whole system, the attack on the metal is dependent on the proportion of dissolved oxygen; and if the proportion of dissolved oxygen in the water could be reduced the rate of corrosion would be reduced. C. Chappell found that for low-carbon steels, the amount of corrosion is proportional to the time of immersion. With respect to the velocity of corrosion, except for very short intervals of time, the extent of the corrosion is not proportional to the time of exposure to the corroding influence. These results, however, were not obtained with one piece of metal, but rather by the use of a series of plates which were all corroding at the same rate. J. A. N. Friend, therefore, measured the absorption of oxygen by a piece of rusting iron, and obtained the results shown in Fig. 367, where the slope of the curve at any given time measures the velocity of the reaction. The attack is more rapid in the early stages of rusting; and as the time of exposure is more prolonged, the rate decreases and becomes more nearly proportional to the time. Here, the metal was fairly pure, and the experimental conditions constant, but under working conditions, this is not the case; and, as emphasized by G. Schumann, the problem is rather complex. According to I. D. van Giessen, open, steel equalizing tanks in waterworks are subject to severe corrosive conditions, since the top layer of water rarely changes, there being but a single bottom connection; the effect is worst on the inside portion facing the south, as this receives the full heat of the sun, and is besides alternately wet and dry. O. Kröhnke, and K. Arndt found that cast iron at first corrodes as rapidly as steel, but afterwards it resists corrosion far better than the other metals. This is in accord with general experience. The following are K. Arndt's data:

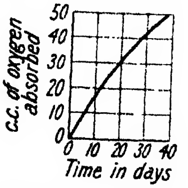

FIG. 367.—The Absorption of Oxygen by Rusting Iron.

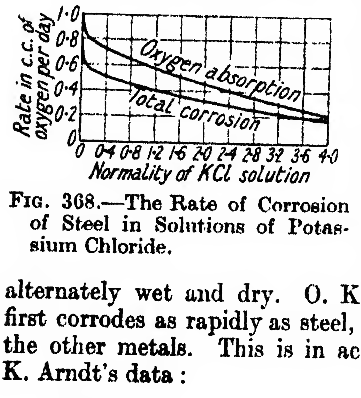

FIG. 368.—The Rate of Corrosion of Steel in Solutions of Potassium Chloride.

Time		1	3	5	10	20	30	43 days
Oxygen absorbed	Cast iron .	13	24	30	45	59	73	95 c.c.
	Mild steel .	13	32	45	63	108	156	213 ,,
	Weldless tube .	5	8	30	109	198	293	389 ,,

G. D. Bengough and co-workers compared the rate of absorption of oxygen and the total corrosion of steel with a soln. of potassium chloride of different concentrations, and the results are summarized in Fig. 368.

Water from mountain streams in showery districts was found by F. J. Rowan [16] to be highly oxygenated, and to be particularly corrosive; and R. Mallet made a similar observation with respect to the corrosive power of rain-water. E. Heyn and O. Bauer found that the relative corrosion of three plates of the same metal immersed in distilled water, in water in which a block of charcoal was suspended, and in water with powdered wood charcoal sprinkled on the surface, was respectively as 100 : 68 : 20. The charcoal acted by reducing the supply of oxygen to the metal. According to J. A. N. Friend, corrosion is not proportional to the area of the exposed surface, because once corrosion has started, oxygen may be absorbed more rapidly than can be supplied to the metal by mere diffusion through the water; and the rate of corrosion will bear some relation to the exposed surface area of the metal, because the supply of oxygen to the metal is determined by the rate of diffusion of the oxygen, and this is determined by the area of the surface to which the oxygen has access. Similarly, also a film of oil on the surface of water helps to reduce the supply of oxygen to the metal; the extent of the protection is determined by the rate at which the oil can absorb oxygen from the air, and deliver it to the water beneath. R. Mallet showed that thick iron plates corrode less rapidly than thin plates; and A. S. Cushman, that doubling the thickness of a plate usually more than doubles its life. W. H. J. Vernon observed that the rate of corrosion of copper was affected by the area but not by the thickness of the plates.

R. Mallet showed that the depth to which an iron plate is immersed in still water will greatly influence its rate of corrosion, because once the oxygen in the vicinity of the plate is used up, the plate is dependent for further supplies on the rate at which oxygen can diffuse downwards from the surface; and this will be slower the greater the depth of the submerged iron. E. Heyn, and E. Heyn and O. Bauer also found the following losses due to corrosion with iron plates immersed in still water:

Time . . .		8	15	22	29 days
Depth	5 cm. . .	0·0268	0·0480	0·0731	0·0783
	28 cm. . .	0·0244	0·0450	0·0628	0·0766
	50 cm. . .	0·0206	0·0364	0·0606	0·0788

As the time of exposure increases, the difference in the rates of corrosion at various depths becomes less marked. This was attributed to the slow reduction of the rust by the iron at the lower depths: $Fe+Fe_2O_3=3FeO$, in accord with the fact that the proportion of ferrous oxide at the greater depths was larger. In air, the partial press. of the oxygen has little influence on the rate of corrosion, because the surface of the metal is being continually swept by fresh gas. The case is different in deep wells where the temp. is more uniform, and the access of fresh air is more difficult. The rate of corrosion of iron submerged in water is dependent on the solubility of the oxygen in water, and this is largely dependent on the partial press. of the gas. Hence, W. H. Walker and co-workers found the following losses due to rusting of iron submerged in water with variable percentages of oxygen in the atmosphere above:

Oxygen . . .	18·2	21·8	28·0	64·5	72·1	97·0 per cent.
Loss by corrosion .	0·018	0·021	0·031	0·057	0·064	0·086

The action of oxygen on corrosion by water was discussed by J. W. Shipley and co-workers, F. Tödt, W. G. Whitman and co-workers, G. Bresch, W. van W. Scholten, J. N. D. Heenan, U. R. Evans, W. R. Whitney, M. Traube, E. Heyn and co-workers, W. H. Walker and co-workers, J. Spennrath, V. Duffek, A. L. McAulay and F. P. Bowden, J. Tillmans and co-workers, J. W. Cobb and G. Dougill, J. R. Baylis, J. A. N. Friend, G. N. Huntley, G. D. Bengough and co-workers, and E. Liebreich. G. Schikorr found that the rate of corrosion in water with the oxygen gas under press. between 0·2 and 5·0 atm. showed a maximum at about 1 atm. press. L. E. Jackson observed a rapid corrosion of iron in a refrigerator plant due to the high oxygen-content of the cold water.

When water is in motion, it will usually contain a high proportion of oxygen provided it is shallow, and the atmosphere has free access to its surface. M. B. Jamieson found that the corrosion in street water-mains is proportional to the amount of water passing through them. E. Heyn and O. Bauer found that a gentle flow of the water increases the corrosion 8-fold; but with still higher velocities, the corrosion is less. Thus:

Cast iron	Velocity	0	6·6	36	240 litres per hr.
	Corrosion loss	0·0350	0·2971	0·2912	0·1470 grm.
Steel	Velocity	0	15	50	350 litres per hr.
	Corrosion loss	0·0566	0·1357	0·0826	0·0377 grm.

J. A. N. Friend employed still higher velocities. The following results were obtained by exposing for 22 to 25 hrs. iron foil—$3\times0{\cdot}5$ sq. cm. in area, and approximately 0·35 grm. in weight—to water with a velocity V ft. per hr.; the loss in weight is expressed in mgrms. per hour:

V	0	540	570	4200	9000	13,000	30,000
Loss	0·082	0·188	0·177	0·054	0·029	0·032	0·034
	Rust			Streams of rust	Traces of rust		No rust

It is assumed that the resistance to corrosion in water at a high velocity is due to the water sweeping away some catalyst which assists the metal to corrode; and that without this catalyst the metal dissolves as postulated by the ionic theory, with such a small velocity that it is almost passive. The catalyst, said J. A. N. Friend, is supposed to be the hydrosol of ferrous oxide. R. F. Passano and F. R. Nagley studied the subject.

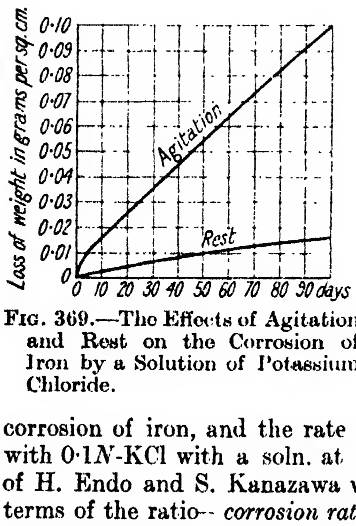

FIG. 369.—The Effects of Agitation and Rest on the Corrosion of Iron by a Solution of Potassium Chloride.

J. Aston, R. J. McKay, U. R. Evans, and H. Endo and S. Kanazawa showed that when iron rusts under water, the area to which oxygen has the freer access becomes cathodic, and the areas shielded from oxygen become anodic. The presence of dissolved oxygen was shown by R. Adie, J. Aston, W. D. Bancroft, A. S. Cushman, H. Endo and A. Kanazawa, U. R. Evans, M. M. Hall, K. Inamura, H. A. D. Jowett and E. Goulding, R. J. McKay, R. Mallet, J. W. Shipley and I. R. McHaffie, W. G. Whitman and R. P. Russell, W. H. Walker and co-workers, and W. R. Whitney—*vide supra*—to favour the corrosion of iron, and the rate of corrosion is favoured by agitation as indicated with 0·1N-KCl with a soln. at rest, and a soln. aerated by stirring. The results of H. Endo and S. Kanazawa with soln. of various salts and acids expressed in terms of the ratio—*corrosion ratio*—of the losses in weight of a specimen when the soln. is aerated by a current of oxygen, and by a current of hydrogen,

Concentration		0·1M-	0·05M-	0·02M-	0·01M-
Corrosion ratio	NaCl	2·8	2·2	1·4	1·3
	KCl	2·7	2·3	1·6	1·4
	K_2SO_4	2·9	2·5	1·4	1·2
	KNO_3	1·2	1·3	1·6	1·2
	$KAl(SO_4)_2$	—	2·2	1·2	1·0
	$BaCl_2$	2·6	2·1	1·6	1·3

Concentration		95	50	20	5	1	0·5 per cent.
Corrosion ratio	H_2SO_4	1·0	1·5	4·2	14·1	—	—
	HCl	—	—	—	15·4	—	70·4
	HNO_3	—	1·1	—	—	1·5	—

H. Endo and S. Kanazawa, adopting the ionic hypothesis, assumed that the corrosion of the iron takes place in two stages: First, a small quantity of the iron passes into soln. as ferrous ion and an equivalent amount of hydrogen is deposited on the surface of the metal as molecular hydrogen: $Fe+2H^{\cdot}+2OH'\rightleftharpoons Fe^{\cdot\cdot}+2OH'+H_2$, or $Fe+2H_2O\rightleftharpoons Fe(OH)_2+H_2$. Second, when oxygen is introduced into this system, the ferrous hydroxide is oxidized to ferric hydroxide, $4Fe(OH)_2+O_2+2H_2O=4Fe(OH)_3$, and the molecular hydrogen is oxidized and so removed from the surface of the iron.

The corrosion of iron by moving liquids was also examined by E. Heyn, G. D. Bengough and R. May, M. Drapier, J. A. N. Friend and co-workers, W. Beck, M. B. Jamieson, J. Tillmans and co-workers, W. R. Whitney, R. P. Russell and co-workers, J. N. D. Heenan, F. N. Speller and V. V. Kendall, M. Straumanis, J. F. Thompson and R. J. McKay, R. J. McKay, and W. G. Whitman and co-workers. S. S. Cook studied water-hammer corrosion, and attributed it to the favourable influence of the motion of the metal surfaces; and C. A. Tomlinson, the corrosion of two, hard steel surfaces subjected to relative motion under load. R. Auerbach observed that differences in the rate of flow of an electrolyte may set up differences of potential on a surface of iron, and he studied the effect of the flow of the liquid in capillaries.

Iron corrodes most rapidly when it is alternately wet and dry—*e.g.* the water-line of iron ships, bridge columns, etc.

R. Mallet found that raising the **temperature** up to a maximum of 79° to 88° favours corrosion. E. Heyn and O. Bauer found a maximum at 60° in one case, and at 80° in another. J. A. N. Friend and co-workers, E. Ramann, I. H. Woolson, A. Lodin, W. van Rijn, E. Heyn and O. Bauer, A. Thiel and H. Luckmann, O. Bauer and co-workers, G. M. Enos, J. R. Baylis, and F. N. Speller also made observations on the subject. The effect of temp. is the resultant of two opposing influences. There is, first, the acceleration of the speed of the reaction by a rise of temp., and second, the retardation of the corrosion owing to the decreasing solubility of oxygen, etc., in water with a rise of temp. A maximum effect will therefore be obtained at some critical temp. which, according to the observations of H. Endo, Fig. 370, occurs between 60° and 70°. This agrees with the previous observation of E. Heyn and O. Bauer. The degree of corrosion in Fig. 370, refers to results expressed in relation to the corrosion at 20° taken as unity. The observed losses in weight in grams per sq. cm. during 30 days were:

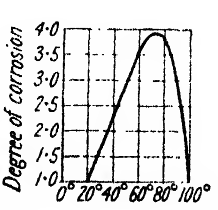

FIG. 370.—The Influence of Temperature on the Corrosion of Iron.

	20°	30°	40°	50°	60°	70°	80°	90°	100°
Loss .	1·00402	0·00605	0·00885	0·01209	0·01405	0·01612	0·01530	0·01410	0·00563

C. H. Cribb and F. W. F. Arnaud, and J. A. N. Friend found that the corrosion is less in darkness than in **light,** with distilled-water, tap-water, river-water, and soln. of various compounds—magnesium chloride, sodium carbonate, hydrocarbonate, and hydroxide, and calcium hydroxide. H. E. Armstrong suggested that the effect might be due to a difference in temp. rather than to the action of light *per se*, but J. A. N. Friend found that light is still active when the effect of temp. is eliminated. H. Endo and co-workers obtained the results summarized in Fig. 371. During the exposure, 11 of the 50 days were cloudy. C. Benedicks and R. Sundberg observed that stainless steel is not quite so much attacked by a soln. of ferrous sulphate, in a photo-cell, in light as it is in darkness. In general, however, light favours the corrosion of metals. The subject was discussed by H. S. Allen, G. Athenasiu, R. Audubert, W. D. Bancroft, W. Beck, G. D. Bengough and O. F. Hudson, S. S. Bhatnagar and co-workers, T. W. Case, W. W. Coblentz and co-workers, H. Endo, G. M. Enos, J. A. N. Friend and co-workers, O. Hähnel, M. Kimura, A. Leighton, J. Nordensen, C. C. Palit and N. R. Dhar, W. H. J. Vernon, and W. P. Wood. According to W. Beck, exposure to **radium radiations** reduces **corrosion.**

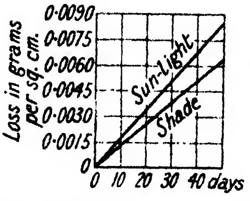

FIG. 371.—The Influence of Light on the Rate of Corrosion of Iron.

R. H. Gaines[17] emphasized the need for reckoning with certain bacterial organisms as an influence favourable to corrosion. The work of iron-bacteria was discussed by D. Ellis, R. Grant and co-workers, and C. Tonami. The effect of sulphides due to the action of bacteria and other forms of life or organic matter on sulphates or decaying organic matter was studied by R. Irvine, P. Agostini, G. D. Bengough and R. May, S. H. Ellis, A. Molteni, and E. V. Smith and T. G. Thompson. C. Darwin showed that worms may excrete acidic fluids; B. Schorler observed the same thing with respect to the *Gallionella ferruginea*; and A. Molteni observed that the humic acid of decaying plants, and the acidic fluids exuded or excreted from some plants, earthworms, and micro-organisms have a marked action on iron structures embedded in soils. The subject was discussed by R. H. Gaines, A. Beythien, O. Adler, and E. Raumer—*vide infra*, limonite.

W. L. Dudley [18] buried iron pipes in various kinds of soil and found the corrosion about half as fast in the case of pipes conveying coal-gas, as it was with pipes conveying no gas. The *corrosion of iron by coal-gas* is usually attributed to the presence of impurities—hydrocyanic acid, carbon disulphide, carbon dioxide and oxygen. J. A. N. Friend noted that water saturated with coal-gas is about two-thirds as active as water alone in the attack on iron buried in moist soils, not exceptionally acidic. The subject was discussed by W. Bertelsmann, A. Bolzinger, H. G. Colman, W. D. Davidson, W. E. Dennison, F. Firth, G. M. Gill, I. Ginsberg, J. T. Haddock, T. Holgate, H. M. Howe, W. Leybold, J. McLeod, G. Masing, R. V. A. Mills, L. Monk, E. Ott and F. Hinden, J. Parker, B. R. Parkinson, F. H. Rhodes and E. B. Johnson, B. Richardson, J. Rollison, R. H. Ruthven, J. G. Taplay and co-workers, C. H. S. Tupholme, C. E. Williams, and R. E. Wilson. In agreement with B. Richardson, and C. E. Williams, J. F. G. Hicks showed that the hydrocyanic acid plays a subsidiary part, for the moist oxygen and carbon dioxide initiate the corrosion. The hydrocyanic acid accelerates the corrosive action, and it plays a most important part, as is indicated by the curves, Fig. 372, showing the rates of corrosion in the presence of moist gases. The speed is greatest when hydrocyanic acid is present. The final product of the action in the case of coal-gas mains is prussian blue. It is estimated that there is thus produced 10 tons of prussian blue per annum in the gas mains of Portland City. No corrosion was observed with dry air, dry oxygen, or dry carbon dioxide.

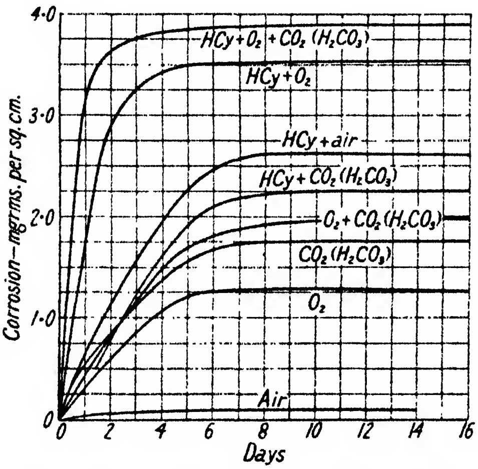

FIG. 372.—Corrosive Action of Moist Gases.

The *corrosion of iron buried in soils* was discussed by F. O. Anderegg and R. V. Achatz,[19] K. Arndt, W. Beck and K. Jacobsohn, F. L. Bassett, F. Besig, L. G. E. Bignell, G. Blanchart, M. J. Blew, O. Bauer and E. Wetzel, J. R. Bradshaw, E. A. Cross, A. S. Cushman, R. O. E. Davies, I. A. Denison, W. L. Dudley, F. Ensslin and F. Buschendorf, S. Ewing, H. O. Forrest, M. Freund, R. H. Gaines, A. F. Ganz, I. D. van Giessen, J. de Graaff, M. Gutierres, F. Haber and P. Krassa, O. Haehnel, R. B. Harper, M. Horioka and M. Iwasa, H. D. Holler, R. Irvine, R. Krzizan, R. J. Kuhn, C. Lepierre, K. H. Logan, K. H. Logan and co-workers, B. McCollum and K. H. Logan, P. Medinger, A. Molteni, G. Murdoch, V. Nagreeff, M. R. Pugh, A. Romwalter, R. P. Russell and W. G. Whitman, R. H. Ruthven, S. G. Sastry, J. E. Schipper, E. H. Schofield and L. A. Stenger, W. B. Schulte, G. N. Scott,

E. R. Shepard, J. W. Shipley and co-workers, E. S. Simpson, E. O. Slater, W. N. Smith and co-workers, W. N. Smith and J. W. Shipley, D. Spataro, F. N. Speller, L. A. Stenger, G. Theim, W. Wark, C. H. Webb, A. Weber, J. R. Weinlinger, and R. E. Wilson. O. Bauer and E. Wetzel observed that cast iron plates 10×2·5×2 cm., during 15 months' exposure lost 6·23 grms. in distilled water; 7·61 grms. in tap-water enriched with calcium sulphate; 10·38 grms. in clay sat. with distilled water; 10·20 grms. in clay sat. with tap-water enriched with calcium sulphate; 5·62 grms. in sand sat. with distilled water; and 6·36 grms. in sand sat. with tap-water enriched with calcium sulphate. F. Hanaman studied the rusting of iron buried in moist sand. J. R. Weinlinger found that an iron gas-pipe which had been in the ground for 25 years was in an excellent state of preservation. For iron embedded in cement and concrete, *vide infra*.

If stray electric currents from tramways, etc., can pass, the iron and soil act as electrodes decomposing moisture into hydrogen and oxygen; and the latter at once attacks iron to form rust. Consequently, iron embedded in concrete is not immune from attack. V. J. Nicholas[20] found that the electrolytic corrosion of structural and reinforcing steel embedded in concrete takes place at the anode. Even neat cement is no protection. The cathode is not affected by oxidation. Cement or concrete immersed in brine will crack when carrying an electric current to or from embedded steel. Concrete conducts electricity electrolytically and not like a metal, its electric resistance being an inverse function of the percentage of sand. It is found that even 0·1 ampere continuously flowing is sufficient to cause the destructive results indicated. The subject is of more direct interest to the electrical engineer. It has been the subject of numerous papers.

H. Hayden studied the effect of an alternating current on the electrolytic corrosion of iron in soln. of salts of sodium, potassium, and ammonium, and in natural and artificial soils; and B. McCollum and G. H. Ahlborn worked with plates immersed in a light clay soil kept moist with a 0·5 per cent. soln. of sodium carbonate. A. J. Allmand and R. H. D. Barklie observed that the superposition of alternating on a direct current increased the corrosion of iron in alkaline soln., and in sub-soil drainage liquor, saturated with carbon dioxide. The presence of chlorides favoured corrosion using a direct current. When an alternating current was employed, a change in the conc. of the alkali in the electrolyte had no particular influence, but the lowering of the current frequency produced an increased corrosive effect, and it is probable that the discharge of $H^{\cdot}$-ions during the cathodic impulse activates the iron by decreasing the oxygen content in the surface layer of metal. The effect of alternating current superposed on direct current was a marked increase in corrosion, and where an anode remained passive either at direct current intensity of 0·125 amp. per sq. cm. or at an alternating current intensity of 0·375 amp. per sq. cm. and 400 frequency, the anode became definitely yellow in two minutes under the combined effect. A high alternating : direct current ratio (more than two) was favourable to corrosion, as was also an increase in current density and low frequency.

The nature of rust.—According to F. N. Speller,[21] films are formed on metals by passivating agents, and rust-resisting alloys, like high-chrome iron, and stainless steel probably owe their resistant qualities to the formation of stable films, so that the life of these metals is more directly dependent on the stability of the film than on the initial tendency of the metal to corrode. This self-protection is more fully developed with some metals than it is with others. A. Ackermann observed the rusting of small particles of iron, iron wire, and spongy iron under the microscope. The forms taken up by the rust depend in the first place on the formation of ferric hydroxide. This colloidal substance assumes forms and passes through the formation processes which are very like the forms and processes which occur in organized nature. Non-rigid threads are formed which grow like organic fibres and which move and change their form when subjected to changes in the external conditions—for example, temperature. Under certain conditions, cell-formation is exhibited, which externally, at least, is similar to organic cell-formation. Drops of a solution of ferric hydroxide possess properties which are otherwise only found in organic cells. They exhibit a solid or semi-solid enclosing semi-permeable membrane or cell-wall, an adhering colloidal layer, and a nucleus. Such drops grow, become broader, and divide in exactly the same manner as is observed in the division of organized cells.

A very great number of analyses of rust have been reported. In analyses by W. R. Dunstan and co-workers of rusts collected from an iron apparatus rusted in the laboratory, and from an iron railing exposed for 30 years to air within 20 yards of the sea, the composition approximated to the limit $Fe_2O_3.H_2O$; but there was about 0·2 per cent. of ferrous carbonate present in the former case, and about 3·25 per cent. of ferrous oxide in the latter case. Both samples contained 1·01 to 1·17 per cent. of hydrogen. This all agrees with F. Wöhler's observation that iron beneath a thin layer of water forms hydrated ferric oxide, but with a thicker layer of water, hydrated ferrosic oxide is produced. Here the transfer of oxygen from air to iron takes place more slowly, and it is inferred that ferrous oxide or hydrated ferrous oxide is the first product of the action, and that this is oxidized to form hydrated ferric oxide, which, uniting with the unchanged ferrous oxide, forms hydrated ferrosic oxide, which, if formed at all, may be regarded as an intermediate stage in the process of oxidation. R. Stumper, for example, found that a 1-day-old rust had 45·3 per cent. FeO, a 5-day-old rust had 22·7 per cent. FeO, and a 15-day-old rust had 9·5 per cent. FeO. He found for $FeO : Fe_2O_3 : H_2O$, 1 : 2 to 20 : 2 to 30. F. C. Calvert observed rust containing 92·9 to 93·10 per cent. Fe_2O_3; 5·8 to 6·2 per cent. FeO; 0·6 to 0·9 per cent. $FeCO_3$; 0·12 to 0·19 per cent. SiO_2; 0·295 per cent. $CaCO_3$; with traces of ammonia. F. M. Stapff observed that the rust on some nails 2000 years old, found in the mines of Mazarron in Murcia, Spain, consists of a mixture of limonite and magnetite. G. T. Moody obtained the following results with half a dozen samples of rust collected from the unpainted interior of some iron flushing-tanks in common use:

Fe as Fe_2O_3 .	55·73	51·12	64·60	65·13	68·89	67·46 per cent.
Fe as FeO .	32·86	36·57	25·74	25·66	23·18	24·40
Fe as $FeCO_3$.	11·40	12·31	9·66	9·21	7·93	8·14

The proportion of calcium carbonate was inappreciable. The proportion of ferrous oxide present in the rust appears to depend on its age, and on the permeability of the rust for oxygen. A. Liversidge found that rust always contained more or less ferrosic oxide. W. Thörner, and P. Longmuir observed that rust collected in railway tunnels had 0·3 to 4·2 per cent. of sulphur expressed as H_2SO_4, and samples collected in the open had 0·8 to 5·5 per cent. H_2SO_4. E. Wilson observed some ferrous sulphide on iron exposed to a London atmosphere. E. K. Rideal found 1·81 per cent. of ferric sulphate in samples collected in the open country, and 7 to 9 per cent. in samples collected from London railway stations.

R. Kattwinkel, and F. Drexler found that the ultimate products of rusting are usually γ-FeO(OH) or Fe_3O_4. F. Drexler said that the formation of α-FeO(OH) or γ-FeO(OH) depends on the chemical nature of the nucleus about which the rust forms. The physical structure of the rust depends on the structure of FeO(OH), and the colour is determined by the grain-size. This subject is discussed in connection with ferric hydroxide, FeO(OH). According to G. Schikorr, the mechanism of rusting may thus be explained: in air-free water a black film is formed, $Fe+2H_2O=Fe(OH)_2+2H$; in the absence of air α-FeO.OH sol reacts with iron to form Fe_3O_4 or a green sol, $FeO.OH+H=Fe(OH)_2$; the green sol reacts with the FeO.OH to produce the green ferrite $Fe(OH)_2.FeO.OH$, or with an excess to form Fe_3O_4, and finally the latter is oxidized to γ-FeO.OH. C. Carius observed the presence of magnetite in rust produced by the corrosion of iron in acidified water, and dried at room temp.; and γ-FeO.OH, in rust obtained in water with $p_H=5{\cdot}5$ to 6·5, and the X-ray spectral lines of γ-FeO.OH decrease in intensity with increasing alkalinity. J. Cates also identified rust with

γ-FeO(OH). J. Huggett said that in the prolonged exposure of iron to aerated water, a mixture of magnetite and rust is first formed, and then lepidocrocite appears. H. O. Forrest and co-workers found the composition of the rust film is dependent on the H'-ion concentration of the liquid near the metal surface, and on the ionic concentration in the liquid film. With oxygenated distilled water, the film is granular magnetic oxide, provided the diffusion of ions from the liquid film to the main body of the soln. proceeds slowly or non-uniformly, whereas with a uniform, rapid ionic diffusion, the film is mainly gelatinous hydrated ferric oxide. The formation of graphite during the attack by water, etc., on cast iron is discussed in connection with sea-water—*vide infra.* R. Richter, and J. Percy mentioned the presence of crystallized silicon in the residue from cast iron; and W. A. Tilden, iron silicide. J. G. Donald observed that there is a loss of carbon during the rusting of pig-iron.

The effect of rust on the corrosion of iron and steel was discussed by R. C. McWane and H. Y. Carson, E. L. Chappell, and J. Aston. W. S. Patterson, and W. H. J. Vernon observed that rust increased the speed of corrosion of iron, and that a certain critical humidity of the atmosphere must be exceeded before the acceleration occurs. J. C. Hudson did not find an abnormal change in the deliquescence of rust at some critical humidity, possibly, said W. H. J. Vernon, because the samples used by J. C. Hudson had already passed through the critical stage. W. S. Patterson and L. Hebbs, however, did observe a critical stage with rust scraped from the metal. The microscopic structure of rust was investigated by A. Ackermann. R. A. Hadfield observed no deterioration in the tensile strength of mild steel, and wrought iron after being immersed in sea-water for five years.

The by-products of rusting.—The production of hydrocarbons was discussed in connection with the carbides—**5.** 39, 20. Reports on the formation of ammonia during the rusting of iron, by A. Chevallier, etc., are discussed in **8.** 49, 15; but R. Mallet said that too much stress cannot be laid on the alleged reports because rust, in common with other porous bodies, greedily absorbs ammonia and many other gaseous substances from the atmosphere—*vide infra,* the action of soln. of ammonium nitrate. U. R. Evans said that the true expansion in rust formation cannot be calculated from the sp. gr. of the components, but it is certain that a considerable expansion force is exerted when iron changes into rust. He discussed the apparent vol. of rust sludges; and A. Ackermann, colloidal rusts.

T. Fujihara found that the uncorroded iron outside a drop of water on a polished surface of iron is protected by a film of ferrous hydroxide—*vide* Fig. 364. The product of the action is protective. The more rapid the initial corrosion, the less the final effect. The formation of protective films in the rusting and corrosion of metals was studied by W. G. Whitman and co-workers, V. Kohlschütter and E. Krähenbühl, F. N. Speller, W. D. Bancroft, G. R. White, C. H. Desch, J. Bresch, W. H. J. Vernon, U. R. Evans, E. M. Enos and R. J. Anderson, J. R. Baylis, and E. L. Chappell.

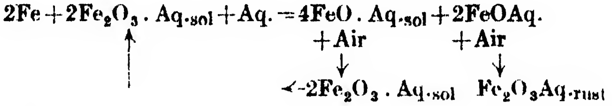
C. F. Schönbein[22] observed that **hydrogen dioxide** is formed when iron amalgam is shaken with water, and this was confirmed by M. Traube, and H. Wieland and W. Franke. The maximum amount is formed in about a minute. It is assumed that the reaction proceeds in accord with the scheme: $Fe+2H_2O=Fe(OH)_2+H_2$, followed by $4Fe(OH)_2+O_2=2(Fe_2O_3.H_2O)+2H_2O$, with hydrogen dioxide an intermediate product resulting from the action of bivalent iron and molecular oxygen: $Fe+O_2+2H_2O=Fe(OH)_2+H_2O_2$. The cycle of reactions is completed by $Fe+H_2O_2=Fe(OH)_2$; and $2Fe(OH)_2+H_2O_2=Fe_2O_3.H_2O+2H_2O$. W. Palmaer said that the formation of hydrogen dioxide in the rusting of iron is due to a side reaction, not an essential part of the process. E. Pietsch and co-workers discussed the subject. No hydrogen dioxide fs iormed in acidic soln., but in alkaline soln. the amount formed increases with the p_H value, *i.e.* with conc. of the OH'-ions. The production does not depend on the occluded hydrogen of the amalgam;

ferrous hydroxide is first produced, and this is further oxidized more slowly than the metal. The presence of hydrocyanic acid retards the autoxidation; and the velocity of oxidation is about ten times as fast in the presence of leucine as it is in water. The acceleration depends on the conc. of the amino-acid. Glycine, alanine, and asparagine act similarly. Salts like sodium sulphate or copper sulphate accelerate the autoxidation of iron. The oxidation is inhibited if the iron be rendered passive by treatment with potassium hydroxide, ferricyanide, chromate, or permanganate. The presence of hydrogen acceptors like quinone, methylene blue, ethyl peroxide, and dithiodiglycollic acid, causes iron to rust in the presence of purified water in an atm. of nitrogen. The presence of sodium or copper sulphate accelerates the action of quinone.

According to a modification of M. Traube's scheme of oxidation, by W. R. Dunstan and co-workers, hydrogen dioxide is formed as an intermediate stage in the rusting of iron: $Fe+H_2O=FeO+H_2$, and $2H+O_2=H_2O_2$, followed by $2FeO+H_2O_2=Fe_2O_2(OH)_2$(rust). Two mols. of dioxide are supposed to be formed by the oxidation of 2 atoms of iron to ferrous oxide, and only 1 mol. of hydrogen dioxide is required to oxidize the ferrous oxide to rust. The excess of hydrogen dioxide is now supposed to oxidize the uncorroded iron, $Fe+H_2O_2=FeO+H_2O$, and $2FeO+H_2O_2=Fe_2O_2(OH)_2$. The inhibitory action of alkalies and chromic acid is attributed to their power of decomposing hydrogen dioxide. W. R. Dunstan and co-workers said that the failure to detect hydrogen dioxide in the oxidation of iron, when its presence could be detected in the case of all other metals which were tried, does not exclude the possibility of its momentary formation—*vide supra*, for H. E. Armstrong's modification of this theory. F. Haber and co-workers, and V. Andström also favoured this hypothesis, but against the hydrogen dioxide theory of corrosion, G. T. Moody argued that a dil. soln. of hydrogen dioxide does not attack iron, but is catalytically decomposed by that metal. W. R. Dunstan and co-workers must have used impure hydrogen dioxide. L. J. Thénard observed that the metal has no action on *eau oxygène*. O. and A. Dony could not detect any traces of hydrogen dioxide, even though, according to the theory, twice as much is produced during the initial oxidation of the iron to form ferrous oxide as is required to convert the latter into rust. G. T. Moody showed that substances which destroy hydrogen dioxide do not necessarily inhibit the rusting of iron—*e.g.* potassium iodide; and E. Divers said that substances which destroy hydrogen dioxide need not necessarily prevent its formation—*e.g.* ferrous sulphate rapidly destroys chlorine, but does not prevent the formation of chlorine from manganese dioxide and hydrochloric acid. W. D. Bancroft reported that in alkaline soln., hydrogen dioxide is decomposed by iron.

When iron has once begun to rust, the subsequent progress of the disease proceeds more quickly even though the temp. be above the dew-point, and under conditions where bright iron would remain unaffected for an indefinitely long time. F. Kuhlmann [23] suggested that the rust acted catalytically as an oxygen carrier; but F. von Hutten, F. C. Calvert, A. Wagner, A. C. Brown, J. A. N. Friend, and H. Bauerman favour the hypothesis that rust is very porous, and hygroscopic, and it becomes charged with liquid water which fills its pores and evaporates very slowly. Hence, corrosion can occur in a damp atmosphere under conditions where bright iron would not be affected. J. Aston showed that wet rust is anodic to bare iron, whilst dry rust is cathodic; wet rust has a high electrical resistance. A compact layer of fired rust thus tends to protect the metal below, but favours anodic attack in the iron immediately around; while flocculent, wet rust favours the corrosion of the metal immediately below. This it does by shielding the affected part from oxygen, and rendering it anodic, so that corrosion is confined to a limited area; the surrounding part is cathodic and hence does not rust—*vide supra*, J. Aston. According to R. J. McKay, the rust accelerates the action in two ways: (i) oxygen is removed by its reaction with ferrous hydroxide; and (ii) iron is removed by precipitation which would retard the reaction and set up a counter e.m.f. in the oxygen concentration cell. J. Aston also showed that the anodic effect produced by wet rust is obtained with other colloidal hydroxides—*vide infra*, colloids.

J. A. N. Friend suggested a modification of F. Kuhlmann's hypothesis in that he considered that the action of rust in promoting further rusting may be due to the presence of the hydrosol of iron which acts as an oxygen carrier as it passes alternately between the ferrous and ferric states. Hence, the modified hypothesis is called **the colloidal theory of corrosion.** The hypothesis is represented schematically:



$$\begin{tikzcd}[column sep=small] 2\mathrm{Fe}+2\mathrm{Fe_2O_3}.\mathrm{Aq}_{\cdot sol}+\mathrm{Aq}.= & 4\mathrm{FeO}.\mathrm{Aq}_{\cdot sol} \arrow[d, "+\mathrm{Air}"] & +2\mathrm{FeOAq}. \arrow[d, "+\mathrm{Air}"] \\ & 2\mathrm{Fe_2O_3}.\mathrm{Aq}_{\cdot sol} \arrow[ul, dashed] & \mathrm{Fe_2O_3Aq}_{\cdot rust} \end{tikzcd}$$

Those salts which favour rusting are supposed to peptize the colloid, and those which inhibit rusting—*e.g.* chromates—are supposed to flocculate the colloid. Against this, U. R. Evans said that chromates also stop the corrosion of other metals—*e.g.* magnesium—which exist in only one state of oxidation; and W. G. Whitman and co-workers showed that the effects of salts on the rate of corrosion do not vary concomitantly with the stability of colloidal iron hydroxide. While J. A. N. Friend said that the destruction of the colloidal iron hydroxide by chromates leaves the iron passive, U. R. Evans considers that the chromate acts by putting a protective film on the anodic portions of the iron and so stops the attack. B. Lambert and J. C. Thomson's work makes it very doubtful if iron hydroxide is needed to start the corrosion, although once started, the presence of the colloidal hydroxide may accelerate the corrosion. The action of electrolytes on the coagulation of the hydrosol is said to resemble their action on the rusting of iron both as regards concentration, and temp.; the retarding influence of alcohol is attributed to its dehydrating action on the colloidal ferric hydroxide; the inhibitory action of arsenious acid or its salts—observed by L. Lindet, G. N. Huntly, etc.—is attributed to the adsorption of arsenic trioxide by the colloidal ferric hydroxide, which prevents it taking part in the sequence of changes just mentioned. Exposure to radium rays retards corrosion by coagulating the hydrosol of ferric hydroxide. G. Schikorr pointed out (i) that the alleged similarity between the action of electrolytes on the coagulation of the hydrosol of ferric oxide and the corrosion of iron does not obtain because in the range of lower concentrations, where the differences in the coagulating action of electrolytes is most marked, there is no corresponding agreement in the rusting process. (ii) The basic assumption: $FeO_{sol}+Air=Fe_2O_{3sol}$ is not confirmed by observation, for under the action, of air, the FeO_{sol} is flocculated as a higher oxide. (iii) The fact that there is maximum corrosion for medium speeds of flow—for the speed of rusting increases to a maximum value in the neighbourhood of 1 atm. as the oxygen press. rises—is satisfactorily explained by other theories but not so by the colloidal theory. The colloid theory was discussed by W. Beck, W. Beck and F. von Hessert, G. Schikorr, T. N. Morris, G. D. Bengough, G. D. Bengough and J. M. Stuart, J. M. Stuart, U. R. Evans, S. G. Sastry, J. K. Wood, J. A. N. Friend and co-workers, W. J. Huff, N. Isgarischer and S. Berkmann, and W. D. Bancroft.

As shown by J. C. Thresh,[24] W. R. G. Atkins, W. Weintraud, and many others, natural waters from peaty districts contain several organic acids derived from decaying vegetation, etc. Water from mining areas may contain sulphuric acid (*q.v.*); and the water of canals and rivers in industrial areas may contain acids and salts derived from discharges of waste liquors. The destructive qualities of water are in many cases related to their acidity which is usually represented in terms of the H'-ion concentration. R. E. Wilson, and F. N. Speller classified waters, arbitrarily, in terms of their acidity: *Acidic waters* have their H'-ion conc., p_H below 4·3, and they rapidly corrode the iron with the evolution of hydrogen even in the absence of the depolarizer oxygen; *neutral waters* have a value for p_H between 4·3 and 10, and they cause rusting in the presence of oxygen; and *alkaline waters* have a p_H-value over 10, they usually act slowly on metals and if the protective film is broken down, as might occur if chlorides are present, local attack may occur. According to W. G. Whitman and co-workers, there is a close relation between the **acidity,** or **H˙-ion concentration,** of the water and the rate at which it can corrode iron. The curves in Fig. 373 refer to water flowing at the rate of 3 ins. per sec., *A* refers to water with 5 c.c. of oxygen per litre, and *B*, to water with 1 c.c. per litre. The results show that with both acidic and alkaline soln. the corrosion varies with p_H, but there is an intermediate range of p_H-values where the rate of corrosion is independent of the acidity, and is represented in the diagram by the vertical portion of the curves. As the proportion of oxygen in the water is reduced, the vertical portion of the curve is reduced, until finally, when no oxygen is present, the velocity falls off continuously as the acidity decreases. This is illustrated by Fig. 374, due to J. W. Shipley and I. R. McHaffie. With water flowing in pipes, the proportion of dissolved oxygen in the water in contact with the metal may become small, so that, as J. R. Baylis showed, corrosion can be controlled by regulating the p_H-value of the water, for, in the absence of oxygen, the speed of attack falls continuously with increasing values of p_H.

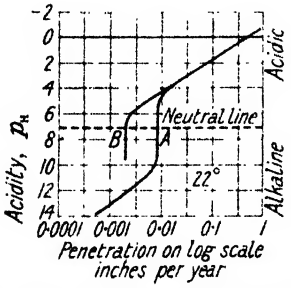


FIG. 373.—The Effect of the Acidity of Solutions on the Velocity of Corrosion (Oxygen present).

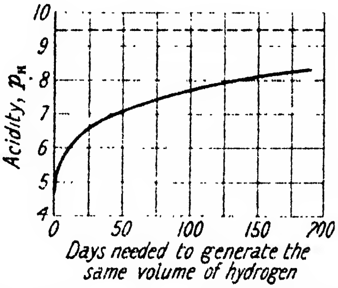

FIG. 374.—The Effect of the Acidity of Solutions on the Velocity of Corrosion (Oxygen absent).

According to J. W. Shipley and co-workers, iron dissolves in purified water, freed from carbon dioxide, when the p_H-value attains 9·4, but not so with higher values. Ordinary purified water has a p_H-value of 7·0 in virtue of the reaction $H_2O \rightleftharpoons H^{\cdot} + OH'$. If OH′-ions eq. to $10^{-4\cdot6}$ mols. per litre be added, the value $p_H = 9\cdot4$ is attained, and this is near the concentration of (OH)′-ions which reddens phenolphthalein. It is inferred by J. F. G. Hicks that the primary cause of corrosion is the dissolution of iron in water, and that this occurs before any chemical action starts. Metallic iron dissolves in an adherent film of water until the resulting soln. of ferrous hydroxide has a value $p_H = 9\cdot4$; the presence of oxygen insures a maximum e.m.f. and acts as an accelerator for the system: $Fe_{solid} \rightleftharpoons Fe_{soln.} + 2HOH \rightleftharpoons Fe(OH)_2 + H_2$. The oxygen removes the ferrous hydroxide by oxidization to less soluble ferric hydroxide, and the hydrogen is also removed by oxidation or depolarization. The presence of carbon dioxide removes ferrous hydroxide by converting it to less soluble carbonate, and it forms carbonic acid, the H˙-ion of which favours corrosion. Indeed, so long as any agent is present capable of removing ferrous hydroxide and hydrogen with sufficient rapidity to prevent the saturation of the adherent water, with respect to ferrous hydroxide and hydrogen, corrosion will occur. R. Girard found that the H˙-ion potential at which corrosion commences is greater with weak acids than it is with strong acids; a film of iron hydroxide appears in acidic soln. when the H˙-ion potential is 3·5. O. B. J. Fraser and co-workers found the maximum in the H˙-ion concentration curve corresponds with the maximum rate of corrosion in sulphuric acid of different concentrations. J. R. Baylis observed that in no case of water corrosion was a concentration of 3 p.p.m. (parts per million) of dissolved iron found in a soln. free from oxygen in which p_H was between 8 and 9. Soluble iron in water with an excess of dissolved oxygen is oxidized faster when $p_H=9·0$ than when $p_H=6·0$. With a concentration of 50 p.p.m., at $p_H=8·0$ less than 0·1 p.p.m. of soluble iron dissolves in the absence of oxygen; about 1·0 p.p.m. when $p_H=7·5$; and about 4 p.p.m. when $p_H=7·0$. With p_H less than 7·0 the proportion of soluble iron increases rapidly.

The effect of the $H^{\cdot}$-concentration of water on corrosion, etc., was discussed by W. R. G. Atkins, J. R. Baylis, W. Blum, W. M. Clark, S. Gottlieb, R. F. Greenfield and G. C. Baker, R. E. Hall and A. R. Mumford, F. Hannan, W. D. Hatfield, J. A. Heymann and A. Massink, E. Imbeaux, I. M. Kolthoff, E. Naumann, W. Olszewsky, S. Rachwal, J. T. Saunders, J. W. Shipley and co-workers, K. Sonden, H. T. Stern, H. Thiesing, J. Tillmans, and W. G. Whitman and co-workers; the effect of acids, and mine waters on the corrosion of iron, by O. Bauer, C. F. Burgess and S. E. Engle, F. C. Calvert and R. Johnson, R. Gans and co-workers, E. Heyn and O. Bauer, A. Ledebur, G. Lunge, R. J. McKay, M. T. Murray, W. D. Richardson, A. Thiel, K. Wagemann, and W. G. Whitman and R. P. Russell; and the effect of soln. of alkalies, by J. H. Andrew, F. Auerbach and H. Pick, R. Baumann, C. H. Cribb and F. W. F. Arnaud, P. W. Evans, A. Fry, G. W. Fuller, I. D. van Giesen, P. Krassa, H. Kriegsheim, G. Lunge, W. Nover and D. Splittgerber, S. W. Parr and co-workers, F. N. Speller and co-workers, D. Splittgerber, T. Steel, C. E. Stromeyer, A. Thiel, A. Vogel, M. Werner, R. S. Williams and V. O. Homerberg, and R. E. Wilson. R. Varet discussed the action of salts dissolved in organic solvents on the metals.

R. E. Wilson said that (i) Strongly alkaline waters have $p_H=10$ and upwards and the $H^{\cdot}$-ion concentration plays here a minor part for protective films are formed on the metal; (ii) Feebly alkaline natural waters have $p_H=9·5$ to 4. The $H^{\cdot}$-ion concentration is not here of importance because the rate of attack depends on the concentration of the oxygen in soln. and the rate of diffusion of the products of the reaction; and (iii) Acidic waters with $p_H=4$ downwards. The overvoltage of hydrogen, the concentration of the $H^{\cdot}$-ions, and the nature of the local galvanic elements are of importance. W. G. Whitman and co-workers represented the effect of variations in the $H^{\cdot}$-ions concentration on iron at 22° and 40°, by the curves in Fig. 375.

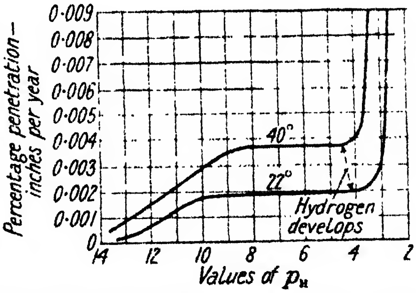

FIG. 375.—The Influence of $H^{\cdot}$-ion Concentration on the Corrosion of Iron.

J. F. Chittum pointed out that the corrosion of iron in air will vary with the p_H-value of the soln. He assumed that ordinary iron is passive, and active iron is the result of a chemical reaction—*vide infra*, passivity. (1) In alkaline soln. where the value of p_H ranges from 9·0 to 12·0, the iron dissolves as (*a*) $Fe+2H_2O \rightarrow FeO_2+4H^{\cdot}+4\oplus$, and a ferrate is formed in soln. as the higher oxide dissolves; where oxygen is not available (*b*) $FeO_2+3H^{\cdot}+2\oplus \rightarrow Fe(OH)^{\cdot}+H_2O$, and where oxygen is available (*c*) $Fe+3H_2O \rightarrow FeO_3''+6H^{\cdot}+4\oplus$. On account of the reaction (*d*) $Fe(OH)^{\cdot}+\frac{1}{2}O_2 \rightarrow FeO_2+H^{\cdot}$, there is a tendency for the formation of the electrode (*b*) over the whole surface; but the reaction (*d*) can establish a state of equilibrium with (*b*) leaving (*c*) to operate where the concentration of oxygen is greatest. Under these conditions, with some other secondary but related reactions, little corrosion occurs; the initial rate of corrosion is about the same as in neutral soln.; and the rate of corrosion rapidly falls to zero, or in extreme cases produces pitting. (2) When the p_H-value lies between 6·0 and 9·0, the iron readily corrodes; the higher oxide dissolves to form a ferrate. As in the preceding case, the differential effect of reaction (*d*) produces an electrolytic cell, with (*c*) as anode and (*b*) as cathode. There is sufficient polarization at the cathode to cause the reaction (e) $Fe+H_2O\rightarrow Fe(OH)+H^{\cdot}+2\oplus$ to be established and the potential is then reversed to produce a corrosion cell in which (c) is the cathode, and (e), the anode. This cell produces the intermittent direct current of corrosion. The ferrate is replenished on the surface of the cathode by the diffusion of the hydroxyferrous ions, and oxidation proceeds in accord with (d). Under these conditions, with other secondary but related reactions, oxidizing agents reduce the rate of corrosion; a low-frequency alternating current superposed on a direct current favours the anodic corrosion of iron; differential aeration effects are marked; oxygen is used in the process of corrosion; and the soln. is made alkaline in the corrosion process up to $p_H=9{\cdot}0$. (3) In soln. where the value of p_H lies between 4·0 and 6·0, iron corrodes rather more quickly than when p_H lies between 6·0 and 9·0. The higher oxide is produced, and being but slightly soluble soon saturates the soln. Owing to reaction (d) a polarization cell with anode (a) and cathode (b) is produced; and when the hydroxyferrous electrode is established, the potential is reversed and a corrosion cell is established with cathode (a), and anode (e) is established. But the electrode (f) $H_2\rightarrow 2H^{\cdot}+2\oplus$ is established and another corrosion cell is established with anode (e) and cathode (f). In this range of p_H-values the potential of the first cell is small, and the potential of the second cell is the greater. Consequently, more corrosion is produced by the second cell. The hydrogen produced at the cathode of the second cell is oxidized with necessary difficulty as the p_H-value of the soln. decreases, and on account of the increasing stability of the ferrous ions, the oxygen does not have so great a tendency to react with ferrous iron to produce ferric oxide. In this case, oxidizing agents slightly increase the rate of corrosion, hydrogen begins to be evolved when p_H lies between 4·0 and 5·0, dependent on the nature of the metal; and general corrosion occurs rather then pitting. (4) With soln. having p_H between 1·0 and 4·0, iron corrodes rapidly and with a greatly increasing rate as the value of p_H diminishes. The difference between this case and the preceding one is that the potential of the cell with (e) as anode and (f) as cathode and that of the cell with (e) as anode and (a) as cathode continually increases as the value of p_H decreases. Here the rate of corrosion is greater than is the case with other values of p_H; hydrogen gas is evolved; and ferrous ions attain a high concentration in the soln.

J. W. Shipley and co-workers found that in the absence of oxygen, the rate of corrosion is proportional to the negative p_H-value of the soln. to $p_H=9{\cdot}4$; and no hydrogen is evolved with soln. more alkaline than $p_H=9{\cdot}4$. The potential of the cell $Fe\,|\,Fe^{\cdot\cdot},H^{\cdot}\,|\,H_2$ should be proportional to the $H^{\cdot}$-ion conc. until $p_H=9{\cdot}0$; and in more alkaline soln., the potential should be independent of the $H^{\cdot}$-ion conc., and should be of the order 0·16 volt. The potentials calculated for slightly acid soln. are greater than they should be to account for the slow dissolution of iron. J. F. Chittum assumes that the first action of iron is to produce a higher oxide *vide infra*, passivity—and that as a result of other reactions the final corrosion cell is $Fe+H_2O+H^{\cdot}\rightarrow Fe(OH)^{\cdot}+H_2$, which has an e.m.f. approaching zero when $p_H=9{\cdot}0$, and this agrees with the results of J. W. Shipley and co-workers.

In the corrosion at a water-air surface in soln. with p_H less than 9·0, there is established an electrolytic cell in which (a) in the surface is anode, and (c), some equivalent electrode, is the cathode. The decreased polarity of the surfaces establishes the anode (a) in the surface film. The fact that the anodic potential of this electrode is greater than that of any other iron electrode in air accounts for the fact that surface corrosion is very important. In more alkaline solutions the boundary potential between the surface film and the main body of the soln. is built up until little surface corrosion occurs in these solutions.

The action of salt and other solutions on corrosion.—The presence of salts in water in contact with iron may have a marked influence on the rate of corrosion. Numerous observations have been made on the action of soln. of various salts on iron. The results with salts of the heavy metals, and ammonium salts, as well as of salts of the oxy-acids, etc., have been indicated in connection with the chemical properties of iron. Effects with some common salts were reported as follow:

Potassium fluoride.—A. W. Chapman.[25] *Sodium chloride.* R. Adie, O. Bauer and co-workers, W. S. Dudley, H. Endo, J. A. N. Friend and co-workers, U. R. Evans and T. P. Hoar, R. H. Gaines, F. Haber and F. Goldschmidt, K. Inamura, S. Micewicz, M. Mugdan, V. K. Perschke and G. I. Tschufaroff, A. Thiel and H. Luckmann, and A. Wagner. The effect of pressure on the results was studied by O. Bauer and co-workers, E. Berl and F. von Taack, and J. A. N. Friend. *Potassium chloride.*—H. Endo, K. Inamura, S. Micewicz, U. R. Evans and T. P. Hoar, and A. Wagner. *Ammonium chloride.* E. Heyn and O. Bauer, J. T. Nance, and A. Wagner—*vide supra*, the chemical properties of iron. *Potassium iodide.*—E. Pietsch and co-workers. *Sodium sulphate.* O. Bauer and co-workers, E. Berl and F. von Taack, H. Endo, J. A. N. Friend and co-workers, E. Heyn and O. Bauer, K. Inamura, U. R. Evans and T. P. Hoar, A. Thiel and H. Luckmann, and A. Wagner. *Potassium sulphate.*—H. Endo, J. A. N. Friend and co-workers, E. Heyn and O. Bauer, K. Inamura, and A. Wagner. *Potassium aluminium sulphate.*—H. Endo. *Ammonium sulphate.*—E. Heyn and O. Bauer, and A. d'Heureuse—*vide supra*, the chemical properties of iron. *Sodium nitrate.*—H. Endo, J. A. N. Friend and co-workers, and E. Heyn and O. Bauer. *Potassium nitrate.*—H. Endo. *Ammonium nitrate*—*vide supra*, the chemical properties of iron. *Sodium and potassium carbonates.*—R. Adie, E. Bosshard and R. Pfenninger, C. H. Cribb and F. W. F. Arnaud, J. A. N. Friend and co-workers, E. Heyn and O. Bauer, C. F. Hickethier, A. Wagner, and F. Westhoff. *Sodium phosphate.*—W. R. Dunstan and co-workers, H. Endo, E. Heyn and O. Bauer, and A. Krefting; and the effect of pressure, by E. Berl and F. von Taack. *Calcium chloride.* R. Girard, E. Heyn and O. Bauer, C. F. Hickethier, P. Medinger, S. Micewicz, W. Palmaer, and G. Zelger. *Barium chloride.*—H. Endo, J. A. N. Friend and co-workers, E. Heyn and O. Bauer, and V. Zemlyanitznin and P. Dobrovolsky. *Calcium nitrate.*—W. Vaubel. *Magnesium chloride.*—O. Bauer and co-workers, E. Bosshard and R. Pfenninger, W. R. Bradbury, H. Endo, F. Fischer, F. Halla, E. Heyn and O. Bauer, S. Micewicz, H. Ost, J. Pfeifer, A. Wagner, and P. West; the effect of pressure, by E. Berl and F. von Taack. *Magnesium sulphate.*—J. A. N. Friend and co-workers, and E. Heyn and O. Bauer.

As observed by G. Wetzler, M. M. Hall, and A. Payen, iron may be kept an indefinitely long time in soln. of potassium, sodium, or an alkaline earth hydroxides, or in aq. ammonia without corrosion, provided the concentration of the solvent be large enough; and iron is corroded in sat. soln. of potassium nitrate or sulphate more slowly than in water, owing, it was assumed, to the liquid dissolving less air than in the case of water alone. A. J. Hale and H. S. Foster found that the action of 0·2*N*-soln. of the following salts on wrought iron and cast iron, between 17° and 20°, per sq. dm. of metal, was represented by the following losses in 7 days using half a litre of soln. per day:

0·2*N*-soln	.	$MgCl_2$	NaOH	$CaCl_2$	NaCl	NH_4OH	Na_2CO_3
7 days	Cast iron	0·85	0·00	0·20	0·10	0·00	0·00
	Wrought iron	0·85	0·00	0·30	0·25	0·00	0·00
7 days	Cast iron	0·45	0·00	0·17	0·32	0·18	0·00
	Wrought iron	0·41	0·00	0·26	0·24	0·00	0·00

According to L. McCulloch, of a number of small particles of electrolytic iron isolated from one another, only a certain proportion will rust in the presence of air, moisture, and sodium chloride. The smaller the particles, the greater the proportion which is "passive," but if the particles are in contact with one another they all rust. Again, in a soln. of ammonia and ammonium chloride pieces of soft iron may either dissolve readily or remain unattacked. "Passivity" in this soln. is produced by heating until temper colours appear, or often merely by cleaning with coarse emery and exposing to the air. The metal is activated by contact with zinc or active iron in the soln. or by cathodic treatment at a sufficiently negative potential. Any of these activating agencies will also cause mill-scale or ferrous oxide to dissolve in this soln., so that the observed passivity of iron is ascribed to a superficial oxide film.

At the beginning of our era, Pliny, in his *Historia naturalis* (31. 19), mentioned the corrosion of iron by the waters of a river in Thessaly; and numerous observations have since been made on the corrosive action of soln. of different salts, and of mineral waters on iron—*e.g.* by E. Berl and F. von Taack, H. G. Denham, H. E. Bellamy, W. B. Lewis and G. S. Irving, U. R. Evans, R. Adie, V. K. Perschke and G. I. Tschufaroff, F. Auerbach and H. Pick, W. D. Bancroft, W. M. Barr and R. W. Savidge, O. Bauer and co-workers, K. Inamura, H. Baucke, C. F. Burgess and S. G. Engle, R. Girard, C. G. Fink and C. M. Decroly, K. Konopicky, M. Scheelhasse, G. D. Bengough and co-workers, F. C. Calvert and co-workers, C. H. Cribb and F. W. F. Arnaud, A. S. Cushman, G. K. Davis, J. B. Dodds, W. R. Dunstan, F. Förster, W. A. Fowler, J. A. N. Friend and co-workers, A. Fry, A. F. Ganz, B. Garre, J. Grossmann, H. C. Haak, A. J. Hale and H. S. Foster, M. M. Hall, E. S. Hedges, M. Heegewaldt, E. Heyn, E. Heyn and O. Bauer, O. F. Hunziker and co-workers, K. Inamura, G. Jüngst, F. Körber and A. Pomp, A. Krefting, O. Kröhnke, O. Lasche and W. Kieser, A. Ledebur, L. Lindet, G. Lunge, E. Maass and W. Wiederholt, R. Mallet, P. Medinger, A. E. Menke, W. Menzel, G. T. Moody, M. Mugdan, J. T. Nance, S. W. Parr and F. G. Straub, W. Peters, P. Petit, J. Persoz, R. Pfenninger, D. Phillips, A. Pomp, P. N. Raikow, W. Ransom, W. D. Richardson, H. Rinne, J. K. Roberts and co-workers, P. Rohland, F. J. Rowan, E. Schulz, J. B. Senderens, R. Stumper, K. Taussig, A. Thiel and H. Luckmann, W. Thomson, M. Usener, M. Vogt, J. H. Vogel, A. Wagner, W. G. Whitman and R. P. Russell, etc.

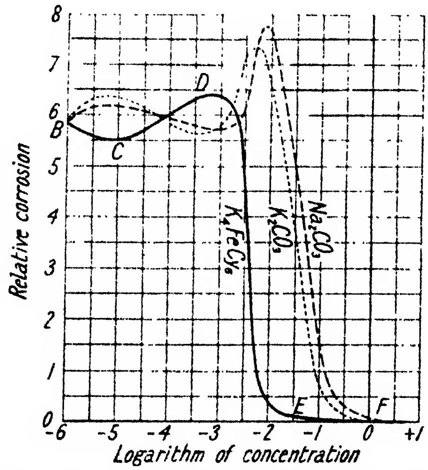

FIG. 376.—Corrosive Action of Solutions of Potassium Ferrocyanide, and Alkali Carbonates.

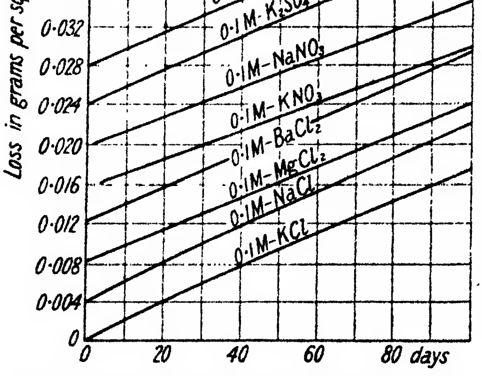

FIG. 377.—The Action of Salt Solutions on the Corrosion of Armco Iron.

U. R. Evans represented the speed of corrosion, dx/dt, for dil. soln., by $dx/dt=k_1(C_0-k_2x)_1$, where k_1 and k_2 are constants; C_0= the initial concentration of the electrolyte; and x, a measure of the corrosion. J. A. N. Friend found that for a concentration, m, of the salt, the rate of corrosion, C, is related to the solubility of oxygen, β; and to the rate of dissolution of oxygen, R, by $C_m=\beta_m R_m$.

H. Endo's observations on the corrosive effect of salt soln. containing 0·1 mol per litre are summarized in Fig. 377. The armco iron in 0·1M-soln. of potassium chromate, dichromate, perchlorate, and permanganate was bright and free from rust during 3 yrs.' exposure; in other soln., the corrosion increased proportionally with the time. With soln. of sodium hydrophosphate, and potash-alum, the corrosion was rapid at first, and then gradual, and finally, as the surface of the iron became coated with a film, corrosion ceased.

In 1845, R. Adie discovered that sat. soln. of potassium or sodium ferrocyanide, ferricyanide, cyanide, carbonate, perchlorate, and permanganate help to resist corrosion. K. Inamura showed that the corrosion with salt soln.—potassium and sodium chlorides and sulphates—increases with increasing concentrations below 0·1*M*. H. Endo also studied the influence of the concentration and found for sodium and potassium chlorides, and sulphate the following losses in grams per sq. cm., and the corrosion ratios—that is, the ratio of the loss in weight of iron in the salt soln. to its loss in distilled water:

NaCl	Conc. .	0	0·1	1·0	2·0	3·0	4·0	5·0	6·0
	Loss .	0·00075	0·00105	0·00097	0·00074	0·00068	0·00037	0·00032	0·00022
	Ratio .	1·0	1·4	1·3	1·0	0·8	0·5	0·4	0·3
KCl	Conc. .	0	0·1	1·0	1·5	2·0	2·5	3·0	3 5
	Loss .	0·00074	0·00112	0·00096	0·00089	0·00077	0·00068	0·00052	0·00044
	Ratio .	1·0	1·5	1·3	1·2	1·05	0·95	0·70	0·60
Na_2SO_4	Conc. .	0	0·1	0·2	0·5	0·6	0·8	0·9	1·0
	Loss .	0·00077	0·00100	0·00095	0·00085	0·00079	0·00058	0·00050	0·00046
	Ratio .	1·00	1·30	1·25	0·10	1·02	0·75	0·65	0·60
K_2SO_4	Conc. .	0	0·1	0·2	0·3	0·4	0·6	0·8	1·0
	Loss .	0·00077	0·00112	0·00093	0·00086	0·00069	0·00062	0·00049	0·00039
	Ratio .	1·00	1·30	1·20	1·05	0·90	0·80	0·64	0·50

There is thus a maximum in the curves where the corrosion is greatest, and larger than that of water; the corrosion then diminishes to less than the value for water; and there is a particular concentration of the salt soln. where the value is the same as that of water, and when the corrosion ratio is unity. H. Endo added that the actual corrosion is a result of two opposing influences. One is due to the solubility of oxygen in water. In dil. soln., where the solubility of oxygen is nearly the same for water, the rate of corrosion increases with an increase in concentration of the salt, but with more conc. soln., where the solubility of oxygen is reduced progressively with increasing concentration of the soln., the corrosion will be reduced. The maximum with the salts under consideration is near 0·1*M*.

According to E. Heyn and O. Bauer, the behaviour of soln. of potassium ferrocyanide is typical of that of many others. *B*, Fig. 376, represents the effect with distilled water; the concentration is expressed in mols per litre. In some cases, with small proportions of salt, say 0·001 to 0·1 grm. per litre, there is a slight retardation, *BC*. Many salts—*e.g.* sodium and potassium carbonates—exhibit no such retardation. As the proportion of salt increases, the corrosive effect increases, *CD*, to a maximum, *D*, which is usually much greater than the effect with distilled water. This represents what has been called *critical concentration*. Subsequent increases in the proportion of salt rapidly depress the activity of the soln. until it reaches what is called a *limiting concentration* at a point, *E*, where corrosion practically ceases; and subsequent increases in the conc. of the soln., *EF*, have no effect on corrosion, for the iron may be kept in contact with these soln. for an indefinite period without corrosion.

According to E. Heyn and O. Bauer, and J. A. N. Friend, the critical and limiting concentrations of a number of salts, expressed in grams per litre, are respectively as follow: *potassium ferrocyanide*, with wrought iron, 0·1, and 1 to 2; and with purified iron, 0·2, —; *potassium ferricyanide*, wrought iron, 0·1, and 1 to 2; *potassium permanganate*, wrought iron, 0·1, and 0·1 to 1·0; *potassium carbonate*, wrought iron, 1·0, and 1 to 10; *potassium iodate*, wrought iron, 0·01, and 0·1 to 1·0; *potassium cyanide*, wrought iron, 0·1, and 0·1 to 1·0; *potassium bromate*, wrought iron, 0·1, and 0·1 to 1·0; *potassium chlorate*, wrought iron, 0·1, and 74·5; *calcium chloride*, steel, 1·27, and 510; *sodium sulphide*, steel, 0·1, and 100; *sodium hydrocarbonate*, wrought iron, 1·0, and 1 to 10; *sodium carbonate*, wrought iron, 1·0, and 1 to 10; *borax*, wrought iron, 0·1, and 1 to 10; *sodium hydrophosphate*, wrought iron, 1·0, and 1 to 10; *ammonium hydrophosphate*, wrought iron, 0·01, and 1·0 to 10; *ammonium acetate*, wrought iron, 0·01, and 0·1 to 1·0; *chromic acid*, wrought iron and pure iron, limiting conc. 0·01 to 0·05; *potassium chromate*, wrought iron, 0·01 to 0·1; and *potassium dichromate*, wrought iron and pure iron, 0·01 to 0·1.

C. H. Cribb and F. W. F. Arnaud showed that the corrosive action of soln. of sodium carbonate is nearly twice as great at 100° as it is at room temp. Ammonium hydrophosphate here acts normally up to its limiting concentration, and before the soln. is saturated, corrosion begins again; but it is not rusting in the ordinary sense, because the metal becomes covered with gas-bubbles, and finally acquires a greyish-green deposit. In the case of soln. of potassium chlorate, calcium chloride, and sodium sulphide, *E* and *F* almost coincide and the limiting conc. is a sat. soln. of the salt. There are no critical conc. with a few salts—*e.g.* chromic acid and its two potassium salts. The slow soln. observed by E. Heyn and O. Bauer with very conc. soln. of chromic acid, and potassium dichromate may be due to the presence of manganese in the iron, for, as A. S. Cushman showed, manganiferous irons are slightly soluble in these soln., but no effect can be observed with pure iron during the course of a few weeks.

Ammonium salts are very corrosive, and of the three tried by E. Heyn and O. Bauer, Fig. 378, the nitrate is the most active, and it is ammonium nitrate which is produced in thunderstorms, and washed down by rain. The rain-water soln., of course, is very dilute, but the concentration increases as the liquid evaporates. Soln. of these ammonium salts were found to attack iron both in the presence and in the absence of air. The ratios: Loss in the absence of air: loss in the presence of air, for the nitrate, sulphate, and chloride are respectively 0·92, 0·17, and 0·023. The activity of the salts is much greater when the temp. is raised. J. A. N. Friend and P. C. Barnet observed that a sat. soln. of ammonium sulphate is less corrosive than distilled water at 6°, but at 18° it is much more corrosive. L. Santi found that iron drillings are attacked by a boiling soln. of ammonium chloride: $Fe+2NH_4Cl = FeCl_2+2NH_3+H_2$; observations on the action of ammonium chloride soln. were also made by J. T. Nance; E. B. R. Prideaux and R. M. Caven made a similar observation with respect to ammonium nitrate; and W. R. Hodgkinson and A. H. Coote, with respect to soln. of ammonium nitrate and nitrite. W. Vaubel observed that while ammonium nitrite is almost without action on iron, ammonium nitrate makes a very effective attack; hydrated ferrous and ferric oxides are formed, and some iron passed into soln. as a complex salt. Ammonium nitrate, said W. Vaubel, is very generally present in common water in contact with iron, for this metal will reduce a portion of the dissolved nitrates to ammonia; the same process, namely, the reduction of the nitrate radicle to ammonia, occurs in the action of ammonium nitrate on iron, the latter undergoing oxidation. The rusting is assisted by the increased activity of oxygen at the attacked spot, and also by the action of the water itself, which, it is stated, in the presence of ammonium nitrate will act on iron, forming iron oxide and hydrogen, especially if the temp. is slightly raised. R. Droste showed that under ordinary conditions, nitrates are reduced by iron to ammonia without forming any appreciable proportion of nitrite. A. A. Bonnema showed that ferrous oxide and hydroxide in contact with air give rise to a certain amount of nitrite. If, as is quite possible, nitrate is produced in the same manner, W. Vaubel added that it is clear that for the rusting of iron only a minimal quantity of an ammonium salt need be present, for the ammonium nitrate could then be easily formed. F. Hanaman discussed the action of soln. of ammonium sulphate.

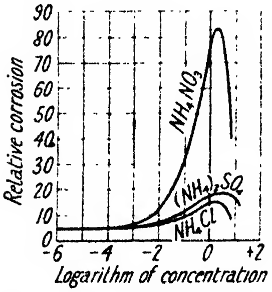

FIG. 378.—The Corrosive Action of Solutions of Ammonium Salts.

There is another series of salts whose sat. soln. are incapable of inhibiting corrosion, and in this sense it can be said that the limiting conc. is imaginary, and that *F* lies to the left of *E*, Fig. 376. These salts therefore show only a critical conc. E. Heyn and O. Bauer, and J. A. N. Friend and J. H. Brown obtained the following results:

Potassium chloride with wrought iron, 50; with purified iron, 5; *potassium sulphate* with wrought iron and purified iron, 10; *potassium nitrate* with purified iron, 1 to 15; *sodium* *chloride*, wrought iron, 10 ; and purified iron, 5 ; *sodium sulphate*, wrought iron and purified iron, 10 ; *sodium nitrate*, wrought iron, 0·1 ; purified iron, 50 ; *calcium hydrocarbonate*, wrought iron, 0·14 ; *calcium sulphate*, wrought iron, 2·034 ; *calcium sulphide*, steel, 0·0014 ; *barium chloride*, wrought iron, 100 ; purified iron, 10 ; *ferrous sulphate*, wrought iron, 100 ; *arsenic trioxide*, wrought iron, 0·064 ; *magnesium chloride*, wrought iron, 100 ; purified iron, 20 ; *magnesium sulphate*, wrought iron and purified iron, 10 to 50 ; *manganese sulphate*, wrought iron, 0·1 ; *ammonium thiocyanate*, wrought iron, 0·01 ; *ammonium chloride*, wrought iron, 100 ; *ammonium sulphate*, wrought iron, 200 ; and *ammonium nitrate*, wrought iron, 500. I. Wasilewsky and W. Bardzynsky discussed the corrosive action of a soln. of ammonium nitrate ; and V. K. Pershke and G. I. Tschufaroff, the corrosive action of potassium salts on cast iron.

The corrosive actions of soln. of potassium and sodium chlorides and sulphates, and of potassium nitrate, by J. A. N. Friend and J. H. Brown, are illustrated by Fig. 379. They show that the corrosive action of conc. soln. of the chlorides is less than that of water alone. This was noticed by R. Adie in 1845, and he explained the results by G. Wetzler's assumption that the solubility of oxygen in brine soln. is less than it is in water alone. F. J. Rowan cited an example where the life of boilers was much greater when run with a higher proportion of sea-water with the fresh water, than when a small proportion of sea-water was used. J. A. N. Friend and J. H. Brown noticed that while at 10°, a soln. of sodium chloride has a critical conc. whose corrosive action is greater than that of distilled water at the same temp., yet at 21°, in agreement with E. Heyn and O. Bauer, the reverse is the case ; and at 14°, the corrosive action is the same as that of distilled water. Hence, a soln. may be less corrosive than distilled water in the tropics and more corrosive in temperate climes ; a similar difference may be shown in summer and winter. E. Heyn and O. Bauer's results with sodium chloride soln. are summarized in Fig. 380, where the concentrations are expressed in mols per litre. The action is nearly twice as great at 40° as it is at 18° ; at 80°, the action with the more dil. soln. attains a maximum. A. Payen, R. Girard, K. K. Järvinen, and L. Aitchison made some observations on this subject. H. Beeny found that the amount of iron which passes into soln. as Fe··-ions when used as anode in a 0·2 per cent. soln. of sodium chloride agrees with the quantity of electricity generated, and it is hence inferred that the corrosion is entirely electrochemical. A. W. Chapman found that *potassium fluoride* below 0·8*N*-conc. act like potassium chloride, but, unlike soln. of the chloride, above that conc. the metal is not corroded. This is attributed to the formation of a protective film of a fluoride or complex fluoride on the surface of the metal. The attack by soln. of potassium fluoride is inhibited by the presence of sodium carbonate or chromate in concentration less than is needed for the chloride. This is attributed to the fluoride being less able to penetrate the protective film formed by the inhibitor. R. Adie, and J. A. N. Friend and J. H. Brown

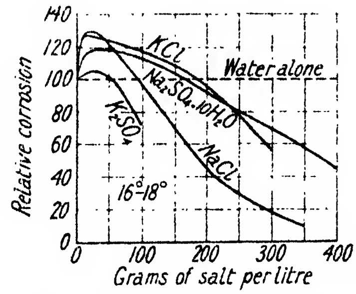

FIG. 379.—The Effect of Aqueous Solutions of Salts on the Corrosion of Iron.

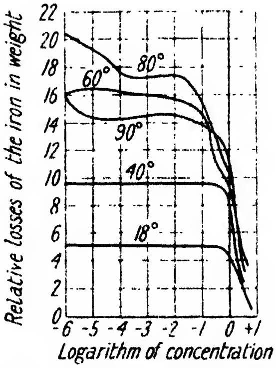

FIG. 380.—The Effect of Temperature on the Corrosive Action of Solutions of Sodium Chloride.

showed that at the temp. of the room, and in the absence of air, soln. of the alkali sulphates and chlorides exert no corrosive action on iron. The results for the alkali nitrates are shown in Fig. 381. P. Rohland observed that whilst most chlorides accelerate the rate of corrosion of iron in water, chromic chloride acts in the converse way, due, it is assumed, to "a transitory separation of chromium by the iron." G. R. White studied the electrolytic corrosion of iron as anode in soln. of sodium chloride, sulphate, nitrate, acetate, and tartrate.

Rain-water, particularly after thunderstorms, contains nitric acid or nitrates, and sewage water also contains nitrites and nitrates. The action of soln. of nitrates on iron was also examined by J. B. Senderens, and J. A. Jones. W. Vaubel found that soln. of the alkali nitrates are not nearly so active as ammonium nitrate; and that soln. of the alkali nitrites are almost without action on iron. F. Hanaman studied the action of soln. of sodium chloride, potassium carbonate, and ammonia. W. vanWüllen-Scholten studied the action of soln. of sodium chloride. M. Mugdan found that the chlorides of the alkalies, ammonium, and the alkaline earths accelerate rusting to about the same extent. Bromides, sulphates, and perchlorates are nearly equally active, potassium nitrate somewhat less so, and purified water less still. Iron remains practically unattacked in soln. of potassium (or sodium) chlorate, bromate, iodate, chromate, dichromate, acetate, oxalate, tartrate, ferro- and ferricyanides, cyanide, hydrogen carbonate, borate, hydroxide, and ammonia. The order in which iron is attacked in these soln. is not changed by adding small quantities of acid, or of alkali, or of oxidizing agents such as hydrogen dioxide, potassium ferricyanide, or sodium hypobromite, although the rate of rusting is increased or diminished. Soln. containing a mixture of salts possess properties intermediate between those of soln. of the pure salts; thus, addition of salt to a soln. of sodium hydroxide causes iron immersed in it to rust, although more slowly than in an equally conc. soln. of pure salt. The effect of dil. alkaline soln. was discussed by H. J. Donker and R. A. Dengg, who found that the surface of iron is uniformly attacked, but in more conc. soln. point-corrosion predominates. Alkali hydroxide is more protective than carbonate—*vide supra*. Sulphate soln. attack iron less than chloride soln. Iron is not markedly attacked by neutral soln. containing dichromate, or dichromate and chloride, but it is vigorously attacked if the soln. is not neutralized. The results of J. A. N. Friend and J. H. Brown with barium chloride, and with magnesium chloride and sulphate are summarized in Figs. 381 and 382. V. Zemlyanitzuin and P. Dobrovolsky found that boiling soln. of barium chloride attain a maximum attack after boiling with the metal for 8 to 16 hrs. The attack then decreases gradually owing to the formation of a protective film of hydrated ferric oxide.

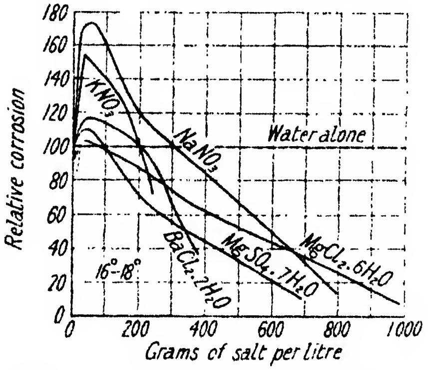

FIG. 381.—The Effect of Aqueous Solutions of Salts on the Corrosion of Iron.

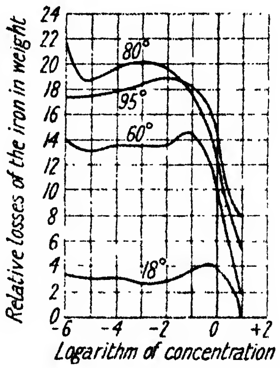

FIG. 382.—The Effect of Solutions of Magnesium Chloride on the Corrosion of Iron at different Temperatures.

The action of magnesium chloride has received much attention owing to its presence in sea-water, which may be regarded as an aq. soln. of sodium and magnesium chlorides. E. Maass and W. Wiederholt, and O. Hauser showed that magnesium salts are strongly corrosive, and in aq. soln. it is largely hydrolyzed to form free hydrochloric acid, particularly if its temp. be raised. E. Heyn and O. Bauer's results with variations of temp. are indicated in Fig. 381, where the concentrations are expressed in mols per litre. The effect with the more dil. soln. reaches a maximum at 80°. The soln. can also act on iron in the absence of air, particularly if the temp. is raised. This was demonstrated by A. Wagner, and R. Pfenninger, and emphasized by J. B. Dodds. E. J. Fox also showed that desert waters containing magnesium chloride have a high H'-ion conc., and are very destructive to steel and iron conveying-pipes. Observations on the corrosive action of *natural waters* were made by F. Auerbach, F. Bamberg, C. O. Bannister and R. Kerr, C. Blacher, H. G. Bowen, G. J. Burrows and C. E. Fawsitt, C. P. Coles, M. J. Falkenberg, A. P. Ford, H. O. Forrest, J. R. Francis, G. W. Fuller, L. W. Haase, R. A. Hadfield, W. M. Hamlet, A. Heinzelmann, T. Hermann, H. M. Howe, G. N. Huntley, I. M. Kolthoff, O. Kröhnke, W. Lulofs, F. Lyon, B. G. McLellan, R. Mallet, A. Mündlein, G. Popp, E. Prinz, W. Reid, J. W. Shipley and I. R. McHaffie, F. N. Speller, F. N. Speller and co-workers, A. Splittgerber, A. T. Stuart, R. Stumper, A. Thiel, F. Tiemann and A. Gärtner, J. Tillmans and co-workers, J. Walker and S. A. Kay, W. G. Whitman and R. P. Russell, R. E. Wilson, W. Windisch, H. Winstanley, and I. H. Woolson; and on the corrosive action of *mine waters*, by R. J. Anderson and G. M. Enos, A. Katz, W. A. Selvig and G. M. Enos, and W. E. Warner. P. Medinger explained the corrosion of gas and water mains in heavy soils, containing *calcium sulphate* as follows: through the ionization of the sulphate, the proportion of calcium ions in soln. becomes so great that the dissociation of the calcium hydrogen carbonate is depressed, and, consequently, the production of H'- and HCO_3''-ions from the free carbonic acid is not so much hindered. The enhanced acidity of a soln. containing free carbonic acid and calcium hydrogen carbonate consequent on the addition of calcium sulphate may be demonstrated by means of litmus.

R. Adie found that iron is attacked more vigorously by **sea-water** in the presence of air than is the case with distilled water. The aeration of sea-water near the surface as it is stirred up by the waves is favourable to corrosion; on the other hand, oxygen was found to be less soluble in sea-water than it is in ordinary water. Again, A. Payen showed that iron is attacked by sea-water in the complete absence of air under conditions where iron can be kept in fresh water an indefinite time without corrosion. The activity of sea-water is consequently due to the salts which it has in soln.—*e.g.* sodium chloride, and magnesium chloride and sulphate. At considerable depths below the surface the supply of air to sea-water is very restricted. From observations by O. Bauer and E. Wetzel, G. D. Bengough and co-workers, J. J. Berzelius, E. Beutel and A. Kutzelnigg, R. Binaghi, J. V. Davies, C. N. Draper, J. A. N. Friend, R. A. Hadfield, H. M. Howe, M. Lidy, R. Mallet, J. T. Milton and W. J. Larke, M. le Naour, D. V. Onslow, J. Percy, M. Portier, J. W. Shipley and I. R. McHaffie, R. Stumper, V. N. Svechnikoff and K. F. Starodoudoff, and H. Wilkinson, on cast iron—guns, cannon-balls, etc.—which had been submerged for 50 and more years in the sea, the iron appears to be slowly converted into ferrous oxide, and partially dissolved, and at the same time the residue becomes soft though retaining its original shape. The carbon appears to form a graphitic mass. Hence, the change is sometimes designated the **graphitization**—or **graphititis**, or *iron cancer*—of cast iron. According to R. Mallet, the sp. gr. of the mass is between 1·3 and 1·8—when that of cast iron ranges from 6·8 to 7·6; and he also quoted the analysis: FeO, 81 per cent.; graphite, 16 per cent.; iron chloride, a trace. In the case cited by J. J. Berzelius, when the mass was first brought to the surface, within half an hour it became too hot to hold in the hand—presumably owing to the oxidation of the graphitic carbon which is almost in a pyrophoric state. F. W. Durkee observed an analogous result by the action of the water of a coal-mine on cast iron. J. W. Shipley and I. R. McHaffie reported cementite and a cementite-phosphide eutectic in the residual skeleton. J. W. Shipley observed a softening of the iron pipes exposed in soils containing calcium sulphate; W. B. Schulte, when exposed to cinders. U. R. Evans noted the breaking down of the cast-iron foundations of a bridge over the Thames.

The graphitization may be produced by other corrosive agents, thus, F. J. Daniell produced a spongy, grey mass, "somewhat resembling plumbago," by the action of dil. hydrochloric acid on cast iron; F. C. Calvert, by the action of dil. hydrochloric or acetic acid for two years; T. Crzeschik, by the action of dil. sulphuric acid; S. Leet, and W. H. Pepys, pyroligneous spirit; T. Thomson, sour paste; R. Mallet, the vapour disengaged by roasting coffee, the action of sherry wine, and of low wines and proof spirit; and M. Freund, by the action of direct electric currents in soln. of sodium chloride or calcium sulphate, although F. Bergius and P. Krassa observed no such action with alternating currents. O. Bauer and E. Wetzel studied the graphitization of cast iron and found that graphitization occurs with iron anodes in tap-water, sea-water, and in 10 per cent. soln. of magnesium chloride or sulphate. R. Mallet also mentioned cases when graphitization was facilitated by the galvanic action caused by the contact of cast iron with a less corrodible metal—*e.g.* copper, or brass. Reports on the corrosive action of sea-water have been also made by T. Andrews, M. Ballay, O. Bauer and E. Wetzel, H. Bauermeister, A. C. Becquerel, B. Bell, G. D. Bengough, R. Binaghi, F. C. Calvert and R. Johnson, E. Cohen, C. P. Coles, P. M. Crosthwaite, P. M. Crosthwaite and G. R. Redgrave, J. V. Davies, E. Davy, W. Denecke, E. Deslongchamps, H. Diegel, S. H. Ellis, U. R. Evans, J. A. N. Friend, R. Girard, J. Grantham, R. A. Hadfield, F. Hanaman, W. J. Hay, T. Holgate, G. Johnstone, W. P. Jorissen, K. Hasegawa and S. Hori, C. J. B. Karsten, F. B. King, G. von Knorre, O. Kröhnke, M. Lidy, A. Liversidge, R. Mallet, T. E. Perks, J. W. Post, H. S. Rawdon, J. Rennie, H. E. Rhoades, H. Rinne, A. Romwalter, A. H. Sabin, F. Schmitz, B. Schultz, E. C. Sherman, J. W. Shipley and I. R. McHaffie, B. Silliman, G. Stauch, T. Steel, F. P. Stowell, R. Stumper, W. Thomson, M. Usener, G. B. Vroom, and H. Wilkinson, etc.—*vide infra* for a comparison of the different varieties of "iron" and steel.

G. Wetzler observed that iron does not rust in aq. soln. of potassium hydroxide, or in aq. ammonia; and A. Payen added that iron remains bright for months when immersed in an aq. soln. of ammonia or of potassium or sodium hydroxide. A soln. of 1 vol. of a sat. soln. of potassium hydroxide and 2000 vols. of water prevents iron from rusting, but the metal is corroded in a 1 : 4000-soln. A soln. of 1 vol. of a sat. soln. of sodium carbonate in 54 vols. of water will prevent rusting, but not so with a 1 : 59-soln. A. Payen also found that a soln. of 1 vol. of a sat. soln. of borax in 6 vols. of water, and 1 vol. of a sat. soln. of lime-water in 3 vols. of water will prevent rusting; but not so with more dil. soln. M. M. Hall also observed that iron does not rust in water containing magnesia or lime. For A. J. Hale and H. S. Foster's observations, *vide supra;* and for the action of alkali hydroxides, *vide supra,* chemical properties of iron. C. H. Cribb and F. W. F. Arnaud observed that very dil. alkaline soln. do not prevent the corrosion of iron. With the conc. of the alkaline soln. expressed as parts of alkali by weight as 100,000 parts of water; and with the corrosion expressed as milligrams of ferric oxide, they found, at room temp., say 16°:

		NaOH				KOH			NH_4OH	
		4	10	20	40	5·6	14·0	28·0	17·0	34·0
Fe_2O_3	16° .	7·0	2·8	0	0	5·8	0	0	5·0	0
	100° .	18·5	19·3	5·8	0	13·7	12·8	0	11·5	0

		$Ca(OH)_2$			$Ba(OH)_2$		
		9·25	18·5	27·75	8·55	21·37	42·74
Fe_2O_3	16° .	7·5	5·0	0	5·2	0	0
	100° .	20·5	3·5	0	14·4	11·3	0

J. D. Pennock and D. A. Morton found that iron does not rust in conc., aq. soln. of ammonia, although freshly rusted iron is attacked. J. A. N. Friend observed no attack by $\frac{1}{30}N$-NH_4OH when kept in sealed tubes for several years. F. J. R. Carulla observed no change in a cast iron still used for ammonia during 18 years; and this was confirmed by J. F. Kempson. Observations were also made by F. Schmitz, W. R. Hodgkinson and N. E. Bellairs, M. Tilgner, C. Matignon and G. Desplantes, and U. R. Evans on the action of aq. soln. of ammonia; by W. Dittmar, W. Venator, G. Zirnite, E. Heyn and O. Bauer, F. Lyon, F. N. Speller and C. R. Texter, J. H. Andrew, M. L. Hamlin and F. M. Turner, H. F. Whittaker, P. D. Merica, and C. E. Stromeyer, on the action of aq. soln. of alkali hydroxides; and by T. Schmelzer by soln. of calcium hydroxide.

The results of C. H. Cribb and F. W. F. Arnaud confirm the observations of A. Payen that dil. soln. of the alkali hydroxides, in ordinary atm. air, do not inhibit the corrosion of iron until a certain limiting conc. of the alkali has been attained. The limiting conc. for alkali hydroxides was found by C. H. Cribb and F. W. F. Arnaud to be respectively 0·10 to 0·20, 0·185 to 0·278, and 0·056 to 0·14 grm. per litre; for sodium and calcium hydroxides, E. Heyn and O. Bauer obtained respectively 10 to 10·0, and 0·18 to 0·89 grm. per litre; and J. A. N. Friend, 1·1 to 2·8 grm. per litre for potassium hydroxide. It must be remembered that in air, the alkali is slowly converted into carbonate, so that permanent protection is attained only when the conc. of the alkali corresponds with the limiting conc. of the carbonate. Using more conc. soln., E. Heyn and O. Bauer found for plates of iron 3×4·5 cm. in area, with the conc. of soln. expressed in grams per litre, and the corrosion as loss of weight in grams:

KOH . .	0·0	2·8	28	168	sat.
Loss . .	0·0685	0·0000	0·0001	0·003	0·0002
NaOH . .	0·0	10	100	sat.	—
Loss . .	0·0653	0·0002	0·0005	0·0002	--
$Ca(OH)_2$ . .	0·0	0·67	sat.	--	--
Loss . .	0·0646	0·0000	0·0000	—	—

U. R. Evans found that soln. of magnesium sulphate at very low concentrations, say 0·001 or 0·01M-$MgSO_4$, produced phenomena not unlike that seen in distilled water, the rust being loose and the upper boundary of the rust-covered area being sinuous. As the conc. of the soln. of magnesium sulphate was gradually increased, the upper boundary of the rust-covered area became straighter and the rust became more clinging; at conc. between 0·15M- and 0·50M-$MgSO_4$, the rust blanket was so adherent that it was not loosened when a jet from a wash-bottle was directed on to the specimen. Conc. soln. of magnesium chloride, calcium sulphate, and calcium hydrocarbonate behaved in the same way; the deposit of iron hydroxide came to within about a mm. of the water-level, the top of this area being often straight and parallel to the water-line. In the intervening space between the deposit of iron hydroxide and the water-line the metallic surface, although free from corrosion, was covered with an adherent white deposit. The rust settling in the vessel was unusually pale, containing calcium or magnesium compounds in addition to iron hydroxide. The explanation of these phenomena is to be found in the limited solubility of magnesium and calcium hydroxides. Electrochemical action commences as soon as the plate is introduced, but the areas which commence to function as cathodes quickly become covered with a deposit of calcium or magnesium hydroxide (or calcium carbonate, in the case of calcium hydrocarbonate soln.). This deposit shields the areas in question from oxygen, stopping the cathodic reaction at the parts shielded, and transferring it to some point still free from deposit; the portions shielded by deposit naturally become anodic. In the course of a few hours the whole of the immersed area has become covered with deposit, and only the narrow strip within the meniscus, which necessarily remains comparatively accessible to oxygen, behaves as cathode, whilst the rest of the immersed area constitutes the anode. Over this large area the soluble iron salts produced by the anodic reaction act on the previously deposited hydroxides of calcium or magnesium, converting them in part into hydroxides of iron, so that the deposit, whitish at first, becomes green and then brown. The rust thus contains variable proportions of magnesium or calcium compounds. Consequently, the action of waters containing calcium or magnesium compounds is slower than that of distilled water, because the access of oxygen to the small cathodic part of the metal is hindered by the white deposit. U. R. Evans also found that zinc sulphate soln. behave like those of magnesium sulphate. J. A. N. Friend and co-workers found that at low temp. magnesium sulphate and chloride retard corrosion at many concentrations; but in some cases there was a marked acceleration. Since these experiments were made on specimens submerged in the soln. where the rate of corrosion is restricted by the conveyance of dissolved oxygen, U. R. Evans repeated the experiments with plates partly immersed in the liquids, and found that for conc. ranging from 0·001M-$MgSO_4$ to 0·5M-$MgSO_4$, the effect of magnesium chloride is always to reduce corrosion below the limit for distilled water:

$MgSO_4$ . .	0M-	0·001M-	0·01M-	0·1M-	0·25M-	0·5M-
Loss . .	0·053	0·034	0·034	0·037	0·033	0·027

The action of solutions of a mixture of salts.—A. Payen[26] observed that with a soln. of equal vols. of sat. soln. of sodium chloride and carbonate and 75 vols. of aerated water, the corrosion of cast iron began in a minute, and with water containing 0·2 per cent. of sodium hydroxide and 0·6 per cent. of sodium chloride, oxidation is confined to small areas around the points at which rusting originates, and it spreads from these patches in vermicular forms. According to J. A. N. Friend and C. W. Marshall, the minimum conc., *C*, of sodium carbonate required to inhibit the corrosion of iron by 0·05N-soln. of various sodium salts runs parallel with the order of the relative strengths, *S*, of the corresponding acids determined by electric conductivity methods; thus:

	Chloride	Iodide	Bromide	Nitrate	Sulphate	Fluoride	Acetate	(Sulphite)
C . .	100	88·9	72·2	53·7	51·85	38·9	8·9	(1·9)
S . .	100	98	98	98	70	10·5	2	(58)

E. Heyn and O. Bauer observed the same critical conc. with mixtures of sodium chloride and carbonate as were obtained with soln. of sodium carbonate alone, although the corrosive action was slightly greater; no limiting conc. was reached. J. A. N. Friend studied the effect with mixtures of potassium chloride and hydroxide, at room temp., and found the following losses of weight in grams, for plates 5×4 cm. in area, with the concentrations of potassium chloride and hydroxide expressed in grams per litre:

KOH	. .	0	2·8	11·2	28	56	168
KCl	0 .	0·0685*	0·0000	0·0000	0·0001	0·0000	0·0001
	5 .	0·0884*	0·0802*	0·0010	0·0008	0·0004	0·0000
	15 .	0·0836*	0·0929*	0·0074*	0·0002	0·0004	0·0000
	50 .	0·0828*	0·0985*	0·0354*	0·0112*	0·0000	0·0001
	150 .	0·0790*	0·0657*	0·0334*	0·0059*	0·0004	0·0003
	300 .	0·0390*	0·0196*	0·0104*	0·0010	0·0004	0·0002

The numbers marked with an asterisk showed that the metal was corroded; the others may be taken to indicate no marked reaction. With no hydroxide present, the attack was uniform, but when the hydroxide was present pitting occurred. In all cases corrosion decreased as the amount of potassium hydroxide increased, becoming zero in the presence of 56 grms. per litre. The results are plotted diagrammatically in Fig. 383. The curve *AB* represents the solubility of potassium chloride in soln. of potassium hydroxide; and *OC*, the minimum conc. of potassium hydroxide required completely to inhibit the corrosion of iron in the presence of the corresponding amounts of potassium chloride. The area *OCA* represents mixtures which attack the iron in spite of the alkalinity of the soln.; and the area *ODBC*, mixtures which prevent the rusting of the iron, The preservation of steel embedded in concrete depends on the complete exclusion of air and moisture, and on the inhibitive nature of the surrounding medium. J. A. N. Friend applied the above results to the preservation of iron in compact **concrete** or **cement,** and showed the need for arranging that the concrete must be so compounded that it is always alkaline enough to inhibit corrosion. This subject was discussed by H. Barker and W. L. Upton, H. Bauerman, L. F. Bellinger, O. Berndt and co-workers, W. J. E. Binnie, B. Blount, P. Breuille, H. P. Brown, H. Buel, C. F. Burgess, W. S. Calcott and co-workers, H. J. M. Creighton, E. A. Cross, E. Donath, H. E. Dünkelberg, W. Dunn, A. P. Ford, W. H. Fox, J. A. N. Friend and co-workers, L. Gadd and C. P. Taylor, R. H. Gaines, H. A. Gardner, F. L. Garrison, M. Gary, M. Girousse, R. Grun, K. A. Goslich, A. Guttmann, M. L. Hamlin and F. M. Turner, A. L. A. Himmelwright, F. W. Hinrichsen, A. A. Knudson, A. S. Langsdorf, M. Lidy, S. Lindeck, K. Lubowsky, H. Luftschitz, F. P. McKibben, C. E. Magnussen and G. H. Smith, A. del Mar and D. C. Woodbury, E. R. Matthews, P. Mecke, W. Michaelis, E. Mörsch, S. Newberry, U. J. Nicholas, E. Noaillon, C. L. Norton, W. Obst, O. T. Olgiati and H. Roberts, J. F. O'Rourke, W. Petry, M. R. Pugh, M. Quedefeld, K. Reinbold, O. Rode, W. Roeder, P. Rohland, E. B. Rose and co-workers, J. W. Schaub, G. F. Shaffer, F. N. Speller, F. W. Taylor and S. E. Thompson, B. H. Thwaite, M. Toch, O. G. Trigg, H. C. Turner, M. C. Tutton, Y. Uchida and M. Hamada, L. Wagoner and F. H. Skinner, W. R. Webster, J. P. Whiskemann, W. G. Whitmann and R. P. Russell, H. F. Whittaker, and B. Zschokke.

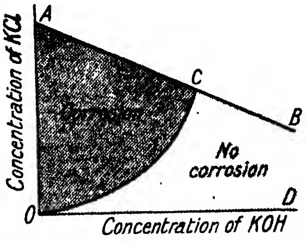

Fig. 383.—The Corrosive Action of Solutions of Potassium Chloride and Hydroxide.

U. R. Evans made analogous observations with respect to the corrosion of mixed soln. of alkali chlorides, nitrates, or sulphates and alkali hydroxide. In the case of a vertical plate immersed in a soln. of alkali chloride, a small addition of alkali will cause the corrosion to be more localized; and there occurs a little corrosion in some pores so constricted that oxygen is excluded and the conditions for anodic attack are set up, while narrow streams of rusting spread downwards from the active pores. The more open pores do not provide the conditions necessary for anodic attack. If more alkali hydroxide is added, the area covered by the corrosion product is reduced, and corrosion will be localized on the sites of a few pores which will be covered by blisters of the membranous hydrated oxide; and, with still higher proportions of the alkali hydroxide, corrosion may be entirely suppressed. At the water-level, with a soln. of alkali chloride alone, the zone just below the water-level is free from attack, but with a mixture of the chloride and hydroxide, intense corrosion may occur at the water-level. The phenomenon—**water-line corrosion**—is thus described by U. R. Evans: At this water-level a dark speck appears on the steel plate. This expands into a dark, triangular flap, floating on the liquid, and attached to the steel; this extends along the water-level, forming a kind of box. The upper side of the box is composed of a tough, dark brownish-red, membranous skin on the water-level, and below, Fig. 384, there is a looser, woolly deposit of hydroxide which is green in the early stages. The iron is not corroded immediately outside the box, but inside, intense corrosion occurs in a short space of time and finally perforation occurs. This corrosion may occur with sulphate, nitrate, or chromate in place of the chloride; and with the liquid agitated or still, hot or

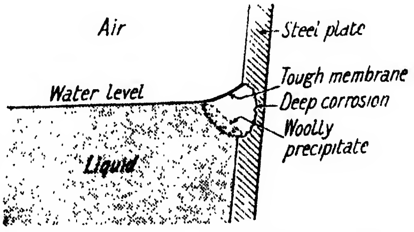

Fig. 384.—Corrosion at Water-level.

cold. The phenomenon is due to the tendency of the protective film to break away at the water-level, and as it springs away from the metal face, and clings to the interface of liquid and air, the conditions for anodic attack are set up, which once started, proceed apace—*vide supra.* The subject was investigated by A. L. McAulay and F. P. Bowden. The water-line or liquid-line corrosion of metals was discussed by G. D. Bengough and co-workers, J. I. Crabtree and G. E. Mathews, U. R. Evans, E. S. Hedges, W. P. Jorissen, E. L. Rhead, W. H. J. Vernon, and K. M. Watson and O. P. Watts; and the submerged corrosion by W. G. Whitman and co-workers.

The passivity induced in iron by contact with soln. of potassium dichromate, etc., has been discussed elsewhere. It is usually attributed to the formation of a thin protective skin of oxide on the surface of the metal. Iron may be kept an indefinitely long time in contact with soln. of potassium dichromate, if not too dilute, without any rusting; and A. S. Cushman suggested that the addition of about 0·36 grm. of the salt per litre should be a suitable protection against boiler corrosion because samples of iron and steel in boiling soln. of this concentration remain free from rust for an indefinitely long time even when air is continually bubbled through the soln. J. A. N. Friend and co-workers discussed the effect of the presence of other salts. For instance, if sodium chloride be present, there will be a state of equilibrium: $2NaCl+H_2O+K_2Cr_2O_7\rightleftharpoons K_2CrO_4+2HCl+Na_2CrO_4$, established, and the free acid will remove the protective film of oxide. Similarly with other foreign salts. If the conc. of the dichromate does not exceed 0·01 grm. per litre, its protective action is slight; and the best results were obtained with 0·1 grm. per litre, except when the conc. of the chlorides is less than about 5 grms. per litre, in which case more dichromate, say 1 grm. per litre, is needed. If potassium chromate be used in place of the dichromate, no free acid is liberated: $2NaCl+K_2CrO_4\rightleftharpoons Na_2CrO_4+2KCl$. J. A. N. Friend and J. H. Brown obtained much better results with this agent, and the presence of a gram of chromate per litre has a marked retarding influence on corrosion. The action of soln. of chromic acid, and potassium dichromate and chlorate was studied by F. Hanaman, M. Mugdan, H. Endo, C. G. Fink and C. M. Decroly, G. W. Heise and A. Clemente, O. P. Watts, A. W. Chapman, F. Numachi, T. G. Thompson, B. E. Roetheli and G. L. Cox, C. V. Thompson, etc. O. Dony-Hérault showed that the corrosion of steel in water can be stopped completely when chromate or chlorate ions are present. F. N. Speller found that ferrous sulphate inhibits the corrosion of iron; and R. E. Hall and W. W. Teague, that ferric salts act as accelerators.

The electrical behaviour of corroding iron was studied by U. R. Evans, and A. L. McAulay and S. H. Bastow. U. R. Evans found that with a mixed soln. of potassium chloride and chromate, the chromate at the cathode plays the same rôle as oxygen. The corrosion at the water-level, Fig. 384, occurs so that inside the box, the metal suffers anodic corrosion, and just outside the box the chromate is reduced, and the yellow soln. disappears. In the cell $Fe|0{\cdot}05M\text{-}KCl|0{\cdot}05M\text{-}KCl, 0{\cdot}025M\text{-}K_2CrO_4|Fe$, the iron electrode not in contact with the chromate is the anode and suffers corrosion, while the other electrode, immersed in the chromate soln., is the cathode and suffers no corrosion. Thus potassium chromate inhibits corrosion at the parts where it can reach, and stimulates corrosion in the parts it cannot reach. A rusting sheet of iron immersed in the soln. of alkali chloride and chromate quickly sprouted fresh rust on the old formations. It was assumed that the chloride diffused through the old rust more quickly than the chromate, and set up the galvanic couple. Hence, concluded U. R. Evans, if chromates are to be used as inhibitors of corrosion, then distribution must be uniform. The action of soln. of borates was studied by F. Hanaman, M. Mugdan, etc. J. A. N. Friend and C. W. Marshall found that borax, on account of its low solubility, is not so convenient an inhibitor of corrosion as sodium carbonate; the conc. of borax required to prevent corrosion by 10 c.c. of a $0{\cdot}01N$-soln. of various sodium salts containing C c.c. of a molar soln. of borax in 10 c.c. of the mixed soln. are as follows. The relative amounts of borax required run parallel with the relative strengths, S, of the acids determined by electrical conductivity methods; thus:

	Chloride	Bromide	Sulphate	Iodide	Nitrate	Fluoride	Acetate	Sulphate	Carbonate
C .	0·36	0·315	0·31	0·33	0·195	0·100	0·070	0·050	0·045
S .	100	97·5	82·5	98	98	17	4	83	?

The action of colloids on rusting.—J. Aston observed that the anodic effect with iron may be obtained by various colloidal hydroxides as well as by gelatin. J. A. N. Friend showed that salts which tend to flocculate the incoherent corrosion product are likely to form a protective coat of a colloid and thus retard corrosion. He suggested that the comparative long life of metal vessels employed in cooking may be ascribed to the colloids in the food. J. A. N. Friend and R. H. Vallance found that the relative corrosion (water 100) produced by soln. with 0·2 per cent. of sucrose is 112·4; and with 0·2 per cent. of the following colloids: gum acacia, 56·9; dextrin, 54·7; potato starch, 54·5; gelatin, 40·9; gum tragacanth, 22·6; egg-albumin, 6·8; and agar-agar, 2·7—*vide supra* for the colloidal theory of corrosion. W. Beck and F. von Hessert discussed the retarding action of agar-agar, starch, silicic acid, and gelatin.

The corrosion and tarnishing of iron exposed to air.—As indicated above, P. A. von Bonsdorff[27] showed that iron remains unaltered in damp air provided no liquid water is deposited on the metal. J. Zumstein mentioned that a polished iron cross fixed on the summit of Monte Rosa in 1820, was found a year later to be entirely free from rust and only a slight bronze-coloured tarnish could be perceived. This can be attributed in part to the low temp., and in part to the purity of the atmosphere at high altitudes. Another famous instance is the iron column at Delhi, described by A. Cunningham, and V. A. Smith, believed to have been erected about A.D. 300. This column is practically free from rust, though it is covered by a bronze-coloured tarnish. R. A. Hadfield attributed the immunity from corrosion at least as much to the purity of the atmosphere as to the composition of the metal. A small portion rusted in a single night when wetted and exposed in England, although a freshly fractured surface suffered no change when exposed four nights to laboratory air. There is also, at the British Museum, an ancient Egyptian hatchet, dating 700 B.C., which is free from rust. W. Rosenhain attributed the apparent immunity of some ancient iron to the corrosion having previously extended down to layers of cinder in the metal, and there stopped; *e.g.* the ancient iron chains which assisted the pilgrims of old to climb Adam's peak, Ceylon, have been worn smooth and round, without perceptible corrosion, but the outer surface is simply a cinder surface which protects the iron below. In London air, a portion of the chain rusted as quickly as any other form of iron. The mechanical protective influence of cinder was discussed by H. M. Howe. J. A. N. Friend and W. E. Thorneycroft found that some specimens of old Roman iron from Richborough and Folkestone were distinctly less corrodible than modern metal. J. Wallace also noticed that iron made in India in the native way does not rust so readily as iron made in Europe.

In dealing with the action of atmospheric air on iron, the surface tarnish appears as a thin adherent film which causes discoloration, and interferes with the bright lustre. It will add to the weight of the metal. The film of oxide producing the tarnish may protect the metal below from further attack, or the tarnish may thicken and flake off to expose a fresh surface of metal to attack. J. A. N. Friend, and W. H. J. Vernon apply the term ***surrosion*** to cases where the metal increases in weight. In corrosion, the metal is eaten away to form a non-adherent product, and when this is removed, the specimen has suffered a loss in weight. G. D. Bengough and U. R. Evans discussed the relation of corrosion to ***erosion***. J. A. N. Friend found that the action of air on iron is indefinitely slow at 100°, for a bright piece of iron-foil showed no perceptible change when kept at this temp. for 5 hrs.; even at 150°, no surface tarnish could be detected by mere inspection, but at higher temp., the surface was tarnished. J. Milbauer observed no change in a piece of polished iron after heating in dry oxygen up to 500°, and 12 atm. press.

The tint of the tarnish produced at higher temp. depends mainly on the time of exposure and temp. With the conditions approximately constant, the tints of the films obtained at different temp. furnish the so-called *tempering colours* used by the old workmen in tempering or annealing steel. Thus, in the case of a steel examined by H. M. Howe, a pale yellow tint was produced at 220°; a straw-yellow at 230°; a golden yellow at 242°; a brown at 255°; a brown and purple at 265°; a purple at 277°; a bright blue at 288°; a full blue at 293°; a dark blue at 316°; and a grey at 350°. The thickness of the films is comparable with the wave-length of light, and they furnish a series of interference tints with the dominant colour altering as the film thickens. The light is reflected from the surface of the metal and also the surface of the film, and as the one train of light-waves merges into the other, the phases may be the same or opposite to one another, and, as shown by L. Nobli, effects analogous to Newton's ring colours may be produced. This subject has been discussed by D. H. Bangham and J. Stafford, F. H. Constable, C. F. Ramann, U. R. Evans, R. C. Gale, G. Jung, K. Inamura, A. Mallock, C. W. Mason, F. Robin, L. Guillet and A. M. Portevin, J. E. Stead, V. Kohlschütter and E. Krähenbühl, C. N. Hinshelwood, M. Kuroda, G. W. Vinal and G. N. Schramm, M. Schmierer, F. A. Fahrenwald, and by G. Tammann and co-workers—*vide supra,* the passivation of iron in air. C. V. Raman studied the reflection of light for various angles of incidence on the oxidized film and concluded that temper colours are produced by the diffraction of light by a granular film of oxide. B. N. Chuckerbutti supported this conclusion. G. Tammann and co-workers, and U. R. Evans support the interference theory of the colours. The colours appear in the correct order during the formation of the film, and by reducing the thickness of the film, the earlier colours are reproduced in the appropriate order. G. Tammann and G. Siebel investigated the rates of change with time of the temper colours of primary cementite, pearlite, pearlitic cementite, and troostite, and found that if the thickness of the equivalent air film, $y\mu\mu$, be plotted against time, t, then, $t=a(e^{by}-1)$, where a is a constant, and b is a coefficient which decreases with increasing temp., T, so that $\log_e b_T = \log_e b_{T_0} - c(T-T_0)$, where c is constant. There are discontinuities with nickel and vanadium steels which are connected with the change of α- to γ-iron. The subject was discussed by J. S. Dunn. T. Turner showed that any colour can be produced by heating the metal long enough at a lower temp. than that corresponding with the particular tint. Thus, the straw-yellow can be obtained at 170° instead of at 220°; and the purple can be obtained at 170° in 12 hrs., at 220° in 1 hr. The subject was also examined by L. Guillet and A. M. Portevin, and C. Barus and V. Strouhal. According to L. Löwenherz, the results vary with the composition of the steel. W. C. Roberts-Austen showed that if steels be heated in vacuo, these colours are not produced, showing that the colours are due to the formation of a film of oxide. S. Stein arrived at a similar conclusion. J. A. N. Friend found that the colours appear even if the air be dried by storage over phosphorus pentoxide for a few months, and concluded that the formation of the colours is a process of direct oxidation of the metal.

G. Tammann and W. Köster, and N. B. Pilling and R. E. Bedworth studied the rate of oxidation of hot metals, and N. B. Pilling and R. E. Bedworth showed that if the vol. occupied by a given amount of the compact oxide is less than the vol. of the metal required to produce that oxide, the film of oxide will be porous and will not protect the metal from further attack. Hence, if M be the mol. wt. of the oxide; m, that of the metal; D, the sp. gr. of the oxide; and d, that of the metal, if Md/mD be less than unity, a porous oxide will be formed, and if greater than unity, a protective oxide will be produced if no cracking occurs. The ratio is less than unity in the case of Li, Na, K, Mg, Ca, Sr, and Ba; and greater than unity in the case of Cu, Zn, Cd, Al, Zr, Th, Sn, Pb, Cr, W, Mn, Fe, Co, and Ni. With iron, the ratio is 2·06. The oxide formed when iron is heated in air is normally slaty-black and consists of two phases, forming a thick outer and a thinner under layer respectively, with an aggregate composition intermediate between FeO and Fe_3O_4. It is prone to form as a hollow, swollen tube around the wire, the surface frequently contorted into grotesque shapes, very often with crests and protuberances of reddish Fe_2O_3, depending somewhat on the temp. of oxidation. When cold, the shape of these suggests that either during oxidation or cooling a liberation of gas occurred, puffing the oxide shell out, and sometimes bursting, leaving small, crater-like mouths. In almost every case the oxide, when cold, was loose and of considerably larger internal dimensions than that of the wire it jacketed; the metal surface was always blue, indicating probably the fracture of the enveloping oxide layer, during cooling, but while still quite hot. This behaviour is apparently closely related to the oxygen conc. of the atm., for Armco iron generally yielded more perfect (*i.e.* smoother surfaced) symmetrical oxides in air than in oxygen, while an extremely perfect coating was formed during an oxidation at a much reduced press., about 10 mm., followed by cooling in vacuo. The rate of oxidation, $dW/dt=k'/H$, where W denotes the weight of oxygen; H, the thickness of the oxide; and t, the time. Since all the oxygen which diffuses through the oxide layer goes to increase its thickness, W is proportional to H, and $dw/dt=k''/W$, so that $W^2=kt$. With electrolytic iron in oxygen, W^2 per sq. cm. per hour is $0{\cdot}17\times10^{-4}$ at 700°, $1{\cdot}00\times10^{-4}$ at 800°, and $6{\cdot}5\times10^{-4}$ at 900°; with Armco iron in oxygen, W^2 is $1{\cdot}95\times10^{-4}$ at 800°, $10{\cdot}1\times10^{-4}$ at 900°, and $43{\cdot}0\times10^{-4}$ at 1000°; and with Armco iron in air, W^2 is $1{\cdot}06\times10^{-4}$ at 800°, $4{\cdot}9\times10^{-4}$ at 900°, and $20{\cdot}5\times10^{-4}$ at 1000°. The nature of the oxidation product is discussed below. The quadratic rule that the quantity of oxygen which combines with the metal is proportional to the square root of the time of exposure is followed by iron in the earlier stages of the oxidation. As soon as the thickness of the oxide increased much, the surface became rough, fissures and local super-oxidized areas developed, and erratic departures from proportionality resulted. Armco iron oxidized at a consistently faster rate, and formed coatings which were, in general, smooth. The oxidation of the Armco then followed the quadratic rule more closely. The oxidation constant, k, for iron at a temp. $T°$ K., is approximately $k=0{\cdot}000028T^{-19{\cdot}3}$, and at 800°, $k=0{\cdot}000100$, and at 900°, 0·00065 grm.^{2} per sq. cm. per hour. G. Tammann and K. Bochoff compared the thickness of films of oxide on iron with the thickness calculated from interference phenomena. The subject was also studied by T. Nishina, F. H. Constable, J. S. Dunn, and Y. Utida and M. Saito. The last-named found for a 2 hours' heating at 1110°, 1000°, 890°, and 770°, that iron wire gained respectively 46·55, 36·03, 14·05, and 5·38 mgrms. of oxygen per sq. cm. According to J. Jahn, with air at:

	Moist air		Dry air	
	199°	200°	198°	297°
Iron . . .	751·1	753·3	747·5	753·9 mgrms.
Gain in weight .	0·0	0·1	0·0	0·3 mgrm.

W. H. J. Vernon found that with copper, the rate of oxidation (tarnish) curve in a humid atmosphere is parabolic; with zinc, linear; and with iron, the attack increases in speed as time goes on—Fig. 385. V. I. Arkharoff studied the X-radiograms of the process of oxidation at high temp.; and A. N. Kossogovsky, the effect of the structure on the scale formation. The heat-tinting of iron-carbon alloys was discussed by L. Guillet and A. M. Portevin, J. Czochralsky, F. Robin, P. Goerens, G. Tammann and G. Siebel, P. Oberhoffer, F. Reiser, T. Turner, L. Löwenherz, and H. Haedicke—*vide supra.*

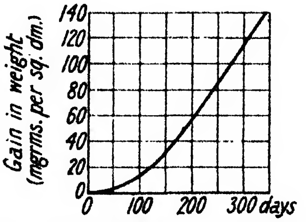

Fig. 385.—The Rate of the Tarnishing of Iron in a Humid Atmosphere.

The composition of the films is discussed in connection with ferrosic oxide. According to J. E. Stead, when iron is heated in air, or oxidizing gases, the surface layers appear to absorb oxygen which passes into solid soln.; and when supersaturated, the oxide falls out of soln. forming separate granules of free oxide; these granules become larger as oxidation proceeds, and eventually join together to form continuous layers. Although there is a fairly sharp line of demarcation between the oxide film and the metal below, the underlying metal is also affected, for the oxidizing gases find the most facile passage into the metal in the boundaries between the crystals, and the gradual changes from solid soln. to free oxide can be traced along the oxidized junctions of the crystals. Fig. 386 shows a longitudinal section through an oxidized steel plate, with a scale of oxide at the top, and steel below. The sample was etched with a cupric reagent, and the white lines indicate the intergranular oxides; and similar remarks apply to the transverse section, Fig. 387, which shows the granular oxides between the crystals. Hence, intergranular brittleness may be developed in the iron. It is also believed that sulphur dioxide, nitrogen, and hydrogen can enter iron and steel along an intergranular path. According to E. H. Hemingway and G. R. Ensminger, after heating 1·01 per cent. carbon steel for 6 hrs. at 1000°, there appeared on the surface delicate pearlitic grains representing a structure stable below the critical point. Independent of this structure was a second system consisting of deeply marked polygonal crystals representing γ-iron boundaries, and also a third system independent of either, which was thought to represent the boundaries of former γ-crystals which had been absorbed by crystalline growth. This outside layer of carbon-free iron was very thin, although with steels of lower carbon-content a layer of greater depth was obtained. This outside layer consisted of ferrite volatilized at the high temp. and redeposited below the temp. at which solid soln. exists. Any iron oxide existing on or in the steel would tend to cause decarburization by breaking down the cementite. G. Tammann and H. Bredemeier considered that the capillary cavities or channels, found in sound metals, probably following the lines where three crystal grains meet, are responsible for the access of oxygen to the interior. The porosity of the metal has been previously discussed. F. H. Constable, J. H. S. Dickenson, G. C. McCormick, W. H. Hatfield, F. Körber, F. Körber and A. Pomp, H. Scott, C. J. Smithells and co-workers, W. Schröder, H. Haedicke, and F. S. Tritton and D. Hanson discussed the formation of films of oxide on iron; E. C. Rollason, intergranular corrosion; and J. Cournot and L. Halm, the effect of polish on the rate of oxidation.

FIG. 386.—Longitudinal Section showing the Intergranular Penetration of Oxygen in Steel (×50).

FIG. 387.—Transverse Section showing the Intergranular Penetration of Oxygen in Steel (×50).

U. R. Evans pointed out that in most cases where iron rusts while it is in contact with a liquid, the rust accumulates outside the pits; but in atmospheric corrosion, where the main surface is dry, water may remain in the pores or pits produced by previous corrosion, and rust will be formed within the pore—*cf.* Fig. 388. The rust occupies a much larger volume than the metal producing it, so that (i) the pore or pit may become plugged with rust and corrosion will cease—Fig. 388; (ii) the liquid will be gradually forced out of the pore or pit by the press. developed;

or (iii) the press. will cause the metal to disintegrate, and corrosion will penetrate further. With pores perpendicular to the surface, the disintegration of the metal is less likely to occur than where the pits run parallel to the surface as in rolled metal, Fig. 389, where the corrosion produces flaking. A. G. E. Matheson discussed the structure of the rolled metal. J. Newman discussed the tendency for rapid corrosion to occur in the "sheltered crevices and nooks" on structural steelwork; and E. F. Law, a failure due to the imperfect welding of a tie-rod which led to the collapse of the roof of a London station. Faulty riveting may produce local corrosion. In all these cases, as U. R. Evans showed, the crannies and nooks may become filled with water, and anodic corrosion by differential aeration currents may be induced.

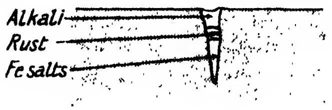

FIG. 388.—Atmospheric Corrosion-plugging.

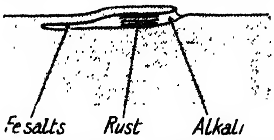

FIG. 389.—Atmospheric Corrosion-flaking.

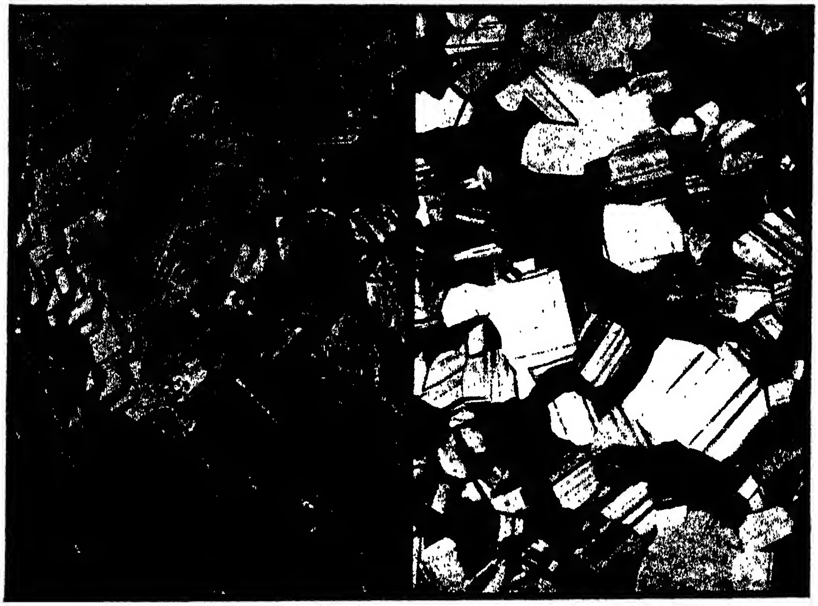
L. B. Pfeil observed that when iron or carbon steel or alloy steel is oxidized at a red-heat, in air, it does not form a homogeneous deposit, but rather a series of three layers: (i) an outside layer consisting mainly of ferric oxide or a mixture of 68·7 per cent. of ferrosic oxide and 31·3 per cent. of ferric oxide; (ii) a middle layer in a lower state of oxidation containing ferrous and ferric oxides in the proportion approximately 3 : 1; and (iii) an innermost layer, in contact with the unoxidized metal, is still richer in ferrous oxide. The layers, of course, are not uniform in composition; it is probable that they vary in composition through their cross-section, becoming richer in iron on passing inwards. Roughly, the outside layer occupies about 10 per cent. of the total scale thickness; the middle layer, about 50 per cent.; and the innermost layer, about 40 per cent. when the iron has been heated from 3 to 7 days in air at 1000°. When the oxidation is severe, each layer can be separated more or less completely from the other layers, though it is rarely possible to separate the whole of each layer from the other layers and from the core. There may be disturbances: for instance, blistering affects the layer formation, and considerable fluctuations of temp., and the presence of certain impurities may spoil the three-layer deposit. The scale is normally smooth, compact, and free from cracks and fissures in spite of the fact that the oxidation involves an expansion of the order of 100 per cent. Foreign substances on the surface of the iron are not forced away by the formation of the scale, but they remain unmoved and become completely enveloped by the scale. When the oxidation is slow, large crystals of the scale may be formed exhibiting plain crystal faces, so that sometimes the scale surface shows in high relief. H. C. H. Carpenter and C. F. Elam described the formation of crystalline deposits on iron heated in vacuo. They ascribed the scale formation to the occluded, oxidizing gases driven from the iron on heating, and they added that the oxide of iron originally produced is isomorphous with α-iron, and the orientation of the oxide produced on any given crystal of iron is determined by the orientation of the α-iron itself. L. B. Pfeil added that the scale formation can be produced on electrolytic iron, high- and low-carbon steels, alloy steels, and cast iron, provided the partial press. of the oxygen is suited to the other experimental conditions. It is almost immaterial whether the oxygen be supplied as gaseous oxygen at a low pressure, as an oxygen and inert gas mixture, as a reactive gas like CO_2, or as a compound, such as iron oxide, which gives off oxygen owing to dissociation. Variations in the appearance of the scale are mainly dependent on the form of the crystal faces. There is good reason to suppose that a solid soln. series belonging to the cubic system exists at high temp. over the composition range of crystalline scales. Many different forms belong to the cubic system, the commonest developed in magnetite being the cube, the octahedron, and the rhombododecahedron. It is often found that the forms which develop in a substance vary with the conditions (temp., press., etc.) under which the crystals grow. Fig. 390 is from a photograph of the scale crystals by L. B. Pfeil.

L. B. Pfeil showed that any explanation of the scaling of iron must explain the formation of the crystals, and also how it is possible that the outer layers of scale on alloy steels can be free from the alloying element. The two outer layers of scale form a dense, glassy deposit, and the idea that iron is progressively oxidized by the forcing of the already formed scale away from the metal core by the press. exerted by the new scale forming beneath does not explain the facts. If oxygen molecules diffused along porous paths in the glassy scale—*e.g.* through cracks—oxidation would corrode the iron irregularly, and the oxidation at the bottom of a crack or porous place would automatically seal the oxygen path and oxidation there would cease. N. B. Pilling and R. E. Bedworth imply that the iron oxide acts as a carrier for oxygen—the oxygen dissolving in the scale and diffusing through to the core owing to the oxygen gradient, and J. H. Whiteley, that ferric oxide is formed in the scale, and reacts with the iron below to form ferrous oxide. It is probable that there is a continuous series of solid soln. over the major portion of the iron–oxygen system from ferric oxide to ferrous oxide, with a gradually decreasing dissociation pressure on passing from the higher to the lower oxygen-content. Thus, where the scale is in contact with the air the soln. will be enriched in oxygen, but this enriched layer will not be in equilibrium with that beneath, so oxygen will pass inwards until it finally reaches the iron, with which it combines to form ferrous oxide. D. W. Murphy and co-workers said that the nature of the oxidation of iron or steel at elevated temp. which results in scaling, can be predicted from the equilibrium in the systems $Fe–O_2–C$, and $Fe–O_2–H_2$; and D. W. Murphy and W. E. Jominy studied the influence of atm. and temp. on the behaviour of steel in forging furnaces.



FIGS. 390 and 391.—Crystals of Iron Scale (× 10).

L. B. Pfeil rejected the hypothesis that the outside of the scale is that which is formed first at the initiation of the oxidation, and that further oxidation displaces the first-formed scale bodily outwards. He said: At the interface of iron and scale, iron is being continually dissolved in the scale, so that the iron is converted into oxide forming part of the scale deposit. There is thus an outward diffusion of the iron through the scale to the interface of scale and air. The outer part of the scale is thus the last to form, and the middle portion the first to form. No volatile compound is known whose transitory existence would play such a part, and hence it is necessary to assume a counter current diffusion—iron diffusing outwards and oxygen inwards through the scale deposit. It is not of essential importance whether the iron diffuses as iron atoms or in some other form. It is difficult to picture the diffusion of iron combined with oxygen (as ferrous oxide, for example) in a solid soln. of iron and oxygen, and consequently for the sake of simplicity the diffusion of iron atoms has been described. Reference has been made to the soln. of iron in the scale. It is immaterial whether the iron be converted into ferrous oxide first and then dissolved in the scale, or whether the iron dissolves directly in the scale. The essential feature is that scale is normally unsaturated with iron, and that metallic iron will join such scale if the two are heated in contact. In support of his hypothesis, L. B. Pfeil showed (i) that a scale of higher oxygen-content will give oxygen to a scale of lower oxygen-content; (ii) that metallic iron is oxidized by a scale rich in oxygen; and (iii) that iron can pass outwards through the scale to the surface.

Similar results were obtained by I. Kotaira in the oxidation of cupriferous steels. A. Ledebur, L. B. Pfeil, and P. Bardenheuer and K. L. Zeyen discussed the effect of carbon on the results. The subject was studied by U. R. Evans and J. Stockdale, K. Hofmann, O. Lellep, G. C. McCormick, J. H. S. Dickenson, and O. Lutherer and E. R. Weaver. Electromotive forces of relatively large intensity have been observed between the film and the metal, and the subject has been discussed by S. Bidwell, S. P. Thompson, J. Franz, J. M. Gaugain, H. C. F. Jenkin, and C. Barus and V. Strouhal. The effect may be thermoelectric, or galvanic in which the electrolyte is the solid film. The oxidation of cast iron is accompanied by a marked increase in bulk—*vide infra*, the growth of cast iron.

Heat-resisting alloys.—Alloy steels, etc., intended to resist oxidation at high temp. were discussed by numerous observers.

L. Aitchison,[38] N. Armann, R. W. Bailey, H. N. Bassett, A. Bensel, G. R. Brophy, H. C. H. Carpenter, P. Chevenard, J. D. Corfield, J. H. S. Dickenson, J. W. Donaldson, T. G. Elliot and co-workers, K. Endell, F. A. Fahrenwald, H. J. French, E. Schüz, A. Fry, J. Galibourg, C. Grard, H. Gruber, R. A. Hadfield and co-workers, H. H. Harris, W. H. Hatfield, O. Hengstenberg and F. Bornefeld, T. Hoffmann, E. Houdremont and V. Ehmcke, G. H. Howe and G. R. Brophy, C. H. M. Jenkins and co-workers, C. M. Johnson, H. Jüngbluth and H. Müller, J. F. Kayser, F. Körber and A. Pomp, L. Losana, A. McCance, R. S. MacPherran, C. E. MacQuigg, S. A. Main, J. A. Matthews, A. Michel, E. Morgan, F. K. Neath, T. H. Nelson, H. D. Newell, A. L. Norbury and E. Morgan, W. Oertel and A. Schepers, A. E. Perkins, H. D. Phillips, R. J. Piersol, E. P. Poste, W. Rohn, W. Rosenhain and C. H. M. Jenkins, R. J. Sarjant, B. J. Sayles, O. Smalley, S. W. G. Snook, L. W. Spring, L. J. Stanbery, J. Strauss, W. B. Sullivan, R. Sutton, C. Upthegrove and D. W. Murphy, and E. Valenta—*vide* chromium-iron alloys.

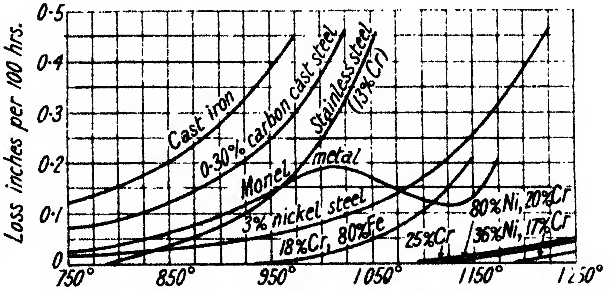


FIG. 392.—The Heat-Resistance of Metals.

F. A. Fahrenwald reported the results indicated in Fig. 392 for the resistance offered by various metals to high temp. oxidation.

The *scaling of iron* similarly refers to the formation of a surface layer of oxide when iron or steel is heated in furnaces; *iron scale* is thus distinct from *rust* in that one is formed at an elevated temp., and the other is formed at ordinary temp. by surface oxidation. The scaling of iron was investigated by H. T. Angus and J. W. Cobb,[29] W. H. Blackburn and J. W. Cobb, J. W. Cobb, J. H. S. Dickenson, J. S. Dunn, W. H. Hatfield, O. Lellep, G. C. McCormick, C. B. Marson and J. W. Cobb, R. Mitsche, J. H. G. Monypenny, R. Stumper, D. W. Murphy and co-workers, A. L. Norbury, J. E. Stead, W. Schröder, and Y. Utida and M. Saito. R. L. Kenyon compared the high temp. oxidation of Armco iron, and mild steel, expressing the results after heating the metal for different periods of time, as the rate of scaling in inches per 1000 hrs. over the entire period of the test:

Time .	1672	3826	6146	7996	10,135	12,295	13,406 hrs.
Armco .	0·0105	0·0099	0·0061	0·00472	0·00453	0·00427	0·00391
Mild Steel	0·0111	0·00693	0·00504	0·00584	0·00790	0·00753	0·00787

The *peeling of malleable cast iron* was studied by F. H. Hurren, W. H. Poole, and J. W. Gardom. According to D. H. Ingall and H. Field, temp. near 950° are most conducive to peeling. The faster the rate of heating to this temp. the greater the tendency to peeling. The peel consists of a layer or layers of ferrite containing granules of free oxide as inclusions. When this layer is once formed, growth will occur with time and suitable temp. conditions. The phenomenon of peeling is a result of oxidation, which commences between 900° and 940°. Once this oxidation has begun, the growth of the oxide layer is a result of a race between the rate of oxidation and the rate of carbon supply from the interior.

The erosion of guns by gases, etc., was discussed by F. Abel and E. Maitland,[30] P. R. Alger, A. E. Bellis, A. Bennington, E. Berl, E. Bravetta, H. C. H. Carpenter, P. Charbonnier, C. Cranz, W. Crozier, E. Demenge, F. A. Fahrenwald, H. Fay, M. Graziani, R. H. Greaves and co-workers, J. Hanny, H. M. Howe, H. G. Howorth, W. J. Huff, H. Hugoniot and H. Sébert, H. J. Jones, W. Klever, A. Lanfroy, H. H. Lester, M. Létang, D. C. McNair, A. Mallock, A. Noble, M. Okochi, F. Osmond, H. Peloux, E. Piantanida, W. C. Roberts-Austen, E. B. D. Secondo, P. Siwy, W. W. de Sveshnikoff, D. K. Tschernoff, T. G. Tulloch, L. Vasseur, P. Vieille, H. E. Wheeler, H. E. Yarnell, and A. G. Zimmermann. J. E. Stead [31] studied the action of blast-furnace gases on iron; U. R. Evans, and H. B. Dixon, the action of the products of combustion of coal gas; J. Parker, the action of town gas; and A. W. Carpenter, L. Losana, A. Dänzer-Ischer, U. R. Evans, A. de Waele, P. Siedler, H. F. Johnstone, F. L. Wolf and L. A. Meisse, O. W. Storey, W. Gumz, and W. H. Hatfield, flue gases, exhaust gases from motors, air in railway tunnels, and the products of combustion of coal. Coal with chlorides (*q.v.*) corroded when coal without chlorides did not. The presence of sulphur dioxide (*q.v.*) is a source of rapid attack.

The corrodibility of different kinds of iron and steel.—*Vide infra* for the various alloys of iron. The general effect of alloys on the corrodibility of iron and steel was discussed by P. Kötzschke and E. Piwowarsky.[32] A. Payen, and J. Newmann observed that grey cast iron corrodes more readily than white cast iron, or bar iron. R. Mallet observed the following results expressed in terms of the corrosion factor:

	Sea-water	Foul sea-water	Foul river-water	Clear river-water
Wrought iron	100·0	118·6	68·8	12·3
Cast iron	63·6	20·5	40·4	9·9
Chilled cast iron . . .	64·4	63·1	51·2	12·9
Cast iron (skin removed) .	77·6	127·8	64·4	23·5

The chilled metals are more susceptible to attack than the metal cast in green-sand, due, he supposed, to the exterior of the chilled casting not being homogeneous; he said that "the voltaic action produced at the surface of chilled cast iron, by want of its homogeneity, increased the corrosion of the metal to a greater extent than its greater density and hardness, and small amounts of uncombined carbon are capable of retarding corrosion, in comparison with other sorts of cast iron." Wrought iron corrodes faster than cast iron except in clear river-water. In clear river-water, wrought iron is nearly as resistant as cast iron, and more so than chilled cast iron. When the outer skin is removed from cast iron, it is more susceptible to corrosion, and it then approximates more closely to wrought iron. L. E. Gruner found that cast irons and spiegeleisen resisted atm. corrosion better than steels, but in sea-water, steels were more resistant. T. Andrews found that cast irons did not resist sea-water so successfully as wrought irons and low carbon steels, although there is little to choose between them and 0·5 per cent. carbon steels. J. Aston and C. F. Burgess found the corrosion factors for the metals exposed to atm. influences: open-hearth iron, 100; Swedish wrought iron, 83; open-hearth steel, 91; Bessemer steel, 65; and medium-grained grey cast iron, 78. E. Heyn and O. Bauer observed for the corrosion factors:

	Distilled water	Tap-water	One per cent. NaCl
Steel . . .	100	100	100
Wrought iron . .	103·7	104·8	103·7
Cast iron . .	97·3	93·2	98·6

Observations on this subject were made by W. Ackermann, D. Adamson, F. Andrews, K. Arndt, J. H. Baker, L. J. Chapman, F. C. Calvert, J. Collins, A. S. Cushman, H. Diegel, G. M. Enos, U. R. Evans, J. Farquharson, J. D. Ford, A. G. Fraser, J. A. N. Friend and C. W. Marshall, W. P. Gerhard, R. Girard, L. E. Gruner, J. T. Haddock, E. Heyn and O. Bauer, H. M. Howe, W. E. Hughes, B. Kosmann, O. Kröhnke, F. Kupelwieser, Langbein-Pfanhauser Werke, R. C. McWane and H. J. Carson, S. Maximowitsch, F. Menne, M. Meyer, H. Otto, W. Palmaer, D. Phillips, H. Pilkington, H. S. Rawdon, E. L. Rhead, W. D. Richardson, M. Rudeloff, M. Schromm, G. Schumann, J. Scott, F. N. Speller, D. M. Strickland, T. N. Thompson, W. Thompson, B. H. Thwaite, M. Uellenhof, W. H. Walker, G. C. and M. C. Whipple, W. G. Whitman and E. L. Chappell, J. H. Woolson, and numerous others.

There are many differences of opinion as to the relative merits of steel, wrought iron, and cast iron in resisting corrosion. H. M. Howe, for example, obtained the opinions of thirty-seven shipbuilding firms as to the relative corrodibility of wrought iron and steel; and of these, seven regarded steel as the more corrodible, eight regarded wrought iron as the more corrodible, and twenty-two were uncertain, or considered that there was no preference. T. Andrews made tests extending over years, and concluded that wrought iron is decidedly the better material. F. N. Speller preferred steel; R. A. Hadfield considered wrought iron better resists the action of sea-water. J. A. N. Friend's observations showed that the superiority of wrought iron, if it exists at all, is comparatively small. H. M. Howe and B. Stoughton came to a similar conclusion, but they found that steel was far less liable to pitting. An analogous conclusion was drawn by A. S. Cushman, J. D. Ford, G. Johnstone, W. Marriott, H. Otto, R. Irvine, W. H. Gibson, A. Schleicher, G. J. Snelus, F. N. Speller, T. N. Thompson, R. H. Gaines, H. Wölbling, W. H. Melaney, F. H. Williams, R. Finkener, etc. K. Arndt found that whilst cast iron rusts uniformly over the surface, the rusting of wrought iron and mild steel is confined to local areas. The difference is due to the adherent character of the protective oxide film on cast iron which is not readily dislodged by rust, whilst the film on wrought iron and steel readily scales off and allows the spongy rust to form. Alterations of wetness and dryness are better resisted by cast iron, and for the same reason. W. Parker found that various steels and wrought irons resisted the action of cold sea-water to the same extent, but steels suffered more than wrought irons when exposed to London air; and steels differed as much amongst themselves in their resistance to corrosion as they differed as a body from the wrought irons. M. Rudeloff also exposed plates of wrought iron, acidic steel, and basic steel to the action of dry air, the air outside exposed to rain, etc., smoke, furnace gases, ditch-water, and sea-water. The results showed as much variation amongst themselves as do steels as a class and wrought irons as a class. A. S. Cushman, and L. J. Chapman said that wrought iron corrodes less than steel. A. G. Frazer found acidic and basic steel plates resisted corrosion in air, river-water, and salt soln. equally well; but in dil. sulphuric acid, basic steel had the advantage. W. G. McMillan came to the same conclusion. Close-grained cast iron is generally superior to steel and wrought iron; and, as emphasized by G. Murdoch, and D. Spataro, provided the metal is free from blow-holes. B. H. Thwaite compiled the available data for cast and wrought iron, and the relative values for corrosion are:

	Foul sea-water	Clear sea-water	Foul river-water	Clear river-water	City and sea-air
Wrought iron	10·450	3·855	7·680	0·655	6·690
Cast iron skin intact	3·50	3·386	2·034	0·604	2·637
Cast iron skin removed	12·275	4·738	3·884	0·584	4·763

Hence, the outer skin formed in the casting acts as a preservative coating. M. Mugdan found that steel behaves like soft iron, whilst cast iron always showed a greater tendency to rusting. S. D. Carothers observed that in sea-air cast iron is less liable to rusting than plain carbon steel, but some varieties of cast iron break down rapidly. Some results by W. H. Hatfield are given in Table LIII—*vide supra* for the action of sea-water on cast iron, etc. R. Girard found that with low concentration of acid, iron and steel behave similarly, but at higher concentrations, polished iron is attacked more quickly than steel. A. Schleicher and G. Schultz found with a rusty and a clean wrought iron plate immersed in water, the latter acts as cathode, and with a clean wrought iron and a cast iron plate, the former acted as cathode.

TABLE LIII.—THE ACTION OF REAGENTS ON DIFFERENT VARIETIES OF IRON AND STEEL.

	Hydrochloric acid		Nitric acid		Sulphuric acid		
	N	Conc.	*N*	Sp. gr. 1·2	*N*	10 per cent.

Stainless steel	*Nil*	*Nil*	*Nil*	0·0232	0·0422	0·0014	0·0018

Many purified metals are more resistant to corrosion than commercial metals. This inertness may be due to the homogeneous nature of the material preventing any but very feeble corrosion currents being set up between different parts, or else a passive state being produced by the formation of a uniform, protective film. L. Losana and G. Reggiani[33] found tempering steel normally increases its resistance to corrosion. B. Lambert and co-workers found that highly purified iron is not corroded in the presence of aerated water under conditions where ordinary iron rusts rapidly. H. E. Armstrong attributed this to passivity. W. E. Hughes observed that electrolytic iron from a chloride bath quickly rusted, owing to the inclusion of traces of chlorides. When iron is deposited from a sulphate bath, it did not rust when wrapped up in filter-paper, and stored in a box. Observations on the apparent inertness of highly purified iron were made by D. J. Demorest, G. P. Fuller, N. S. Kurnakoff and A. N. Aschnasaroff showed that the eutectic with alloys slowly cooled is coarse-grained, and fine-grained if rapidly cooled. The alloys in the former case were readily attacked by some reagents, while the latter resisted attack.

L. Aitchison also found that many metals which formed a solid soln. with iron tend to reduce the attack by dil. acid, and soln. of sodium chloride, but metals which do not form such soln. render the iron more susceptible to attack.

J. A. N. Friend tested the action of aerated water on steels with between 0·05 and 0·32 per cent. **carbon.** There is not a marked difference in the rates of corrosion, and the differences do not always follow the carbon-content. In general, there is a slightly increased corrosion with an increase in the carbon-content of the steel. This agrees with the result of L. Aitchison, who found that steels having between 0·07 and 1·46 per cent. of carbon show very little difference in their resistance to corrosion in a 3 per cent. soln. of sodium chloride. There is a maximum rate of corrosion near the eutectic with about 0·9 per cent. of carbon. G. M. Enos observed that the corrosion of steel by aerated distilled water is not much affected by the carbon-content. The work of H. M. Howe, A. Sang, A. Ledebur, W. D. Richardson, G. Dillner, O. Kröhnke, G. Bardenhauer and K. L. Zeyen, K. Daeves, U. R. Evans and R. T. M. Haines, H. Otto, and W. Parker indicated that the resistance offered by steel to corrosion increases with the proportion of hardening carbon. H. Endo found the losses, expressed in grams per sq. cm., during 5 hrs.' attack, at ordinary temp., with iron containing

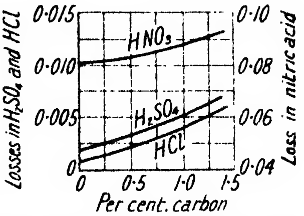

FIG. 393.—The Effect of Carbon on the Corrosion of Iron by Acids.

Carbon		0	0·31	0·52	0·64	0·96	1·16	1·32	1·41 per cent.
Loss	H_2SO_4	0·00197	0·00270	—	0·00338	0·00470	0·00534	0·00702	0·00762
	HCl	0·00092	0·00210	—	0·00328	0·00401	0·00481	0·00568	—
	HNO_3	0·07981	0·08079	0·08303	0·08590	0·08741	0·09135	0·09204	0·09074

This shows that the losses with the three acids vary almost linearly with increasing proportions of carbon. The rate of dissolution of steel is greatly influenced by the state of the carbon, as well as by the condition of the aggregation of the existing phases. P. Bardenhauer and K. L. Zeyen found that cast iron in which the graphite is coarsest is least attacked by *N*-HCl, *N*-H_2SO_4, and *N*-CH_3COOH, but no definite relations were observed with *N*-HNO_3; on the other hand, O. Kötzschke and E. Piwowarsky observed that within the usual limits of graphite, the physical characteristics of the graphite have no effect on the metal in corroding media. L. Aitchison found that the corrosion by 10 per cent. sulphuric acid is a maximum on steel with about 0·9 per cent. of carbon. E. Heyn and O. Bauer observed that the state of the carbon in steel exerts a very great influence upon the rate of dissolution of the metal, at 14°–18°, in 1 per cent. sulphuric acid. H. Endo repeated the work, and his results are summarized by the curves in Fig. 393. Here the losses in weight are in grams per sq. cm. The results with different periods of time are similar with steels with the 0·5 and 0·9 per cent. carbon. Thus, the rate of dissolution decreases up to about 150°, it then increases very rapidly in two stages

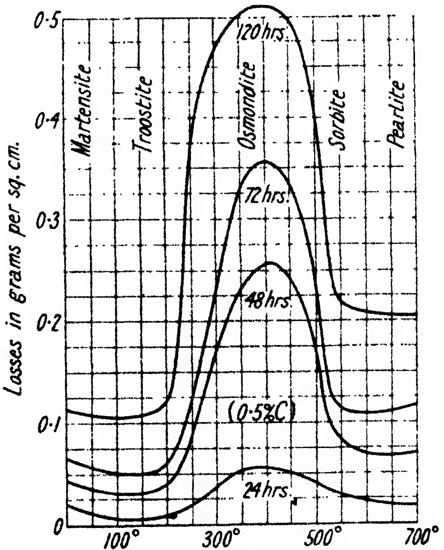

FIG. 394.—The Action of Dilute Sulphuric Acid on Steels Tempered at Different Temperatures.

between 150° and 300°, and between 300° and 400°. After passing the maximum at about 400°, the dissolution decreases rapidly until it becomes nearly constant in the range from 550° to 700°. H. Endo said:

> The decrease of the dissolution up to about 150° is due to the change of the retained austenite into martensite and also to the gradual change of the α-form of martensite to the β-form. From 170°, the carbon dissolving in the martensite begins to set free partly as carbon itself and partly as very fine particles of cementite, the separation taking place most actively at about 250°; hence the rapid increase of the dissolution. The maximum dissolution at about 400° is due to the formation of cementite from the separated carbon and the ground mass of iron, and also to the coagulation of cementite particles to form fine crystals, these changes producing the very fine structure known as osmondite. The decrease of dissolution seen in the range of 400° to 550° may be attributed to the coalescing of the cementite and to the recrystallization of ferrite crystals which result in the reduction of the degree of heterogeneity of the structure, and the further grain-growth of cementite above 550° has no effect on the corrosion.

E. Heyn and O. Bauer's observations were made with a hard steel having 0·95 per cent. of carbon; 0·35, of silicon; 0·17, of manganese; 0·012, of phosphorus; and 0·024, of sulphur. One set of their curves for steels with different proportions of carbon, and tempered at different temp., is shown in Fig. 394. They said:

> The shapes of the curves in Fig. 394 reveal some interesting features. According to the opinions hitherto prevailing, and still held by some, the transition of the martensite of hardened steel into the pearlite of annealed steel is continuous throughout the intermediate stages of tempering. This would lead one to suppose that the curve of solubility in dil. sulphuric acid, instead of showing any sharply defined peaks, would form a line indicating the gradual transition from the solubility of martensite to that of pearlite. The curve, however, runs up to a sharply defined maximum at a temp. of 400°. The simplest and most obvious explanation of this phenomenon is as follows: The transition of the martensite from the unstable phase below 700° into the stable phase of pearlite, due to tempering, does not proceed directly, but indirectly through an intermediate metastable form, to which the name of osmondite has been given. Osmondite is the most soluble of all the forms intermediate between martensite and pearlite. As the tempering temp. gradually increases, the martensite first gradually changes into osmondite, until at 400° the whole mass consists of this alone. In order to prevent confusion in nomenclature, the term troostite has been retained for the designation of the intermediate states between martensite and osmondite, and for the stages intermediate between osmondite and pearlite the term sorbite is used. If the tempering temp. is raised above 400° there again occurs a gradual transition from the readily soluble osmondite to the less easily soluble pearlite. Such transitions from a preliminary condition to a stable final condition, through one or more less stable intermediate conditions, are of not infrequent occurrence in physical and chemical processes. Another remarkable point is the low value for the solubility at a tempering temp. of 100°, which differs little from that of untempered steel. The variation lies, however, within the margin of error for the process, so that whether still another metastable form occurs is not yet proved.

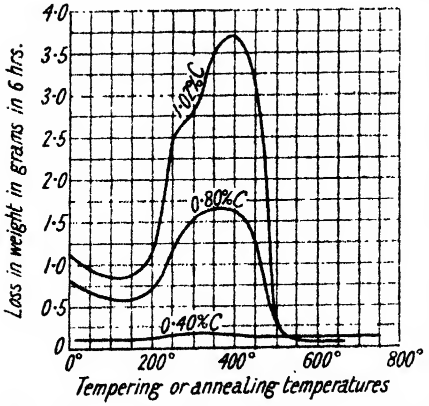

FIG. 395.—The Action of Dilute Sulphuric Acid on Steels Tempered at Different Temperatures.

T. Matsushita and K. Nagasawa's results with 1 per cent. sulphuric acid are shown in Fig. 395. E. Heyn and O. Bauer observed that a definite maximum occurred when the percentage of carbon was only 0·07; with mild steel, there was a minimum on the solubility curve for the quenching temp. 1000° to 1050°, and also two maxima respectively at 850° to 950°, and 1100° to 1250°. The solubility of tempered carbon steel in dil. sulphuric acid rapidly decreases when the tempering temp. lies between 450° and 500°; and from 550° upwards there is no appreciable change of solubility up to the Ac_1-point, indicating that the coagulation of the pearlite is almost complete at 550°. T. Matsushita and K. Nagasawa accordingly classify the temper structures of quenched steel: 100° to 300°—martensite and troostite; 300°—troostite; 300° to 400°—troostite and sorbite; 400°—sorbite (osmondite); 400° to 550°—sorbite and granular pearlite; and 550° to the Ac_1-point—granular pearlite. C. Chappell examined the influence of carbon on the corrodibility of the following steels:

	Carbon	Silicon	Manganese	Sulphur	Phosphorus	Aluminium
No. 1 . .	0·10	0·019	0·091	0·030	0·011	0·02
No. 2 . .	0·24	0·037	0·072	0·028	0·015	—
No. 3 . .	0·30	0·030	0·094	0·021	0·012	—
No. 4 . .	1·55	0·053	0·100	0·020	0·017	0·03
No. 5 . .	0·81	0·048	0·168	0·028	0·016	—
No. 6 . .	0·96	0·018	0·133	0·027	0·014	0·02

The results are indicated in Table LIV. The corrodibility of rolled, normalized, and annealed steels rises to a maximum as the proportion of carbon increases to the sat. point 0·89 per cent. carbon, and it decreases with a higher proportion of carbon. With quenched and tempered steels, there is a continuous increase in corrodibility

TABLE LIV.—THE EFFECT OF CARBON ON THE CORRODIBILITY OF STEEL BY SEA-WATER AT 12°.

Treatment	Steel No.	Carbon per cent.	Loss after 91 days' immersion, per cent.	Loss after 166 days' immersion, per cent.
Annealed at 900° for 20 hrs. and slowly cooled	1	0·10	0·366	0·752
	2	0·24	0·424	0·803

	6	0·96	0·570	0·956

as the proportion of carbon rises to 0·96 per cent., and no maximum appears. Quenching increases the corrodibility to a maximum; annealing tends to reduce it to a minimum; and normalizing gives intermediate values. In agreement with the results of the action of dil. sulphuric acid, tempering reduces the corrodibility of quenched steels, and the extent of its influence varies with the tempering temp.—*vide supra,* chemical properties, and corrosion of iron. C. Chappell and F. Hodson showed that the corrodibility of steel increases as the percentage of carbon increases; that hardened steels are less liable to corrode than annealed steels. The subject was studied by L. Aitchison, O. Bauer and O. Vogel, C. Chappell, V. Duffek, G. M. Enos, and R. A. Hadfield and J. A. N. Friend. W. Schreck observed that graphite in cast iron increases the rate of dissolution in acids; whilst P. Bardenhauer and K. L. Zeyen, and P. Kötzschke and E. Piwowarsky observed that the mode of graphitic separation and the quantity per cent. area did not affect the corrodibility of cast iron—*vide* local elements. The effect of various alloying elements on the corrodibility of iron was discussed by G. F. Burgess, A. S. Cushman, G. Delbart, V. Duffek, E. Piwowarsky, R. Girard, H. Baumeister, etc.—*vide* the alloys of iron.

M. Rudeloff inquired if rusting affected the mechanical properties of the underlying metal, and found that rusting diminishes the elongation of the metal, and this diminution is relatively the greater the greater the degree of elongation of the metal before rusting. The tensile strength is also diminished, and the degree, as also in the case of the elongation, appears to be proportional to the duration of the rusting. The degree to which the wires could be bent and twisted was most seriously affected by rusting at the commencement. After seven months' exposure to rusting this seemed to have almost entirely ceased to have any influence on these last-mentioned properties. Rusting also rendered the wires distinctly brittle, while the reduction of area had been diminished by as much as 10 per cent. in the worst portion.

The effect of mechanical treatment on the corrosion of iron and steel has been examined by T. Andrews[34] who concluded that the effect of stresses of various kinds—tension, torsion, and flexion—on the corrosion of various kinds of iron and steel is to make the unstrained metal electropositive to the strained metal, so that the unstrained metal was less liable to corrosion than the strained metal. W. H. Walker and C. Dill, and C. Chappell and F. Hodson, came to the same conclusion, but the very opposite conclusion was drawn by C. Hambuechen, T. H. Turner and J. D. Jevons, B. Garre, J. H. Whiteley and A. F. Hallimond, R. A. Hadfield, C. H. Desch, C. F. Burgess, and H. Endo—*vide supra.* G. D. Bengough and co-workers considered that the effect of internal strains is of minor importance in the corrosion of metals in distilled and industrial waters. G. P. Fuller said that the high resistance of electrolytic iron to chemical corrosion is further increased by cold-work. P. Breuil found that the corrosion of cast copper steels is less than with rolled steels, and he attributed the phenomenon to the greater fineness of the rolled steel. Observations were also made by M. F. Cloup, and A. Portevin. According to T. W. Richards and G. E. Behr, if a difference of potential does exist between the strained and unstrained portions of a rod, the effect must be extremely small. J. A. N. Friend said that strained portions of a metal may sometimes act as anode, and at other times as cathode—*vide supra.*

The distribution of corrosion in a manner dependent on the stresses is often ascribed to the change of potential produced by the stress. Thus, W. Spring, and W. H. Walker and C. Dill have shown that an e.m.f. can be produced from a cell of the type: Cold-worked metal | Salt soln. | Annealed metal, and the cold-worked metal is usually the anode or attackable pole. Similarly, an unequally annealed piece may behave in this respect as if it were composed of two different metals. U. R. Evans, indeed, showed that corrosion may follow the highly deformed parts where capillary channels are also laid open—*vide supra.* C. Barus concluded that in rupturing a piece of iron, "as much as one-half of the work done in stretching up to the limit of rupture, may be stored up permanently" in the strained iron.

This energy will be released when the metal is oxidized, and hence, other things being equal, the strained metal will be attacked more readily, the potential of the strained metal increasing with the strain. C. F. Burgess, C. Hambuechen, E. Heyn and O. Bauer, and J. A. N. Friend found this to be the case in acidic media, and the results, summarized in Fig. 396, show that the rate of corrosion in 0·1 per cent. sulphuric acid is roughly proportional to the elongation of the steels with up to 1·35 per cent. of carbon. Incidentally, the steel with the eutectic proportion of carbon was the most readily dissolved. J. A. N. Friend also exposed the same steels in neutral water– *e.g.* in tap-water, artificial sea-water, and with alternate wet and dry exposures– and observed no appreciable difference in the results with the strained and unstrained metals, although some alloy steels showed a difference. G. Tammann observed generally that, other things being equal, metals are less noble after cold-working, that is, they are more readily attacked after being hardened by strain than when in the soft state. If the reverse results are obtained, other disturbing factors may be involved– grain-size, etc.

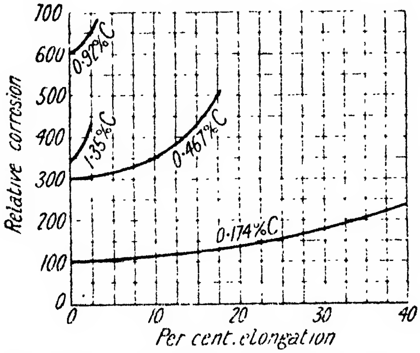

FIG. 396.—The Effect of Strain on the Corrosion of Steel by Dilute Sulphuric Acid.

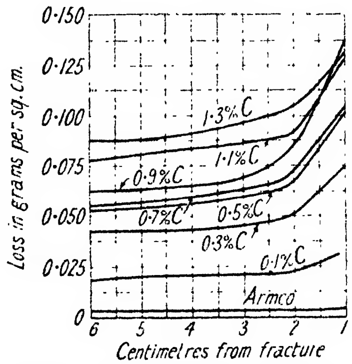

FIG. 397.—The Effect of Tensile Strains on the Corrosion of Iron.

H. Endo found the losses in weight, in grams per sq. cm., during 72 hrs.' action in 1 per cent. sulphuric acid, at 25°, of portions of broken test-bars cut in 1, 2, . . . 6 centimetre-portions from the tensile fracture. The maximum **tensile stress**— kgrms. per sq. cm.– of the carbon alloys, and of Armco iron—free from carbon—were:

Carbon .	0	0·1	0·3	0·5	0·7	0·9	1·1	1·3 per cent.
Stress .	3260	3600	5140	5560	7360	8600	7970	7660

The results showing the effect of tensile strains are plotted in Fig. 397. The amount of corrosion runs parallel with the amount of deformation so that where the stress is greatest, the greatest corrosion occurs, and this with a steel containing 0·9 per cent. of carbon steel. The effect of carbon is shown more clearly in Fig. 398, where the tension refers to the portion nearest the seat of fracture. The results with **torsional strain** are similar, the loss in weight, in 72 hrs. in 1 per cent. sulphuric acid at 25°, increases with the amount of torsion. The maximum loss also occurred with the 0·9 per cent. carbon steel. The effect of carbon is more clearly shown in Fig. 398 where the torsion was obtained by twisting the test-piece through 720°. The most severe attack by the acid occurs where the twist is greatest. In agreement with this, B. Garre observed that the rate of dissolution of iron in dil. sulphuric acid increases linearly with the number of twists to which the metal has been subjected. Twisted rods become softer after being immersed in 1 per cent. sulphuric acid. The annealing of a piece of bent iron decreases its rate of dissolution in acid, but not so much as to make it dissolve at the same rate as the unbent metal.

H. Endo also examined the effect of **compression strains,** and found that the losses, expressed in grams per sq. mm. during 72 hrs.' action of 1 per cent. sulphuric acid at 25°, here increase with the load, but the maximum effect was not obtained with the steel containing 0·9 per cent. of carbon. With **impact strain,** the effect of a number of repeated impacts small enough to cause no permanent deformation is inappreciable.

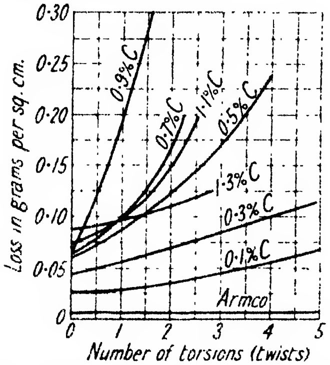

FIG. 398.—The Effect of Torsional Strains on the Corrosion of Iron.

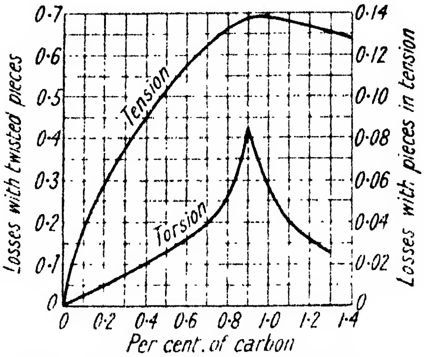

FIG. 399.—The Effect of Carbon on the Corrosion of Steel under Tensile and Torsional Strains.

J. H. Whiteley and A. F. Hallimond found that the products of the reaction of normal and cold-worked iron on nitric acid, with 33·5 grms. of HNO_3 per 100 c.c. at 100°, are very different. Thus, using 0·3 grm. of iron :

		NO	N_2O	N_2	NH_3
Hammering	Normal . . .	96·0	1·0	3·0	1·2 c.c.
	Cold-worked . .	50·0	2·0	5·0	16·7 ,,
Drilling	Normal . . .	75·0	2·0	6·0	5·5 ,,
	Cold-worked . .	55·0	4·0	4·6	13·0 ,,
Wire-drawn	Normal . . .	66·0	3·5	7·0	7·5 ,,
	Cold-worked . .	46·0	2·0	7·0	15·4 ,,

By plotting as ordinate the weight of iron consumed in forming the nitrogen and ammonia in accord with $10Fe+36HNO_3=10Fe(NO_3)_3+3N_2+18H_2O$, and $8Fe+27HNO_3=8Fe(NO_3)_3+3NH_3+9H_2O$, and as abscissæ, the conc. of the acid in grams per 100 c.c., a curve characteristic of the reaction is obtained and it can be termed the *reaction curve.* Wire deformed by twisting or drawing yields progressively advancing reaction curves. The measured differences in the composition of the gases are produced by an amount of energy which, if developed as heat, would not raise the temp. of the material by 1°. The results for twisted and drawn wires are taken to show that cold-working takes place in two stages : (i) the elastically strained crystal units are brought into an interlocked condition ; and (ii) the crystal structure is progressively broken up with the production of the

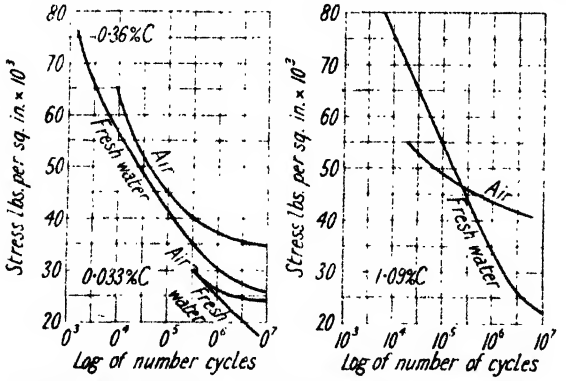

FIG. 400.—The Fatigue and Corrosion-Fatigue Tests of Iron-Carbon Alloys.

so-called amorphous material. The effect of cold-work is removed by annealing at 520°. The energy differences due to differences in grain-size produce no appreciable difference in the reaction curves with nitric acid. J. H. Whiteley and A. F. Hallimond also examined some carbon steels and found similar results. They also inferred that the ferrite component of pearlite is in a partly strained condition.

Observations on the simultaneous effects of stress and corrosion were made by H. Baucke, H. J. Gough and D. G. Sopwith, N. P. Inglis and G. F. Lake, E. Jonson, W. P. Jorissen, A. P. Hague, G. D. Lehmann, and R. R. Moore. D. J. McAdam observed that when metals are simultaneously subjected to corrosion and fatigue, failure may occur at stresses far below the endurance limit—fatigue test—and the effect was designated **corrosion fatigue.** Severe corrosion prior to fatigue, lowers the fatigue resistance much less than a slight corrosion simultaneously with fatigue. The damaging effect of corrosion is greater, the harder the steel. The following represent some of the results of the static and endurance tests obtained when the corrosion was due to a fresh, carbonate water; and with metal ranging from ingot iron with 0·033 per cent. of carbon through 0·11 to 1·09 per cent. carbon steels:

Carbon . .	0·033	0·11	0·24	0·36	0·49	1·09 per cent.
Tensile strength .	43,900	46,400	59,200	79,200	82,900	103,400 lbs. per sq. in.
Elongation . .	45·5	47·5	37·8	31·3	27·8	29·5 per cent. in 2 ins.
Reduction area .	75·0	72·0	59·0	48·7	43·7	50·8 per cent.
Endurance limit .	24,000	25,000	27,000	34,000	34,000	42,000 lbs. per sq. in.
Corrosion fatigue .	20,000	16,000	16,000	25,000	23,000	23,000 ,, ,,

The fatigue tests were conducted with 1450 revs. per minute. The abscissæ of Fig. 400 represent the logarithm of the number of revolutions, and the ordinates, the stresses. H. W. Gillet, B. P. Haigh, A. P. Hague, G. D. Lehmann, A. M. Binnie, F. N. Speller and co-workers, N. P. Inglis and G. F. Lake, and T. S. Fuller also studied corrosion fatigue; and A. M. Binnie, the effect of oxygen on the corrosion fatigue.

§ 25. The Valency and Atomic Weight of Iron.

According to H. E. Roscoe and A. Harden,[1] J. Dalton's note-books show that, in 1804, he gave 16 (oxygen 7) for the at. wt. of iron; in 1806, he gave 40; in 1807, 50. About this period, on the assumption that the ferric alums are isomorphous with those of aluminium, so that the isomorphism rule is applicable, the atomic weight of iron calculated from the ratio $2Fe : Fe_2O_3$, by J. J. Berzelius (1811) was 54·27; by J. L. Gay Lussac, 56·6; by J. Davy, 55·96; by G. Magnus, 54·25; by W. H. Wollaston, 55·2; and by F. Stromeyer, 55·6. The assumption that the at. wt. of iron is in the vicinity of 56, and not a multiple or submultiple of this number, is in accord with the sp. ht. rule, the isomorphism rule, and the periodic law. The position of iron and the elements of the same family group in the periodic table has been discussed by D. Balareff, E. H. Büchner, G. Oddo, H. Teudt, E. Thilo, and R. Vogel.

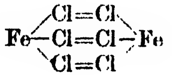
Iron is usually either bivalent or tervalent, and A. Laurent and C. Gerhardt distinguished the two forms by using the terms *ferrosum* (Fe=28) and *ferricum* (fe=⅔ of 28) for the eq. of iron in the ferrous and ferric salts respectively, so that the corresponding sulphates were represented $(Fe_2)SO_4$ and $(fe_2)SO_4$, respectively. This was discussed by A. Scheurer-Kestner, A. Wurtz, and M. d'A. Albuquerque.

The *bivalency* of iron is not so well established by the vapour density of ferrous chloride, since below 1300° the data agree with the assumption that there is a balanced reaction: $Fe_2Cl_4 \rightleftharpoons 2FeCl_2$; but mol. wt. determinations in bismuth trichloride and in pyridine, according to A. Werner, indicate that the molecule is $FeCl_2$, so that the associated molecules, Fe_2Cl_4, are probably constituted:

$$\mathrm{Fe}{<}\begin{matrix}\mathrm{Cl}=\mathrm{Cl}\\ \mathrm{Cl}=\mathrm{Cl}\end{matrix}{>}\mathrm{Fe}$$

The metal might be octovalent in the tetracarbonyl, $Fe(CO)_4$, and decavalent in the pentacarbonyl, $Fe(CO)_5$, but it is more probable that the iron is here bivalent, and that the bivalent carbonyl radicles are arranged in closed chains—**5**, 39, 27. The bivalency of the iron in ferrous sulphate is confirmed by its isomorphism with the corresponding salts of copper, magnesium, and zinc. The ferrous salts are readily oxidized to ferric salts, where the iron is tervalent. M. Traube assumed that the atom of iron is bivalent. The *tervalency* of the iron in the ferric salts is indicated by the vapour density of ferric chloride which was found by V. Meyer to agree with $FeCl_3$ at temp. between 750° and 1077°; below these temp., the formula was found by H. St. C. Deville and L. Troost to agree with the formula Fe_2Cl_6, so that there is a region where balanced reactions: $Fe_2Cl_6 \rightleftharpoons 2FeCl_3$ obtain. According to P. T. Muller, ferric chloride is unimolecular, $FeCl_3$, in pyridine, alcoholic, or ethereal soln. G. Urbain and A. Debierne found that a soln. of ferric acetylacetonate in benzene has a mol. wt. in agreement with $Fe(C_5H_7O_2)_3$. The tervalency of iron is also confirmed by its replacing aluminium in the alums. Ferrosic oxide is regarded as a ferrous ferrite, $Fe(FeO_2)_2$, where Fe_2O_3 is regarded as an acidic anhydride. W. Küster suggested that the iron in hæmaglobin is bivalent, but W. Manchot said that a tervalent iron atom better explains the facts. The ferrates, M_2FeO_4, are usually taken to illustrate the *sexivalency* of iron, and they are regarded by J. Beckenkamp, G. Grube and H. Gmelin, F. Haber, and W. Pick as salts of the unknown acid anhydride, ferric trioxide, FeO_3. M. Traube also said that there is a doubled atom, or a sexivalent radicle. The compounds FeO_2 and Fe_2O_5 have been discussed by W. Manchot and O. Wilhelms, and L. Moeser and B. Borck—*vide infra.* D. K. Goralewitsch supposed that in the perferrates, M_2FeO_5, the iron atom is *octovalent.* W. C. Bray and M. N. Gorin discussed the possibility of the existence of a *quadrivalent* form of iron.

W. Manchot and co-workers assumed that the iron in Roussin's red and black salts—**8.** 49, 35—is present in a *univalent* state; the same hypothesis had been previously suggested by I. Bellucci and P. de Cesaris. On the other hand, L. Cambi and co-workers, and H. Reihlen and co-workers maintain that the iron atom is here not univalent, but that these salts can be regarded as hyponitrites of tervalent iron. E. Drechsel, S. H. Emmens, and W. G. Brown have tried to make iron *quadrivalent* in ferrosic oxide, and indeed in the other oxides; and W. C. Bray and M. H. Gorin explained some reactions—*e.g.* the oxidation of ferrous salts by hydrogen dioxide, and the reduction of ferric salts by stannous chloride—on the assumption that quadrivalent iron is formed as an intermediate compound. The work of L. Wöhler and co-workers on the equilibrium relations of the oxides with hydrogen is in agreement with the bi- and ter-valency of iron in these oxides. The vapour density of ferric chloride under certain conditions appears to support the quadrivalent hypothesis for the doubled molecule $Cl_3Fe–FeCl_3$; but the doubling of the molecule is attributed by R. F. Weinland and co-workers, and P. Pfeiffer to the effect of the auxiliary valences of the halides:



According to A. Werner, the **co-ordination number** of iron is 6, as in the complex salts $M_3[FeCl_6]$, $M_3[FeCy_6]$, etc., but F. W. Hinrichsen and E. Sachsel added that this hypothesis does not explain the existence of salts of the type $FeCl_3.3CsCl.H_2O$. G. F. Hüttig is in favour of A. Werner's assumption; and H. Lessheim and co-workers added that in Fe^{II}-compounds the co-ordination number is 4 or 6; in Fe^{III}-compounds, 6; and in the Fe^{VI}-compounds, 4. F. Ephraim and E. Rosenberg, and P. Pfeiffer added that in some compounds, $[Fe^{VI}(NH_3)_8][O.CO.C_6H_5]_2$, the co-ordination number is 8; R. F. Weinland and co-workers, and P. Pfeiffer consider that in some complex salts—*e.g.* $M[Fe^{III}(H_2O)_{12}(SO_4)_2]$, and $[Fe^{II}(H_2O)_{12}]$-$[Bi_2Cl_7]_2$- the co-ordination number is 12. F. Hölzl, and P. Pfeiffer studied this subject.

H. Weden discussed the complex salts of iron with various organic compounds. P. Ray investigated the conditions of stability of the co-ordination compounds. E. Hartley, and W. Thomas obtained an optically active *potassium ferric oxalate*, $K_3[Fe(C_2O_4)_3].3H_2O$, etc.; and F. Blau, and A. Werner, optically active complexes of ferrous bromide, iodide and tartrate with *tri-α-dipyridyl ferrous bromide, iodide, and tartrate, e.g.* $[Fe(Dipyr)_3]Br_2.6H_2O$, etc. The subject was discussed by T. M. Lowry.

E. Donath and J. Mayrhofer studied the relation between the affinity and density of the elements; T. Bayley, the **affinity** of the elements Cu, Fe, Co, Ni for oxygen as shown by the colour of the compounds; F. Ephraim, W. Biltz, and A. Werner, the relation between the affinity and the temp. of decomposition of the ammines from which it is inferred that the affinity of ammonia for the central atom is in the order $Ni>Co>Fe>Mn>Cu>Cd>Zn>Mg$; and H. Moissan, and M. Berthelot, the relation between the affinity and heat of formation from which it is inferred that the order is Cr, Mn, Fe, Co, Ni.

A review of the early observations on the at. wt. of iron was made by A. C. Oudemans. T. Thomson made a study of the subject in 1821. In addition to the analyses indicated above, based on determinations of the composition of ferric oxide, some later observations were made on the oxidation of iron, $2Fe : Fe_2O_3$; thus, J. J. Berzelius (1844) obtained 56·05; L. F. Svanberg and E. C. Norlin, 55·83; and E. J. Maumené, 56·00; while other observations were based on the reduction of ferric oxide in hydrogen to give the ratio $Fe_2O_3 : 2Fe$. Thus, H. W. F. Wackenroder obtained 55·97; L. F. Svanberg and E. C. Norlin, 56·09; O. L. Erdmann and R. F. Marchand, 56·03; and L. E. Rivot, 54·25. J. Torrey obtained 55·777 for the at. wt. calculated from the eq. of iron obtained by measuring the volume of hydrogen evolved when the metal is dissolved in an acid. J. B. A. Dumas analyzed ferrous and ferric chlorides, and obtained from the ratio $FeCl_2 : 2Ag$, 56·09; and from the ratio $FeCl_3 : 3Ag$, 56·23. C. Winkler also titrated a soln. of iodine in potassium iodide before and after iron had been dissolved therein. The value of the ratio $I_2 : Fe$ so obtained corresponds with the at. wt., 56·21. O. Hönigschmid and co-workers obtained from the ratio $FeCl_3 : 3Ag$, 55·852, and from the ratio $FeCl_3 : 3AgCl$, 55·854.

The reduction of ferric oxide by hydrogen was examined by T. W. Richards and G. P. Baxter, and found to be affected by several errors which, when eliminated, gave for the ratio $Fe_2O_3 : 2Fe$, an at. wt., 55·887; while G. P. Baxter and C. R. Hoover's observations with the same reaction gave 55·847. The results were discussed by R. Ruer and J. Kuschmann. There is a doubt as to the stability of the ferric oxide between 1050° and 1100°, since 5 grms., previously heated to constant weight in oxygen, lost 0·2 mgrm. when ignited in air. They assumed that the higher weight was due to adsorbed oxygen, whereas the observations of R. B. Sosman and J. C. Hostetter showed that the higher value was more probably correct since the lower value is due to a slight dissociation of ferric oxide into ferrosic oxide and oxygen. This reduces the value 55·847 to 55·840. G. P. Baxter calculated from the ratio $FeBr_2 : 2AgBr$, 55·833; and from the ratio $FeBr_2 : 2Ag$, 55·842. The early calculations give higher values because a different value was taken for the at. wt. of silver. G. P. Baxter, T. Thorvaldson and V. Cobb obtained for $FeBr_2 : 2Ag$, 55·838; and for $FeBr_2 : 2AgBr$, 55·838 using terrestrial iron; and with meteoritic iron, G. P. Baxter and T. Thorvaldson obtained respectively 55·837 and 55·836 by rejecting two results of doubtful value. A. Bilecki discussed the at. wt. of iron. F. W. Clarke calculated for the best representative value for the at. wt. of iron, 55·880; while the International Table for 1931 gave 55·84. G. D. Hindrichs, and M. Gerber discussed some relations of the at. wts.

The **atomic number** of iron is 26. F. Sanford [2] discussed the relation between the at. number, at. charge, and the physical and chemical properties of the element; A. F. Scott, the relation between the at. number and the properties of the ions in the crystal lattice; P. Vinasse, the molecular numbers; and J. D. de Barros, the nuclear numbers. F. W. Aston observed **isotopes** corresponding with at. wts. 56 and 54, the ratio of the two being approximately as 20 : 1 when estimated from the intensities of the lines. The subject was also discussed by W. D. Harkins, and F. H. Lorong. The **atomic disruption** of the atom by bombardment with the α-particles was observed by G. Kirsch, H. Petterson and G. Kirsch, R. Holoubek, G. Stetter, W. Bothe and H. Fränz, A. Wegerich, J. D. Cockcroft and E. T. S. Walton, and H. Pose; but not by E. Rutherford and J. Chadwick, or C. Pawlowsky. R. A. Millikan and G. H. Cameron discussed the possible synthesis of iron by the action of cosmic rays. The **electronic structure,** according to N. Bohr, is (2) for the K-shell; (2, 2, 4) for the L-shell; (2, 2, 4, 3, 3) for the M-shell; (2) for the N-shell; and W. Gerlach suggested that of the 26 electrons there are 2 in the N-shell; 14 in the M-shell; 8 in the L-shell, and 2 in the K-shell. The subject was discussed by N. Akuloff, H. S. Allen, A. E. van Arkel and J. H. de Boer, S. J. Barnett, M. de Broglie, B. Cabrera, A. H. Compton and O. Rognley, K. T. Compton and E. A. Trousdale, P. D. Foote, W. Gerlach, E. H. Hall, W. D. Harkins, A. W. Hull, L. C. Jackson, M. Kimura, H. Lessheim and co-workers, G. A. Lindsay and H. R. Voorhees, J. C. McLennan and co-workers, R. A. Millikan and G. H. Cameron, J. W. Nicholson, C. D. Niven, H. Perlitz, H. Eyring and A. Sherman, G. I. Pokrowsky, P. Ray, W. H. Rothery, R. Samuel and E. Markowicz, H. Shoji, J. D. M. Smith, J. C. Stearns, E. C. Stoner, R. Swinne, F. Wächter, P. Weiss, L. A. Welo, T. D. Yenson, and L. Zehnder. A. T. Williams discussed the relation between the valency and spectral multiplets; P. Vinasse, the relation between the electron arrangements and the fusibility; R. Swinne, the ferromagnetism; D. Jones, the allotropic transformations; J. Beckenkamp, the variable valency; and G. I. Pokrowsky, the synthesis of iron.

J. N. Lockyer, and J. Parry inferred that the evolution of hydrogen from iron when it is heated in vacuo indicates that iron is not an element, but a compound of hydrogen which dissociates under these conditions. The inference is ill-founded.

§ 26. The Passivity of Iron.

> Ferrum peculiarem monstrat indolem. Lamina polita hujus metalli, mallas egregie obedientis, argenti solutioni immersa per plures hebdomadas nullo visibili modo mutabatur.
>
> T. BERGMAN.

Towards the end of the eighteenth century, T. Bergman,[1] in his essay, *De diversa phlogisti quantitate in metallis*, observed that when a piece of iron is immersed in a soln. of silver in nitric acid, no visible change occurs although the affinity of iron for the acids in general is known to be much stronger than that of silver. Even with regard to nitric acid, other experiments evince the superior affinity of iron, for, as iron precipitates copper from this acid, and copper precipitates silver, we must infer the greater affinity of iron than of silver. In some cases, however, instances of precipitation occurred, which he attributed to the peculiar quality of the varieties of iron which he then employed. Observations similar to those by T. Bergman were made by R. Kirwan in connection with the precipitation of lead by iron; and it is not at all improbable that C. F. Wentzel noticed the peculiar behaviour of iron during his investigation of the neutralization of acids by the metals. In 1790, J. Keir said :

> I digested a piece of fine silver in pure and pale nitrous [nitric] acid, and while the dissolution was going on and before the saturation was completed I poured a portion of the solution upon pieces of clean and newly scraped iron wire into a wine-glass and observed a sudden and copious precipitation of silver. The precipitate was at first black, then it assumed the appearance of silver, and was five to six times larger in diameter than the piece of iron wire which it enveloped. The action of the acid on the iron continued some little time and then it ceased, the silver redissolved, the liquor became clear, and the iron remained bright and undisturbed in the solution at the bottom of the wine-glass, where it continued during several weeks without suffering any change or effecting any precipitation of the silver.

The liquid had not lost its power of acting on fresh iron, although it had ceased to act on the piece already exposed to it, so that the change was in the iron, and not in the liquid. Once the iron has acquired the state where it no longer precipitates silver, it will not precipitate that metal from other soln. of silver nitrate. The iron is altered in some way " without the least diminution of its metallic splendour, or change of colour. The alteration, however, is only superficial, as may be supposed, for, by scraping off its altered coat, it is again rendered capable of acting on a soln. of silver." The inactive iron was called *altered iron*, and ordinary iron, *fresh iron.* C. F. Schönbein's term **passive iron** has been generally adopted for the inactive iron. J. Keir continued : When the altered iron in a soln. of silver nitrate is touched with a piece of fresh iron, it instantly becomes active ; but in a little while the silver precipitated on both pieces redissolves leaving both pieces of iron in the passive state. The inactive or passive iron does not precipitate copper from a soln. of copper nitrate or sulphate. The iron can be converted into the passive state by being treated with conc. and red fuming nitric acid. The passive iron gradually loses its peculiar property when dried, or when kept in water, but it can be preserved in the passive state by being kept in aqua ammonia. W. Beetz found that the direction of the current in the partitioned cell with copper and dil. sulphuric acid against nitric acid and iron is dependent on whether the iron is active or passive. E. Liebreich said that, unlike active iron, the reaction $Fe \rightarrow Fe^{\cdot\cdot} + 2\ominus$ does not occur, or else it is *nur unmerklich.* E. Becker and H. Hilberg said that the appearance of oxygen at the anode of an electrolytic cell indicates that the iron is entering into the passive state, and the rate of evolution of oxygen indicates whether the metal is wholly or partially passive when measured in terms of Faraday's law. M. le Blanc, indeed, considers iron to be in the passive state when it exhibits chemical polarization in a cell even when the anode liquor contains chlorides, etc., in place of oxidizing agents. F. Tödt said that passive iron gives no current when it is associated in a cell with one of the noble metals ; and R. Kremann and R. Müller considered iron becomes passive when it does not react chemically under conditions where, from its behaviour in the active state, the existence of a driving force for the reaction would be assumed.

J. B. Senderens stated that iron is to be regarded as passive when it remains unattacked in dil. nitric acid, but there are degrees of passivity short of complete inertness. Consequently, for the purposes of a definition, some writers have postulated arbitrary conditions. C. F. Schönbein considered that iron is passive when it is not visibly attacked by acid of sp. gr. 1·35, and no bubbles of gas escape at room temp. An acid of this concentration will itself induce passivity, and accordingly, H. L. Heathcote recommended the use of nitric acid of sp. gr. 1·2, between 15° and 17°, as a test for passivity. An acid of this concentration shows no tendency to passivate iron, and it activates passive iron but very slowly—about 24 hrs. A rod of iron is supposed to be passive when, after immersion in the acid of sp. gr. 1·2, shaking, and then holding motionless, it shows no sign of chemical action on its surface. W. A. Hollis said that iron is passive if it can be placed in fuming nitric acid for 10 seconds, at room temp., without visible attack. W. R. Dunstan and co-workers found that active iron at once begins to deposit copper from a 0·5 per cent. soln. of copper sulphate, but passive iron will remain for hours bright and unaffected. Also, active iron usually shows signs of corrosion in distilled water in 8 to 10 mins., whereas passive iron will remain bright for hours.

F. Flade recommended the electrical potential test of passivating caused by anodic polarization, since passive iron has a lower potential than active iron.

F. Förster distinguished between what he called *chemical and mechanical passivity* according as the reaction is retarded by the inactivity of the metal, or retarded by a protective film on the metal. W. Kistiakowsky said that the iron is *superactive* when it is polarized in alkaline soln. and behaves like platinum charged with hydrogen, $H_2 \rightarrow 2H^{\cdot} + 2\theta$, and the electrode potential is $E_n = -0{\cdot}9$ to $-0{\cdot}5$ volt; *active*, when the surface of the metal is clean, $F_\epsilon \rightarrow Fe^{\cdot\cdot} + 2\ominus$, and $E_n = -0{\cdot}5$ to $-0{\cdot}4$ volt; *subactive*, when there is a film with large pores on the metal, there are local currents, and $E_n = -0{\cdot}4$ to $-0{\cdot}2$ volt; *subpassive*, when there is a film with fine pores on the metal, there are local currents, and $E_n = -0{\cdot}2$ to $+0{\cdot}2$ volt; and passive when the film on the metal is continuous, and $E_n = +0{\cdot}2$ to $+0{\cdot}9$ volt.

The inertness of iron in conc. nitric acid had been noted before J. Keir's observations in 1790, by C. F. Wenzel in 1782, by T. Bergman in 1783, and by R. Kirwan in 1787, yet J. Keir can be regarded as the discoverer of the passivity of iron. The phenomenon, however, must have been waiting for the appropriate "why?" from the time the behaviour of iron in dil. and conc. nitric acids was compared.

H. L. Heathcote observed that the inertness of passive iron is true only so far as the sense of sight is concerned; passive iron is not wholly inactive, but it is the seat of a multitude of changes. E. L. Nichols and W. S. Franklin also showed that the passive metal is not absolutely insoluble in the acid, but the rate of dissolution is extremely slow. If an iron rod be allowed to stand for a considerable time in fuming nitric acid, green crystals of iron nitrate are formed, and, according to H. Gautier and G. Charpy, traces of ammonia and nitrogen peroxide are simultaneously evolved—*vide supra*, the action of nitric acid on iron. C. E. W. Belck, H. Gautier and G. Charpy, H. L. Heathcote, A. J. Maass, E. L. Nichols and W. S. Franklin, E. Ramann, A. Renard, A. Scheurer-Kestner, and L. Varenne also observed that some passivated iron dissolves in the acid. H. Gautier and G. Charpy found that for samples of iron with a given sectional area, the percentage amounts dissolved per 24 hrs. after 2 and 10 days' exposure to nitric acid were:

Sp. gr. of nitric acid		1·28	1·34	1·38	1·48	1·58	
Loss	in 2 days	0·82	0·75	0·29	0·34	5·80	per cent.
	in 10 days	0·59	0·45	0·25	0·33	5·75	,,

Z. C. Mutaftschieff observed with reduced iron after

Time		10	120	300	600	900	1443 mins.
Loss in acid	sp. gr. 1·39	0·00005	0·0015	0·0035	0·0065	0·0090	0·0196
	sp. gr. 1·42	0·00000	0·0014	0·0035	0·0050	0·0093	0·0160

G. Wetzlar first studied the electrochemical properties of passive iron, and said that iron in the passive state occupies a different position in the electrochemical series from what it does in the natural state, and he recognized different degrees of passivity between the active and the inert metal. G. T. Fechner gave for fuming nitric acid the electrochemical series +Pt, An, Fe, Ag, Cu, Bi, Sb—; and for dil. nitric acid, A. de la Rive gave +Ag, Cu, Fe (passive), Fe, Pb, Hg, Sn, Zn—, and with conc. nitric acid, +Fe (passive), Ag, Hg, Pb, Cu, Fe, Zn, Sn—. The electrochemical relations of passive iron to platinum were also discussed by H. Buff, J. F. Daniell, M. Faraday, F. Sanford, and C. F. Schönbein—*vide infra*.

The passivity of iron has been discussed by **E. Baars** and co-workers, **E. Becker** and **H. Hilberg**, **C. Benedicks** and **P. Sederholm**, **G. D. Bengough** and **O. F. Hudson**, **M. Bickermann**, **M. Le Blanc**, **K. Bornemann**, **L. Brunet**, **H. Eggert**, **F. Eisenkolb**, **U. R. Evans**, **F. Flade**, **F. Flade** and **H. Koch**, **F. Förster**, **F. Förster** and **A. Piquet**, **A. Fourgeaud**, **W. Frese**, **H. Freundlich** and co-workers, **A. Günther-Schulze**, **J. A. N. Friend**, **T. Fujihara**, **H. Gerding** and **A. Karssen**, **J. Gillis**, **G. W. Rothmund, A. S. Russell, G. C. Schmidt, E. P. Schoch, G. Senter, S. E. Sheppard, R. Swinne, G. Tammann, T. G. Thompson, F. Tödt, W. H. J. Vernon, E. Yamazaki, etc.

When an iron rod is immersed in nitric acid of sp. gr. 1·35, the metal is vigorously attacked for a few seconds; the rate of evolution of gas then slackens; and finally, to all appearances, ceases. The passivation of iron by conc. nitric acid was observed by W. Beetz, H. Braconnot, H. Buff, H. L. Heathcote, J. F. W. Herschel, J. Keir, R. Kirwan, A. Mousson, E. Ramann, C. F. Schönbein, and L. Varenne; and by fuming nitric acid, by G. T. Fechner, J. Keir, G. S. Ohm, J. M. Ordway, and L. Varenne. According to T. Andrews, the more concentrated the acid, the shorter the period of activity, so that in fuming nitric acid there is virtually no evolution of gas, and the iron does not appear to be attacked any more. G. T. Fechner, and A. de la Rive observed that the passivation is dependent on the concentration of the acid; and, as shown by A. Renard, it is favoured by lowering the temp. Thus, J. F. W. Herschel found that no passivation occurs with boiling acid of sp. gr. 1·399; M. Martens observed no passivation at ordinary temp. with an acid of sp. gr. 1·34; and N. A. E. Millon, that nitric acid with 4 or 4·5 mols. of water passivates the metal at ordinary temp., but not when warmed; H. M. Noad showed that a rod which has been made passive in conc. acid remains passive when transferred to dil. acid of sp. gr. 1·204, although dil. acid gradually destroys the passive state and the metal then dissolves freely in the acid. H. L. Heathcote, and U. R. Evans found that at room temp., the metal is passive in an acid of sp. gr. 1·40, and active in acid of sp. gr. 1·20; S. W. Young and E. M. Hogg found that at room temp. iron can be passivated by an acid of sp. gr. 1·250 or upward but not so at 0°. H. Gautier and G. Charpy observed that the metal is active at 15° in an acid of sp. gr. 1·21, and at 60° in an acid of sp. gr. 1·38; and J. M. Ordway observed that the passive state, *P*, and the active state occur at different temp. with acids of different sp. gr., thus:

1·38		1·42		1·42 (fuming)	
31°	32°	55°	56°	82°	83°
P	*A*	*P*	*A*	*P*	*A*

According to L. Varenne, if the acid has less than 47 per cent. HNO_3, the passive state is not inaugurated. However, even in an acid of that concentration, passivity is induced if the rod be lifted out of the acid and re-immersed; or if the rod be dropped with a shock to the bottom of the containing vessel; or touched with a piece of platinum or gold wire, or a carbon rod; or made the anode of an electric circuit. The curve, Fig. 401, is based on the measurements of S. W. Young and E. M. Hogg; it shows the rate of dissolution of iron in nitric acid of different concentrations when the surface area, the time, and the metal are constant. The decrease in the rate of dissolution in nitric acid of different concentrations takes place in three stages represented in the diagram, Fig. 401, (i) by the curve *AB*, where the speed of the reaction decreases rapidly as the concentration of the acid diminishes; (ii) by the curve *BC*, where the speed of the reaction falls abruptly to a very small value; and (iii) by the curve *CD*, where there is a very slow decrease in the speed of the reaction in the passivating acids. There is thus a fairly definite concentration of acid below which the speed of the reaction increases rapidly, this region is called the *passive break*. The passive break, *BC*, at 0° occurs in an acid containing between 49·78 and 52·09 grms. HNO_3 per 100 c.c.; that is, in an acid of sp. gr. between 1·250 and 1·260. The concentration of the

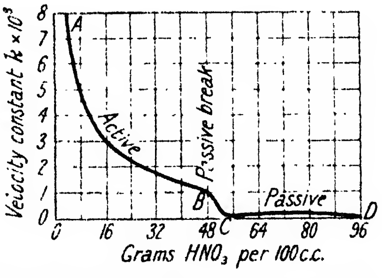

FIG. 401.—The Rate of Dissolution of Iron in Nitric Acid of Different Concentrations at 0°.

acid at which the passive break occurs decreases as the temp. rises from 0° to 10°, and thereafter increases; thus:

		0°	10°	20°	100°
Passive break	Sp. gr.	1·26	1·23	1·25	1·30
	Grms. HNO_3 per 100 c.c.	52·09	45·82	49·78	61·74

T. Andrews, and W. A. Hollis also showed that the passive state can be produced only below a certain temp. which is a characteristic of each metal. Thus, passive iron dipping in nitric acid of sp. gr. 1·42 becomes active at 90°, so that the critical temp. with iron is a little below 100°; with nickel, about 72°; and with cobalt, about 10°. E. S. Hedges found that the temp. at which gas appears when passive iron is heated with 90 to 100 per cent. nitric acid is independent of the concentration of the acid, being between 74·5° and 75·5°. The temp. at which iron goes into soln. is:

Nitric acid	90	95	98	99	100 per cent. HNO_3
Temperature	75·0°	77·5°	83·0°	85·0°	86·5°

Freshly-ignited ferric oxide does not dissolve appreciably until this temp. is reached. This temp. does not correspond with the formation of an allotropic modification of iron. According to W. A. Hollis, the critical temp. depends on whether the iron is heated with the acid, or whether the iron and acid are heated separately before being brought into contact; in the former case, the critical temp. was 94°, and in the latter case 74°, but the actual results are dependent on the degree of purity of the iron. Observations on this subject were made by T. Andrews, T. Bergman, H. G. Byers, M. Corsepius, E. St. Edme, H. L. Heathcote, J. F. W. Herschel, J. P. Joule, J. Keir, R. Kirwan, H. G. Byers and A. F. Morgan, J. M. Ordway, J. B. Senderens, L. Varenne, and G. Wiedemann. W. Heldt said that finely-divided iron does not passivate so readily as compact iron, and T. Andrews found that wrought iron when first dipped in the acid may appear more passive than steel, but after some hours' immersion in the acid it becomes less passive; wrought iron is permanently more passive than tungsten steel; hard steels, with their higher content of combined carbon, are more passive than mild steels. H. M. Noad observed that a preliminary washing of the metal with water renders passivation more difficult. Stirring the acid was found by C. W. Bennett and W. S. Burnham, H. L. Heathcote, E. S. Hedges, W. Kistiakowsky, and P. de Regnon to favour passivation. Z. C. Mutaftschieff found that the stirring of nitric acid of sp. gr. 1·20 for up to 5 hrs. favoured the passivation of iron, but no difference could be detected when the acid was stirred for 5 to 24 hrs.

The presence of nitrous acid or of nitrogen peroxide in the acid was found by W. Beetz, M. le Blanc, R. Escales, P. Günther, W. Heldt, J. F. W. Herschel, A. Klemenc, and A. Voigt to retard the passivation, but if ferrous sulphate be present, the nitrous oxides are absorbed, and the acid then favours passivation. U. R. Evans observed that electrolytic iron is not attacked by nitric acid of sp. gr. 1·40 when solid potassium nitrite or ferric nitrate is present. The admixture of sulphuric acid was found by W. Beetz, M. Boutmy and M. Chateau, and J. F. Daniell to favour passivation. F. Fujihara studied the passivation of iron in dil. alcoholic soln.; and C. Benedicks and P. Sederholm, in soln. of ethyl alcohol, or other organic liquid which reduces the degree of ionization of the nitric acid.

G. S. Ohm, and A. Renard stated that iron is rendered passive when treated with nitrous acid or different nitrogen oxides; and R. Weber passivated iron by contact with fused nitrogen pentoxide at 30°.

S. W. Young and E. M. Hogg consider it probable that when nitric acid is the passivating agent, nitrogen peroxide or trioxide does the actual work because the exposing of iron to either of these agents makes the metal passive, while nitric oxide does not effect this transformation. Colourless, or the so-called water-white, nitric acid does not passivate iron, but the transformation is effected by yellow or red acid. The colour indicates that the acid contains higher nitrogen oxides in soln. The passive break occurs when the conc. of the acid is such that the reaction develops relatively large amounts of nitrogen peroxide. When nitrogen peroxide is bubbled through nitric acid in which iron is normally active, it has the effect of producing passivity; and a similar result is obtained by the addition of nitrites. It is probable that with nitric acid with a conc. lower than that of the passive break, nitrogen peroxide is still being developed because the values for the velocity constant increase with dilution. There is a slow but continuous dissolution of iron in passivating acids no matter how concentrated they are.

Passivity is developed through the agency of oxidizing reactions.—Acids other than nitric acid may passivate iron; thus, W. Beetz, and A. S. Cushman found that *chromic acid* will do the work; R. Phillips, *iodic or chloric acid;* and J. W. Turrentine, *hydrazoic acid.* M. Martens stated that conc. *acetic acid* will passivate iron, but W. Beetz, and W. Rollmann could not confirm this. E. Heyn and O. Bauer showed that soln. of *sodium and ammonium acetates*, 1 grm. per litre, will passivate iron. The statement of M. Martens that alcohol will passivate iron was opposed by W. Beetz, W. Rollmann, and C. F. Schönbein. M. Boutmy and M. Chateau, and N. A. E. Millon found that *arsenious acid* will passivate iron; and W. R. Dunstan and J. R. Hill, that a 1 per cent. soln. of *sodium arsenate* soon passivated iron. The inhibitory action of arsenic films on iron was discussed by E. Heyn and O. Bauer—*vide supra*, the action of sulphuric acid on iron. W. R. Dunstan and J. R. Hill, E. Heyn and O. Bauer, and G. Grube studied the passivation of iron by soln. of *potassium ferrocyanide* and *potassium ferricyanide;* A. Finkelstein, H. L. Heathcote, C. Fredenhagen, and F. Heyn and O. Bauer, by soln. of *potassium cyanide.* Iron becomes more or less passive with conc. *sulphuric acid,* and cast-iron vessels are used for storing 90 to 100 per cent. acid. For concentrations below 80 per cent. H_2SO_4, ordinary cast iron is attacked by the acid, and special ferrosilicon iron is used for containers. The subject was discussed by H. L. Heathcote, J. Meunier, C. E. Fawsitt and A. A. Pain, etc.—*vide infra.* According to Z. C. Mutaftschieff, the prolonged exposure of iron to air reduces its reactivity with nitric acid of sp. gr. 1·39 to 1·42. The potential acquired by iron on exposure to air was discussed by W. Muthmann and F. Frauenberger, and F. Flade; and it is assumed that the iron acquires a film of an oxide by exposure to *air.* The same assumption was made by U. R. Evans, M. Faraday, H. Freundlich and co-workers, F. Haber and F. Goldschmidt, W. Kistiakowsky, R. Mallet, W. Rollmann, G. Tammann, and G. Wetzlar. A. Renard observed that the heating of an iron rod in the flame of a spirit lamp for a few seconds will make the metal passive. The passivation of iron by heating it in air, and the formation of oxide films when iron is heated in air or *oxygen* was discussed by W. Beetz, C. E. W. Belck, M. Boutmy and M. Chateau, H. le Chatelier and B. Bogitch, U. R. Evans and co-workers, M. Faraday, A. Finkelstein, E. Grave, W. Hittorff, M. Martens, H. M. Noad, L. Nobili, E. Ramann, W. Rollmann, C. F. Schönbein, and G. Wetzlar. According to C. A. L. de Bruyn, the inertness of iron covered with a film of oxide is not related to the abrupt change of potential which occurs in the ordinary passivation of iron. The subject was discussed by W. R. Dunstan and J. R. Hill, U. R. Evans, H. L. Heathcote, I. Langmuir, E. K. Rideal, and C. F. Schönbein.

G. Wetzlar, W. R. Dunstan and J. R. Hill, M. Martens, and C. von Hutton observed the resistance of iron to attack by soln. of ammonium or potassium hydroxides. With low concentrations of alkali-lye, A. Thiel and H. Luckmann found that the iron may be attacked in the presence of oxygen. The passivity of iron in soln. of barium hydroxide was studied by W. R. Dunstan and J. R. Hill, and in soln. of calium hydroxide by E. Heyn and O. Bauer. According to C. E. W. Belck, the resistance of iron to soln. containing sufficient alkali hydroxide has not definitely been proved to be due to the passivation of the metal, because W. R. Dunstan and J. R. Hill showed that the apparent passive state is not maintained after the metal has been washed in water, whereas it is so with iron passivated with nitric acid; and M. Mugdan, that with increasing concentration of the alkali-lye, the metal gradually, not abruptly, passes into what appears to be the passive state, and, at the same time, the potential steadily increases to the equilibrium potential of hydrogen. The subject was also discussed by U. R. Evans, J. A. N. Friend, F. Haber and W. Maitland, E. Heyn and O. Bauer, E. Liebreich, W. H. Perkins, E. K. Rideal, and G. W. Whitman and co-workers. F. Haber and F. Goldschmidt showed that iron may resist attack by soln. of alkali-lye, in the presence of carbon dioxide so long as the carbonate and hydrocarbonate can be formed. W. R. Dunstan and J. R. Hill studied the passivation of iron by soln. of *sodium and potassium carbonates*, and by soln. of *borax—vide supra*, the corrosion of iron. G. T. Fechner, and M. Faraday noted that the metal is not attacked by soln. of *alkali sulphide*, although, according to G. S. Ohm, a surface skin of iron sulphide may be formed. Similarly, F. Förster did not consider the resistance of iron to soln. of alkali sulphides to be the same in kind as the phenomenon of passivity. W. R. Dunstan and J. R. Hill, J. A. N. Friend and C. W. Marshall preferred to call these agents *inhibitors* rather than passivifying agents.

O. Dony-Hérault, and W. Beetz showed that soln. of *potassium chlorate, bromate, or iodate* in conc. sulphuric acid passivate iron, but, according to M. Mugdan, soln. of *potassium perchlorate* do not do so. Iron was also found by M. Mugdan to be passive in soln. of alkali chlorates, bromates and iodates. E. Heyn and O. Bauer observed that soln. of potassium chlorate, up to the highest concentrations, perceptibly attack iron, but soln. of potassium bromate and iodate containing 1 grm. per litre, do not do so. W. R. Dunstan and J. R. Hill found that a 1 per cent. soln. of potassium chlorate did not passivate iron, but a 4 per cent. soln. did, whilst 1 per cent. soln. of potassium bromate or iodate were usually effective in passivating iron—as indicated above.

M. Boutmy and M. Chateau, and G. T. Moody observed that iron becomes passive in contact with neutral *hydrogen dioxide*. Thus, clean electrolytic iron can be immersed in a warm dil. soln. of perhydrol without showing any sign of corrosion even though its surface is swept with bubbles of oxygen due to the catalytic decomposition of the hydrogen dioxide. Iron readily dissolves in the presence of acids and hydrogen dioxide. The action of hydrogen dioxide was also studied by W. R. Dunstan and co-workers, and by H. E. Armstrong and R. E. Colgate.

E. Grave attributed the passivity iron acquires when heated in nitrogen to the removal of the activating hydrogen. W. R. Dunstan and J. R. Hill said that passive iron remains passive after it has been heated in nitrogen. G. Tammann discussed the passivity of nitridized iron. A. Renard found that the vapour of nitric acid will passivate iron; and L. Varenne added that compressed nitric oxide acts similarly. According to S. W. Young and E. M. Hogg, nitric oxide does not act at ordinary press., but nitrogen peroxide produces a passivity far greater than that produced by nitric acid when dry gas is allowed to come in contact with the metal—*vide supra*. Iron passivated by dry nitrogen peroxide is more persistently passive than that which is passivated by nitric acid. Mere traces of nitrogen peroxide can render iron passive; for if a little of the gas is allowed to escape into the atmosphere of a room all the iron articles in the room become passive.

E. Ramann observed that iron is passivated by soln. of *ammonium nitrate*; and J. Keir, G. Wetzlar, and B. Lambert, by soln. of *copper nitrate*. G. Wetzlar observed that neutral soln. act more quickly than acidic soln., and J. B. Senderens added that some copper separates from neutral soln. G. Wetzlar also noted that raising the temp. is not favourable to passivity, and B. Lambert, that pressing the iron in an agate mortar before or while in the soln. of the copper salt, activates passive iron. G. Wetzlar reported that iron passivated by a soln. of copper nitrate retains its passivity for weeks, but dipping the passive iron in water makes it active. G. Wetzlar, and M. Martens found that iron is passivated in an alcoholic soln. of copper nitrate. The passivating action of soln. of *copper sulphate* was studied by C. F. Buchholz, G. Wetzlar, J. B. Senderens, and W. Beetz; of a soln. of *copper chloride*, by J. B. Senderens, and of alcoholic soln. of the chloride, by G. Wetzlar, and M. Martens; of aq. soln. of *copper acetate*, by G. Wetzlar, J. B. Senderens, and M. Mugdan; of neutral or ammoniacal soln. of *copper tartrate*, by G. Wetzlar and M. Mugdan. T. Bergman, J. Keir, N. W. Fischer, G. Wetzlar, and W. Beetz observed that iron is passivated by aq. soln. of *silver nitrate;* and E. Ramann, by ammoniacal soln. of that salt. W. Beetz found that silver nitrate is more active than is copper nitrate; and J. Keir, and G. Wetzlar studied the passivation by mixed soln. of copper and silver nitrates. The addition of nitric acid to the aq. soln. of silver nitrate tends to activate the iron. The action was studied by T. Bergman, J. Keir, G. T. Fechner, M. Faraday, W. Heldt, and G. Wetzlar; the action of neutral soln., by G. Wetzlar, W. Beetz, and J. B. Senderens; and the activation by a rise of temp., by J. Keir. G. Wetzlar, and J. B. Senderens observed that the passivity produced by a nitric acid soln. of silver nitrate is retained some weeks on exposure to air. J. B. Senderens studied the passivation of iron in soln. of *silver sulphate;* and J. B. Senderens, and G. Wetzlar, in soln. of *silver acetate.* The passivation of iron by soln. of *mercurous nitrate* was studied by J. Keir, C. F. Schönbein, G. Wetzlar, W. Heldt, and M. Boutmy and M. Chateau; by soln. of *aluminium nitrate*, by E. Ramann; by soln. of *lead nitrate*, by R. Kirwan, J. Keir, and J. B. Senderens; and by soln. of lead acetate, by J. B. Senderens; and by soln. of *ferrous and ferric nitrates*, *cobalt nitrate*, and *nickel nitrate*, by E. Ramann.

M. Boutmy and M. Chateau, J. A. N. Friend, E. Liebreich, G. T. Moody, W. R. Dunstan and co-workers, U. R. Evans, T. P. Hoar and U. R. Evans, R. G. van Name and D. U. Hill, G. W. Heise and A. Clemente, and E. Heyn and O. Bauer discussed the passivation of iron by soln. of chromic acid, *chromates*, and *dichromates;* and M. Boutmy and M. Chateau, M. Mugdan, W. R. Dunstan and J. R. Hill, and E. Heyn and O. Bauer, the passivation of iron by soln. of *potassium permanganate.* Most of the observations on passivity were made with iron containing carbon as an impurity, but R. Lenz showed that purified iron becomes passive under similar conditions, so that the passive state is a property of iron *per se.*

W. Hisinger and J. J. Berzelius, and C. F. Schönbein studied the passivation of iron by anodic polarization. According to E. Ramann, iron readily assumes the passive state when it is used as anode or positive electrode in an aq. soln. of various electrolytes. If the iron be made the anode of an electric circuit, the NO'_3-ions at the surface of the metal passivate the iron. The subject was studied by H. G. Byers, F. Flade and H. Koch, G. Grube, J. L. R. Hayden, H. L. Heathcote, W. Rathert, C. F. Schönbein, and W. Hittorf. M. Faraday found that the dissolution of iron by nitric acid of sp. gr. 1·3 at once ceases if a material like platinum, gold, or carbon is brought in electrical contact with the iron. Here a short-circuited electric cell is set up, and passivity is quickly produced. Contact with zinc under similar conditions has the reverse effect. The effect of zinc in starting activation waves, which, if started in two parts of the passive iron, meet and mutually extinguish one another, was studied by R. S. Lillie.

According to T. Andrews, J. MacLeod-Brown, M. Martens, and P. de Regnon, if an iron rod dipping into nitric acid or other oxidizing agent be in electrical contact with a strip of platinum, it becomes passive, due to the anodic polarization of the iron, for if the two metals be in electric contact, the iron becomes the anode, the strength of the current falls to a very small quantity, and then remains virtually constant for several days. The subject was also studied by H. Buff, M. Faraday, W. Heldt, J. F. W. Herschel, A. J. Maass, L. McCulloch, M. Martens, H. M. Noad, E. Ramann, P. de Regnon, A. Renard, W. Rollmann, and C. F. Schönbein. No passivation was observed by M. Faraday to occur when the iron is in contact with copper; but the effect with silver was observed by M. Faraday, and J. F. W. Herschel; with gold, by J. MacLeod-Brown, E. Ramann, A. Renard, and C. F. Schönbein; and with graphite, by M. Faraday, J. MacLeod-Brown, E. Ramann, P. de Regnon, A. Renard, and J. L. Schönn. The passivation of iron by contact with lead oxide and silver peroxide was noted by M. Boutmy and M. Chateau, H. M. Noad, and C. F. Schönbein. C. F. Schönbein observed that a rod of passive iron may passivate a rod of active iron, if the two rods be placed in electrical contact in the acid. If the surface area of the active rod is relatively greater than that of the passive rod, the phenomenon may be reversed, and the passive rod may become active. J. MacLeod-Brown said that if part of an iron nail is made passive, the remainder of the nail does not assume the passive state. The passivation of active iron by contact with passive iron was studied by U. R. Evans, M. Faraday, G. T. Fechner, H. C. Oersted, E. Ramann, C. F. Schönbein, H. Schröder, G. Wetzlar, and G. Wiedemann.

G. Wiedemann described a number of cases of the passivation of anodic iron in cells with various electrolytes, and various metals—copper, silver, gold, zinc, cadmium, tin, lead, antimony, bismuth, and platinum—by A. Avogadro, W. Beetz, J. G. Brown, M. Corsepius, J. F. Daniell, H. Davy, M. Faraday, N. W. Fischer, F. Flade, W. Hisinger and J. J. Berzelius, A. J. Maass, M. Martens, C. H. Pfaff, A. de la Rive, W. Rollmann, and C. F. Schönbein.

The anodic polarization of iron in soln. of alkali hydroxides was studied by A. J. Allmand and R. H. D. Barklie, H. G. Byers and co-workers, M. Corsepius, C. Fredenhagen, F. Förster and A. Piquet, E. Grave, G. Grube, F. Haber and co-workers, E. S. Hedges, P. Krassa, E. Müller and F. Spitzer, and C. F. Schönbein. The effect in soln. of various salts—*e.g.* sodium chloride was studied by W. J. Müller; sodium chlorate, by H. G. Byers; ammonium sulphate, by E. S. Hedges; sodium sulphate, by H. G. Byers and co-workers, E. S. Hedges, H. W. Moseley, and W. Rathert; potassium sulphate, by A. Finkelstein, and E. P. Schoch and co-workers; copper sulphate, by W. Rathert, and C. F. Schönbein; ferrous sulphate, by C. A. L. de Bruyn; ferric sulphate, by A. Finkelstein; ammonium nitrate, by J. L. R. Hayden: sodium nitrate, by H. G. Byers; potassium nitrate, by H. G. Byers, J. L. R. Hayden, E. P. Schoch and co-workers; alkali carbonates and hydrocarbonates, by H. G. Byers, J. L. R. Hayden, and F. Haber and F. Goldschmidt; mixtures of potassium ferrocyanide and ferricyanide, by G. Grube; potassium cyanide, by A. Brochet and J. Petit, H. G. Byers, A. Finkelstein, E. S. Hedges, and W. Hittorf; potassium phosphate, by H. G. Byers and M. Darrin; potassium permanganate, by H. G. Byers; and potassium dichromate, by H. G. Byers and co-workers. The effect in various acids—*e.g.* hydrochloric acid was studied by H. G. Byers and S. C. Langdon, and E. S. Hedges; in sulphuric acid, by J. Alvares, H. E. Armstrong and R. T. Colgate, H. G. Byers and co-workers, M. Corsepius, U. R. Evans, A. Finkelstein, F. Flade and H. Koch, C. Fredenhagen, E. Grave, E. S. Hedges, H. Koch, W. Rathert, P. de Regnon, G. C. Schmidt and W. Rathert, and C. F. Schönbein; in nitric acid, by T. Andrews, H. G. Byers and co-workers, C. Fredenhagen, E. S. Hedges, W. Hisinger and J. J. Berzelius, M. Martens, H. W. Moseley, W. J. Müller, P. de Regnon, W. Rollmann, and C. F. Schönbein; in phosphoric acid, by H. G. Byers and co-workers, E. S. Hedges, H. W. Moseley, and C. F. Schönbein.

Passive iron was found by A. Finkelstein to behave with respect to oxygen like a reversible gas-electrode, and the cell was studied by F. Flade, C. Fredenhagen, C. M. Gordon and co-workers, G. Grube, M. Mugdan, W. Muthmann and F. Frauenberger, and F. Tödt. The passive iron behaves in this way with no gas other than oxygen. If platinum be replaced by passive iron in the gas-cell, H. Koch found that the intensity of the current is reduced, showing that oxygen is being taken up by the passive iron. O. Scarpa could not decide whether a film of oxide or a film of oxygen was formed on the passive metal. H. C. Byers and S. C. Langdon showed that the potential, E volt, of the cell is dependent on the press. of the oxygen—p lbs. per sq. in. with an iron electrode in $0{\cdot}2N\text{-}H_2SO_4$:

p . .	0	25·8	30·5	34·6	43·9
E . .	1·770	−1·760	−1·751	−1·740	−1·730

The potential of the anodically polarized, passive iron gradually decreased with time. C. A. L. de Bruyn showed that while platinum is not attacked, an electrode of passive iron is attacked by mixed soln. of ferrous and ferric sulphates:

	$FeSO_4$	67·5	48·5	29·0	16·0	1·0 per cent.
	$Fe_2(SO_4)_3$ . .	32·5	51·5	71·0	84·0	99·0 ,,
E	platinum . .	0·632	0·655	0·680	0·699	0·812
	passive iron . .	0·620	0·642	0·665	—	0·745
	ferrosic oxide .	0·619	0·651	—	0·686	0·765

The passivation of iron or anodic polarization of iron in soln. of alkali hydroxide was discussed by F. Förster and co-workers, C. Fredenhagen, H. Freundlich and co-workers, G. Grube and H. Gmelin, F. Haber and co-workers, D. F. Holmboe, P. Krassa, E. Müller and F. Spitzer, and L. Tronsted; and the anodic polarization of iron in fused alkali hydroxide, by C. Liebenoff and L. Strasser, R. Lorenz, C. J. Reed, L. Rolla and R. Salani, and J. F. Sacher. The general results show that the iron behaves as an oxygen, and that the passivation is due to the formation of a film of oxide, or a film of gas electrode.

According to F. Goldmann and E. Rupp, the impact of electrons on non-evacuated surfaces of silver or copper causes them to become passive, so that the bombarded surface is not attacked by iodine vapour, whilst the unprotected parts are quickly covered with a violet film, which is thickest near the boundary. Positive ions or the prolonged action of ultra-violet light produces the same effect. Since passivation does not occur when the surfaces are evacuated or when the evacuated surfaces are subsequently brought into contact with hydrogen, but is pronounced if oxygen is introduced, it is considered to be due to the formation of an oxide film on the exposed part of the metal.

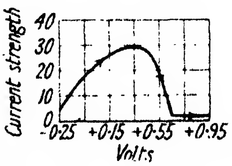

Fig. 402.—The Potential of Iron and the Current Density.

The activation of passive iron.—J. Keir, and H. Buff observed that the activation occurs when the passive metal is left in contact with water—*vide supra.* It is only the moist passive metal that reverts so easily to the active state. The passive metal may be activated if left in contact with nitric acid below the concentration required for passivation, thus, L. Varenne found that iron passivated by nitric acid of sp. gr. 1·42 was depassivated in contact with

Sp. gr. nitric acid .	1·3	1·28	1·26	1·16
Time	264	120	32	12 hrs.

Analogous observations were made by E. St. Edme, H. L. Heathcote, W. Heldt, J. F. W. Herschel, and C. F. Schönbein. U. R. Evans, and H. L. Heathcote, found that iron passivated in conc. nitric acid becomes active on exposure to air; and T. Fujihara, that Armco iron or electrolytic iron, passivated by a 5 per cent. alcoholic soln. of nitric acid, was not attacked by distilled water in an atm. free from carbon dioxide, but in the presence of carbon dioxide, it began to rust in 10 to 20 mins.

H. L. Heathcote obtained the passive metal in a dry state by rapidly spraying, in succession, upon a recently passivated rod of metal, (i) a sat. aq. soln. of potassium dichromate containing 2·8 grms. of potassium hydroxide per 100 c.c.; (ii) a mixture of 100 c.c. of water, 10 c.c. methylated spirit, and 2·5 grms. of potassium hydroxide purified by alcohol; and (iii) absolute alcohol. The dry, passive iron behaved exactly like a metal covered with a film of oxide. The rods were not activated by allowing them to remain several days in the atmosphere of a laboratory; rubbing them well with dry cotton-wool had no effect; and contact with zinc or scratching with glass failed to activate the portions of the passive rod which were not touched. L. Varenne said that passive iron becomes active under a press. of 15 mm. of mercury; and C. E. W. Belck also stated that activated iron becomes passive in vacuo, but H. L. Heathcote did not agree. According to H. L. Heathcote, if a vessel containing iron immersed in nitric acid be evacuated, bubbles of gas form on the surface of the metal and rise to the top of the liquid; but although the mechanical action of these bubbles may sometimes render the iron active, more usually the bubbles cease to form at an early period, and the iron remains quite passive for hours at 15 mm. press. The sudden admission of air sometimes activated the passive iron. He also found that passive iron may be kept in a high vacuum for some hours without change, although spots of activity may develop—possibly because of local action produced by impurities forming local voltaic couples. The general results show that the presence of a gaseous film on the metal is not the cause of the passivity. W. R. Dunstan and J. R. Hill found that at 400°, passive iron remains passive, but at a higher temp., the metal becomes active. According to E. Grave, active iron heated in vacuo is passive in consequence of the removal of occluded hydrogen, but F. Flade and H. Koch found that active iron remains when it has been heated in vacuo to remove as much as possible of the occluded hydrogen. For the presence of occluded gases in iron, *vide supra.*

H. M. Noad, and others have noticed that dil. nitric acid activates passive iron—*vide supra.* A. Meyer, C. F. Schönbein, and others found that the same result is produced by the action of chlorine, bromine, hydrochloric acid, sulphuric acid, and a soln. of potassium nitrate, chloride, etc. Passive iron was found by G. Wetzlar to be activated by various salts—*e.g.* by sodium or ammonium chloride, or by potassium nitrate or sulphate in alkaline soln.; M. Mugdan observed that sodium chloride or sulphate activated passive iron, but not so with potassium nitrate or chlorate. E. P. Schoch and C. P. Randolph found that the anions: halides, sulphates, acetates, perchlorates, nitrates, chromates, chlorates, bromates, iodates, and hydroxides, have a decreasing tendency to activate passive iron. The activation of passive iron by the halides was discussed by A. J. Allmand and R. H. D. Barklie, G. Bodländer, H. G. Byers and co-workers, W. R. Dunstan and J. R. Hill, U. R. Evans, F. Flade and H. Koch, J. A. N. Friend, F. Haber and F. Goldschmidt, J. L. R. Hayden, E. Heyn and O. Bauer, E. Liebreich, A. Smits, and A. Smits and C. A. L. de Bruyn. W. R. Dunstan and J. R. Hill also observed that sulphuric, hydrochloric, formic, acetic, citric, and carbonic acids rapidly activate passive iron. E. St. Edme found that hydrogen converts passive into active iron, but, according to W. Hittorf, and E. Grave, molecular, *i.e.* ordinary, hydrogen does not restore the activity of passive metals. According to W. Beetz, E. Grave, and C. F. Schönbein, however, if the metal be heated in hydrogen—W. R. Dunstan and J. R. Hill said at 240° to 250°—the passive metal is activated. E. Grave, W. Rathert, O. Sackur, G. C. Schmidt, G. C. Schmidt and W. Rathert, and J. Stapenhorst observed that hydrogen *in statu nascendi*, or $H^{\cdot}$-ions, strongly activated the passive metal; and W. Hittorf, J. F. W. Herschel, M. Martens, M. Boutmy and M. Chateau, and M. Bibart observed that the passive metal is activated by treating it with reducing agents—*e.g.*, according to C. F. Schönbein, alcohol and ether make the passive metal active. G. C. Schmidt found that the diffusion of hydrogen through a passivated surface activates the metal. The subject was studied by A. M. Hasebrink, and H. Eggert. In general, the passive state is destroyed by making the metal the cathode of a voltaic couple. M. Faraday, and R. S. Lillie—*vide supra*—observed the activation of the passive metal by contact with zinc.

According to M. Faraday, F. Förster, J. F. W. Herschel, J. Keir, M. Martens, C. F. Schönbein, F. W. Schweigger-Seidel, and G. Wetzlar, passive iron is usually activated when it is in contact with active iron, or when it is in contact with a more electropositive metal like zinc or lead. In J. F. W. Herschel's experiment, an iron rod was divided into two parts by a band of wax about the centre of the rod; and passivity was induced on both ends of the rod. Activity is restored to *one end* by touching that end with a piece of copper while the whole rod was exposed to air; if one end be touched while the whole rod is dipping in the acid, *both ends* become active. In the former case a voltaic couple is formed—the piece of copper is the anode, the end of the rod which is in contact with the copper is the cathode, and the film of acid the electrolyte. The cathode extends only to the wax ring because the electrolyte does not wet the wax. When the rod is wholly immersed, the electrolyte is continuous, and the whole rod acts as cathode and becomes active.

The passive metal can be activated by mechanical treatment—*e.g.* J. F. W. Herschel, J. Keir, F. W. Schweigger-Seidel, J. B. Senderens, C. Tomlinson, L. Varenne, and G. Wetzlar noticed that the active condition may be restored to passive iron by scraping or scratching the metal, or by a mechanical shock, although P. de Regnon was unable to verify this. N. Izgarischeff said that the scratched iron immediately becomes passive if it be returned to the nitric acid; and W. R. Dunstan and J. R. Hill observed that iron passivated by chromic acid, scratched, and then placed in water begins to rust along the scratches. W. Muthmann and F. Frauenberger observed that metals which have become more or less passivated by exposure to air become active when the surface is cleaned mechanically. L. Varenne found that vibratory movements of various kinds activate passive iron. E. S. Hedges observed that iron, previously rendered passive by nitric acid, becomes active when whirled at 3000 revs. per min. after a short period of induction representing the time required for removing the film of oxide which produces the passivity.

W. Hittorf observed that when the circuit of the cell $Fe | NaNO_3, H_2CrO_4 | Pt$ is closed by dipping the iron in the salt soln., the e.m.f. gradually drops from 1·83 to 0·1 volt, the iron becomes quite passive, retaining its metallic lustre, and it is not attacked however long the cell is short-circuited. Passive iron is not really insoluble in nitric acid, for M. Faraday showed that a little passes into soln. during the passage of the current; and C. E. W. Belck observed that the rate of dissolution of the passive iron depends on the conc. of acid, being less in the more dil. acids. H. G. Byers, and H. G. Byers and S. C. Langdon observed that the establishment of anodic passivity in iron is influenced by the condition and previous history of the iron, the nature and concentration of the electrolyte, the stirring of the electrolyte, the temp., the current density, the time of flow of the current, and the concentration of the oxygen dissolved in the electrolyte.

In the electrolysis of sulphate soln., at low current densities, the dominant anion, SO_4'', is alone discharged at the anode to any appreciable extent, but at high current densities, the OH'-ions are also discharged, and oxide or hydroxide, or hydrated oxide begins to accumulate on the anode, and interferes with the dissolution of the iron. It is at this stage that passivity occurs. The electrical passivation of the iron occurs more readily in alkaline soln. since these soln. are favourable to the discharge of OH'-ions; and in soln. of alkali hydroxide alone, a low current density makes the anode passive because the only possible anode product is the sparingly soluble hydroxide. E. P. Schoch and C. P. Randolph found the approximate limiting current densities, in milliamps., to be with N-K_2SO_4, 300; with 0·01N-KOH, 250; with N-K_2SO_4 and with 0·1N-KOH, 10.

According to F. Förster, A. Adler, M. Schlötter, G. C. Schmidt, E. Grave, W. Rathert, and M. le Blanc, passivity is the normal state of purified iron, and the metal is rendered active by contact with some catalyst, say hydrogen (G. C. Schmidt), an alloy of the metal and hydrogen (F. Förster), or $H^{\cdot}$-ions (E. Grave); and this hypothesis is supposed to be supported by B. Lambert and J. C. Thomson's observations—*vide supra*, the corrosion of iron. F. Flade and H. Koch attempted to decide between the hypothesis that (i) purified iron is active and the passivity is connected with the presence of oxygen, and the hypothesis that (ii) purified iron is passive and the activity is connected with the presence of hydrogen. If a specimen of active iron be heated in vacuo, to remove all hydrogen, it still remains active; and if a passive electrode be heated in carbon monoxide to remove oxygen without affecting the hydrogen, a passive electrode remains passive, and an active electrode becomes passive. This last result is attributed to an equilibrium condition between carbon, oxygen, carbon dioxide, and carbon monoxide, and the oxygen formed passivates the active metal. According to W. Rathert, and G. C. Schmidt, the potential at which the passive metal becomes active is not the same as that at which the active metal becomes passive, and that the point of sudden change of potential observed by F. Flade does not represent the boundary potential below which the metal is active and above which it is passive. A metal may be active or passive on both sides of this point, depending on its previous treatment. The potential at which iron becomes passive is dependent in a marked degree on the concentration of the electrolyte in which the anodic polarization is effected, whilst the potential at which passive iron becomes active is not. The appearance of the passivity potential and the activity potential during anodic polarization is dependent on the current density, and consequently on the oxygen concentration on the electrode. These various facts are said to be explained better on the hydrogen than on the oxide theory of passivity. J. Stapenhorst found that iron which has been made passive by chromic acid, becomes active under the influence of hydrogen dissolved in the metal. He believed that this change cannot be explained by the removal of dissolved oxygen or by the destruction of an oxide film. Under suitable conditions, the reverse change may be brought about by the diffusion of nascent oxygen. The potential assumed by a metal in a neutral electrolyte depends on the quantity of oxygen present in the electrolyte soln. If the surface of the metal is renewed by grinding with an emery-wheel, the potential changes from that characteristic of the passive form to the value peculiar to the active form of the metal. Hydrogen and nitrogen tend to preserve the potential of the active form, but otherwise behave as indifferent gases. Oxygen, on the other hand, is not an indifferent gas. Both in the gaseous and dissolved states it exercises a very considerable influence on the electrode potential and conduces to the appearance and maintenance of the passive state. The passivating potential was studied by J. Alvares, C. A. L. de Bruyn, H. G. Byers and co-workers, F. Flade, F. Flade and H. Koch, F. Giordani, C. Fredenhagen, E. Grave, E. Liebreich and W. Wiederholt, W. J. Müller and co-workers, W. Rathert, G. C. Schmidt and W. Rathert, and E. P. Schoch and C. P. Randolph.

According to W. J. Müller and co-workers, in the electrolysis of N-H_2SO_4 sat. with ferrous sulphate, a visible film is formed on the iron anode, and the resistance rises at first slowly, and then rapidly to a maximum. A critical current density at which passivity occurs is attained after a definite time, t; and the mean current density for passivation is directly proportional to $\log t$. H. G. Byers and C. W. Thing found that a current density which is insufficient to cause passivity quickly may do so if a longer time is allowed. They also found iron to be passive at all current densities in a soln. of potassium dichromate and sodium sulphate, and becomes passive in $0{\cdot}2N$-H_2SO_4 at all current densities above 6·0 amps. per sq. dm. H. G. Byers and S. C. Langdon observed that with iron as anode in $0{\cdot}2N$-H_2SO_4, the time required for passivation is much shorter if dissolved oxygen is present at the anode surface. U. Sborgi and G. Cappon found that with iron in an ethyl alcohol soln. of calcium and ammonium nitrates, the metal is passive with high and low current densities; and U. Sborgi and P. Marchetti observed that with an acetone soln. of lithium chloride, iron dissolved as a bivalent metal, and the metal is passive in an acetone soln. of silver nitrate.

C. A. L. de Bruyn found that with a soln. of ferrous sulphate, an iron electrode suddenly becomes passive when the current density reaches 0·4 amp. per sq. cm. This abrupt change was not observed with soln. of ferrous chloride. In an electrolytic cell giving off oxygen from the passive iron electrode, only about 1 per cent. of the current was consumed in the dissolution of iron; the remainder was used in producing oxygen. For active iron, with 0·1 per cent. of carbon, dissolving anodically in a soln. of sodium sulphate, the current efficiency and the current density, in amperes per sq. cm., were:

Current density . . .	0·013	0·020	0·027	0·034
Current efficiency . .	99·9	99·6	99·4	99·1 per cent.

indicating that as long as iron remains active, the current efficiency diminishes slightly as the potential increases. The current efficiency during the anodic dissolution of passive iron, when the current density is 0·0005 amp. per sq. cm., is 1·09 for iron with 0·1 per cent. of carbon; 1·21 per cent. for iron with 0·4 per cent. of carbon; 1·24 per cent. for steel with 1·1 per cent. of carbon; and 4·75 per cent. for cast iron with 3·5 per cent. of carbon. The greater effect with cast iron is attributed to the high carbon-content and coarser structure. Electrolytic iron under similar conditions became active. Passive iron is thus slightly attacked and a comparison of a passive iron anode with a non-corrodible platinum anode in $0{\cdot}1N$-soln. of ferrous and ferric sulphates furnishes the curves, Fig. 403, which show that the potential of passive iron is rather less than that of platinum. G. R. White also showed that iron dissolves anodically in a soln. of sodium nitrate when the current density is low, say, 0·3 amps. per sq. dm., and the current efficiency is 99 to 101 per cent.; but if the current density is raised to 1·7 to 3·3 amps. per sq. dm., the iron becomes passive, and only 0·3 to 1·1 per cent. of the current is then employed in the corrosion of iron. U. R. Evans observed that the relatively small dissolution of iron which occurs when iron is passivated occurs mainly along the water-line, just where any protective skin, which may be formed, breaks down most readily; as a result, a passive electrode through which a current has been flowing some time, may be deeply corroded along the water-line and unchanged over the immersed portion. This attack is not due to contact with the oxygen of the air—Fig. 403—since in the passive state, oxygen bubbles are freely given off all over the immersed portion; when the anode is in the active state, it is often much less attacked near the water-line than it is elsewhere.

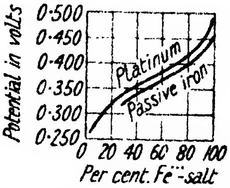

Fig. 403.—The Potentials of Passive Iron and of Platinum.

In general, the corrosion of iron is a result of the electrochemical action caused by the passage of currents between portions of the metal which are at different potentials with respect to the electrolyte in contact with them. Differences of potential with a homogeneous metal may be produced by differential aeration. Two pieces of the same electrolytic iron, similarly ground, were found by A. L. McAulay and S. H. Bastow to give widely different potentials when immersed in an electrolyte. In general, when a piece of iron is placed in an air-free electrolyte, there is a stable potential to which it tends, probably ultimately determined by the hydrogen-ion concentration of the soln. It does not immediately acquire this potential, but after prolonged immersion the stable condition, which proved to be easily reproducible, is attained, and the behaviour of the metal when subjected to experiments using this condition as a starting-point is also reproducible. Mild steel, and cast iron behave similarly, and a difference in composition has but little effect provided that it is not such as to produce air passivity, as in the case of "stainless" steel. Such steel shows completely different behaviour: it resembles a noble metal, is easily polarized by minute currents, and shows no very definite normal potential. The potential which an iron electrode reached after prolonged immersion in an air-free electrolyte was taken as standard. In $0{\cdot}5N$-potassium sulphate this is between 0·75 and 0·80 volt on the sat. calomel scale, the actual value probably depending on the p_H of the soln. When electrodes in the standard state are exposed to air, and then re-immersed in the same electrolyte, they recover the standard state. The film which is responsible for the corrosion current increases in protective power and resistance to destruction with the time of exposure of the iron to air up to about 2 hrs., after which but little further change takes place on further exposure. When this stage is reached, the immersion of the iron in air-free $0{\cdot}5N$-potassium sulphate causes a destruction of the ennobling film in about an hour, and a consequent return of the metal to the standard state in this time. Some film is formed even in the shortest exposures it is possible to give. The destruction of the film is due to action by the electrolyte, it is not destroyed if the electrode is merely left in contact with an inert gas after exposure. More drastic oxidation, such as anodic treatment in alkali-lye, produces a film which takes considerably longer to destroy on exposure to electrolyte than any that are air-formed; eventually, however, the same standard state is achieved in each case. The passage of corrosion currents has no effect on the ennobling film that gives rise to the potential difference which produces them. The potentials are modified temporarily owing to polarization effects, but these effects rapidly disappear when the current is stopped, leaving the film unchanged except for the action of the electrolyte.

A. J. Allmand and R. H. D. Barklie, M. le Blanc, A. Brochet and J. Petit, A. Löb, and R. Ruer compared the corrosion of iron by direct and alternating current. W. J. Shutt and V. J. Stirrup found the time of passivation of iron in $2N$-H_2SO_4 with current densities, D amp. per sq. cm., at 20°, to be:

D . .	0·78	0·911	1·40	2·21	3·23
Time . .	6·01	4·29	2·19	0·86	0·19 secs.

and at 6°:

D . .	0·729	0·923	1·56	2·22	2·57
Time . .	4·44	3·00	0·69	0·32	0·19 secs.

The time of recovery was 0·93 sec. at 20° and 3·21 secs. at 6°.

W. J. Müller studied the time required to produce passivity with an iron anode treated with unit current density in sulphuric acid of different concentrations, and found:

H_2SO_4 . . .	0·06	0·24	0·48	0·94	1·75	3·13	4·88	9·14	13·2
Time (secs.) . .	0·22	0·26	0·60	1·84	2·99	2·99	2·10	1·54	0·92

Increasing the concentration of the acid first decreases the liability to passivity to a minimum with about $3N$-H_2SO_4, and after that the tendency to passivity increases. The effect of high acid concentrations may be attributed to the depression of the solubility, S, of heptahydrated ferrous sulphate in the acidic soln., but the short time needed with low acid concentrations cannot be so explained, but it may be due to the formation of basic salts, in place of hydrated sulphate, as a covering (protective) layer. The activity coeff. for sulphuric acid has a minimum value when the time of passivation is a maximum. The time of passivation is greatly affected by temp., being doubled by a rise of 10°. W. J. Müller found that the time of passivation, t, of iron as anode in soln. of sodium sulphate follows the rule $t=a+b\log(e_m-\epsilon)/(\epsilon-e_s)$, where a and b are constants; e_m denotes the reversible potential of the metal in the pores; e_s, the potential of the coating; and ϵ, the measured potential of the electrode at the time t. The potential-time curves of iron and its alloys were examined by R. May, A. Travers and J. Aubert, W. J. Shutt and V. J. Stirrup, H. G. Byers and co-workers, A. Smits, C. W. Bennett and W. S. Burnham, E. S. Hedges, E. P. Schoch, F. Förster, C. Fredenhagen, E. Heyn and O. Bauer, V. Kohlschütter and H. Stäger, M. Mugdan, U. R. Evans, and W. J. Müller and co-workers.

L. C. Bannister and U. R. Evans used soln. of potassium chromate, and of potassium chloride, and observed that when a metal is covered with a porous film of oxide, it may furnish any value between the potentials of the clean metal and that of the solid oxide. If the oxide film is highly discontinuous, the measured potentials will approach that of the film-free metal—A, Fig. 404; if the pores in the skin of oxide are very small, the measured potential will be higher—B, Fig. 404; and in C, Fig. 404, on the assumption that the elevated potential is due to the high

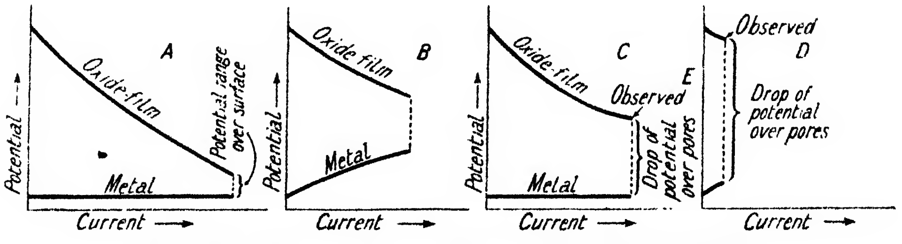

FIG. 404.—Potential Curves of Metals with a Film of Oxide.

resistance imposed by the narrowness of the pores. If, when this stage is attained, the break-down extends from the original weak points, the potential will fall, first rapidly, and then slowly, as the conditions approach the limiting case of *A*, Fig. 404. The shutting off of oxygen by secondary rust will contribute to the fall. Conversely, if repairing conditions prevail, causing the pores to become narrower or less frequent, or rendering the film thicker, the measured potentials will rise. In the limiting case, the pores vanish, and the potential becomes equal to that of the solid oxide—*D*, Fig. 404. It follows, therefore, that a rising potential indicates that weak points in the film are being repaired; and a falling potential, that the break-down is extending; a high final potential indicates that the metal resists attack, a middle value indicates slight rusting; and a low value, profuse rusting. A treatment which increases the resistance of iron to attack, raises the potential; and a treatment which favours corrosion, lowers the potential. The anodic overvoltage was studied by E. Newbery, U. R. Evans, and E. Liebreich and W. Wiederholt. The abrupt change of potential, observed by F. Flade, and others, to occur when iron, as anode in sulphuric acid, becomes passive, was found by W. Rathert to be different from the abrupt change which occurs when the passive metal becomes active. C. F. Holmboe observed that in the anodic passivation of different forms of iron and steel, the rule that the passivation is greater the greater the degree of purity of the iron, is not of general application.

If the potential of an iron anode which has been passivated in a soln. of ferrous sulphate be measured at definite intervals of time, the metal becomes activated; taking time in seconds after the interruption of the current, and referring the potential to a normal calomel electrode:

Time . .	3	12	21	32	40	49	55	64	69	75
Volts . .	0·300	0·265	0·254	0·238	0·220	0·202	0·180	0·130	−0·420	−0·550

The results represented by curve Fig. 405 were obtained with a soln. of 0·473 mol of ferrous sulphate per litre, on an automatic recorder, by C. A. L. de Bruyn. The potential first falls rapidly, *ab*, then slowly, *bc*, and finally, rapidly again, *cd*. The iron is passive until the second rapid decrease occurs. During anodic polarization, hydrogen is displaced by oxygen; when the current is interrupted, the absorbed oxygen is gradually destroyed by the hydrogen diffusing back. The retardation of the activation by the oxygen gradually decreases, and when the concentration of the oxygen is reduced to a low enough value, a rapid change to the active state occurs and the iron then contains hydrogen. The proportion of ferric ions in the soln. is also of importance since they retard the process of activation and favour passivation. The results II, Fig. 405, were obtained with a soln. to which 0·00024 mol per litre of $FeCl_2$ was also added; curve III, with 0·00036 mol $FeCl_2$; and curve IV, with 0·00048 mol $FeCl_2$. This shows that Cl′-ions are powerful catalysts in accelerating the activation which is favoured by a rise of temp.; thus, at 93°, the polarizing current, in milliamps. per sq. cm., is 1·0; at 79°, 0·6; and at 64°, 0·3.

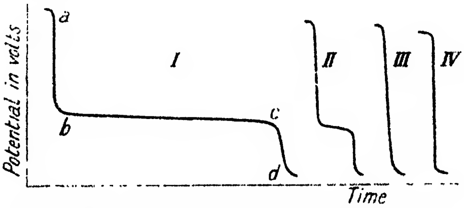

FIG. 405.—The Activation of Passive Iron.

In general, under the conditions necessary for producing the passive state, the anodic potential of iron is reduced. According to J. F. Chittum, in conc. nitric acid soln., the anodic potential of the iron is reduced to a much lower value than is thought to be accounted for by the presence of an insoluble oxide, even by a higher oxide, if any such could be formed under the conditions. In alkaline soln., the anodic potential of iron is reduced to a lower value than can be explained by the presence of an insoluble oxide, and the higher oxide, FeO_2, is soluble in most alkaline soln. Iron, if not disturbed, dissolves very slowly in conc. nitric acid; and in alkaline soln., differential passivity accompanies differential aeration.

The potential of iron in a finely-divided state, as in amalgams $Fe(Hg) \rightarrow Fe^{\cdot\cdot} + 2\oplus$, was shown by W. H. Hampton, and W. J. Sweeney to be 0·441 volt at 25°; and J. C. Warner, and W. J. Sweeney showed that the e.m.f. of a cell $Fe \mid Fe(OH)_2$ sat. soln. $\mid H_2$ is 0·169 volt at 25° with hydrogen at 1 atm. press.; if less than this press., the potential is greater. J. F. Chittum defines passivity as the "tendency of iron to exhibit a potential lower than that of an iron amalgam under the same conditions if the amalgam should behave like sodium amalgam." According to J. F. Chittum, soft iron, and annealed and alloy steels are in equilibrium with $Fe(OH)^{\cdot}$-ions over the range $p_H = 1·0$ to 6·0 when no oxidizing agent is present; and the slope of the curve for the potential with different concentrations of the $H^{\cdot}$-ions is different if chlorides and sulphates are present. Tempered steels are in equilibrium with a higher oxide of iron with values of p_H from 3·0 to 6·0, presumably because the higher oxide is inclosed in surface crevices. In the presence of oxidizing agents, soft iron, and annealed, ordinary and alloy steels are in equilibrium with $Fe(OH)^{\cdot}$-ions over the range $p_H = 1·0$ to 3·0, and in equilibrium with a higher oxide of iron over the range $p_H = 4·0$ to 6·0. With values of p_H exceeding 6·0, the kind of iron oxide with which the metal is in equilibrium is soluble, and as its solubility increases, the tendency for this kind of iron to revert to metallic iron increases to nearly a constant value. This is true only of a higher oxide of iron which is increasingly soluble in alkaline soln. as a ferrate. Consequently, in soln. with p_H exceeding 6·0, the iron behaves as the electrode $Fe + 3H_2O \rightarrow FeO_3'' + 6H^{\cdot} + 4\oplus$. The higher oxide is here assumed to be FeO_2, and it is concluded that a rod of iron behaves as the electrode $Fe + 2H_2O \rightarrow FeO_2 + 4H^{\cdot} + 4\oplus$ except under conditions where the oxide dissolves or is reduced. In the absence of oxidizing agents, or in the presence of reducing agents in soln. with values of p_H between 4·0 and 9·0—the neutral range—the condition unfavourable for the higher oxide electrode is the absence of sufficient oxygen for the catalytic oxidation of the secondary products of corrosion, *e.g.* ferrous ions, should the higher oxide be reduced, or the hydrogen be depolarized if the hydroxyferrous iron electrode is established. This condition may occur when oxygen is absent, or when only a limited supply is present. When the $H^{\cdot}$-ion concentration is greater than corresponds with $p_H = 3·0$, and in the absence of strong oxidizing agents, the higher oxide is unstable, and is largely reduced to the ferrous state. With conditions unfavourable for the existence of the higher oxide, the iron behaves like the electrode $Fe + H_2O \rightarrow Fe(OH)^{\cdot} + H^{\cdot} + 2\oplus$; and the electrode $FeO_2 + 3H^{\cdot} + 2\oplus \rightarrow Fe(OH)^{\cdot} + H_2O$ is present before the iron behaves as a hydroxyferrous ion electrode. The cathode potential of the latter electrode is greater than that of the electrode $FeO_2 + 4H^{\cdot} + 4\oplus \rightarrow Fe + 2H_2O$ until the electrode $Fe + H_2O \rightarrow Fe(OH)^{\cdot} + H^{\cdot} + 2\oplus$ is established; the hydroxyferrous ions are produced except in alkaline soln. where they are catalytically oxidized to the higher oxide through the intermediate formation of a peroxide. When the hydroxyferrous ion electrode is established, it is assumed that there will be both the higher oxide electrode and hydrogen electrode to behave as cathodes.

The iron electrode has its greatest anode potential when it is covered with a film of water, because the lack of polarity in the film prevents the dissolution of the FeO_2 and the presence of FeO_3''-ions; that is, the reaction $FeO_2 + 2OH' = FeO_3' + H_2O$ is suppressed because of the lack of OH'-ions, and the electrode $Fe + H_2O \rightarrow FeO_2 + 4H^{\cdot} + 4\oplus$ has its greatest potential because of the small concentration of the $H^{\cdot}$-ions. The iron electrode has its greatest cathode potential when it is covered with a conc. acid soln. of a strong oxidizing agent. There is then built up a high local concentration of $Fe^{\cdot\cdot\cdot\cdot}$-ions, on account of the solubility of FeO_2 in conc. acid soln., according to the reaction: $FeO_2 + 2H_2O \rightarrow Fe^{\cdot\cdot\cdot\cdot} + 4OH'$, and the stability of the $Fe^{\cdot\cdot\cdot\cdot}$-ions, in the presence of a strong oxidizing agent.

In J. F. Chittum's theory of passivity it is assumed that ordinary iron is passive, and the active iron is the result of a chemical reaction in which iron behaves as a higher oxide electrode, and dissolves in the higher state of oxidation. The time observed by W. J. Müller to be required for the production of the passive state by anode polarization is the time it takes a reversal of the electrode $FeO_2+3H^{\cdot}+2\ominus \rightarrow Fe(OH)^{\cdot}+H_2O$ to raise the concentration of the higher oxide until the iron behaves as the electrode $Fe+2H_2O \rightarrow FeO_2+4H^{\cdot}+4\oplus$.

U. R. Evans pointed out that high $H^{\cdot}$-ion conc. and low current density favour anodic corrosion at a high efficiency, while a low $H^{\cdot}$-ion conc. and high current density favour passivity. Under intermediate conditions it is sometimes possible to produce a condition of **periodic dissolution** in which the iron alternates periodically between the active and passive states—*periodic passivity*, Fig. 406, by A. Smits and C. A. L. de Bruyn. The phenomenon was first mentioned by G. T. Fechner in 1828. Observations were also made by A. Adler, M. Faraday, C. Fredenhagen, H. L. Heathcote, E. S. Hedges, J. F. W. Herschel, J. P. Joule, R. Kremann, W. Kistiakowsky, A. J. Maas, W. Rathert, W. Rollmann, and C. F. Schönbein. J. F. W. Herschel noticed that the current sometimes surges back and forth, and the evolution of gas shows similar pulsations, somewhat resembling those obtained by A. Avogadro with an iron-bismuth couple in conc. nitric acid. A. Smits and C. A. L. de Bruyn pointed out that since the passive state of iron can be removed by bringing the metal in contact with soln. containing halogen ions, it might be possible to set out periodic phenomena which would make their appearance if the halogen ions were added to the electrolyte during anodic polarization. When iron is anodically polarized in a soln. of ferrous sulphate, and a soln. of ferrous chloride is introduced, the catalytic influence of the chlorine ions manifests itself in a fall of potential; if the addition of ferrous chloride is continued, at a given stage, a rapid fall of potential occurs as the iron passes from the passive to the active state. For a given rate of dissolution of iron, determined by the current density, there exists a Cl'-ion conc. at which, at any given moment, the chance of iron remaining passive is just equal to its becoming active. If, at this moment, activation occurs, then whilst the ion anode dissolves extremely slowly when in the passive state, when it becomes active, it passes into soln. at a rate which corresponds with the strength of the current. The influence of Cl'-ions on the anode now changes, for the extent to which the Cl'-ions dissolve in the metal depends on the rate at which the metal ions pass into soln. If this rate be great, fewer Cl'-ions can be dissolved in the metal surface than when the rate of dissolution is small. This changes the state of the active iron. If the iron becomes passive, the soln. of Cl'-ions in the metal again becomes large, and at a definite moment activation occurs. By measuring the potential immediately after the current is interrupted, A. Smits and C. A. L. de Bruyn observed that if the current density is not great enough to cause the iron to become passive, instead of being less negative, the iron becomes more strongly negative, showing that after anodic polarization, iron exhibits a change of potential in the opposite direction to that observed during the passage of the current. Immediately after the anodic polarization of iron, the potential passes through a minimum and then rapidly rises to its original value. The periodic phenomenon was investigated by W. Ostwald, A. Smits and C. A. L. de Bruyn, E. S. Hedges and J. E. Myers, A. Adler, E. S. Hedges, R. S. Lillie, and C. Fredenhagen.

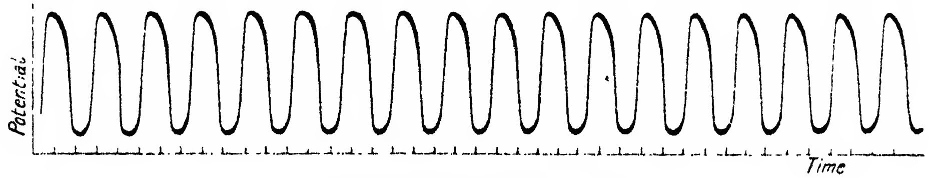

FIG. 406.—Periodic Passivity.

R. S. Lillie showed certain analogies in the activation of passive iron and an irritable and conducting living element like a nerve fibre or a muscle-cell. Thus, when passive iron wire is dipped into nitric acid of a concentration above a certain critical concentration, the activation is only temporary, and is followed immediately by an automatic return of the metal to the passive condition. Activation initiated at any part of such a wire is thus transmitted rapidly along its whole length in a wave-like manner, each region as it becomes active activating the region adjoining, and immediately becoming passive again itself. In order to maintain activity in the living system, constant repetition of stimulation is necessary, and, similarly, chemical activity in a passive wire immersed in nitric acid (sp. gr. 1·42) is an automatically self-limiting process, which can be maintained only by repeated contacts with the activating metal. After a wire has been activated in the usual manner, and has reverted to the passive state, it is found to be impossible to reactivate it until a definite interval of time has elapsed.

G. Wetzlar could not detect any influence by a magnetic field on passive iron, but, according to E. L. Nichols, E. L. Nichols and W. S. Franklin, and T. Andrews, magnetization is also an activating agent, for magnetized steel bars are less passive in warm nitric acid than unmagnetized ones. Thus, T. Andrews found that iron which remained passive in nitric acid of sp. gr. 1·42 up to 90°, became active at 51° when placed in a magnetic field. H. G. Byers and co-workers also observed that the current density required to make iron passive is increased when in a magnetic field. Thus, with 5 per cent. nitric acid, and with hard steels, the current densities in milliamps. per sq. cm. required to make the iron passive without a magnetic field were respectively 382 and 411; with a current for the N-pole, respectively 426 and 466; and with a current for the S-pole, respectively 454 and 503. Hence, soft steel is affected to a greater extent than hard steel; and the positive pole of a magnet is more easily rendered passive than is the negative pole. H. Eggert observed that the anodic behaviour of iron in non-aqueous electrolytes is similar to what it is in aq. electrolytes. Z. C. Mutaftschieff observed that the rate of attack of iron by nitric acid of sp. gr. 1·39 to 1·41 is not affected by the application of magnetic field, but with acid not sufficiently concentrated to effect passivation, the rate is much increased. G. Berndt, T. Gross, R. S. Dean, and U. Sborgi and A. Borgia also studied the effect.

It is probable that most of the metals may be passivated under suitable conditions, for the phenomenon has been recorded with the metals tin, lead, cadmium, zinc, magnesium, silver, copper, tungsten, molybdenum, uranium, platinum, ruthenium, gold, manganese, vanadium, columbium, tantalum, bismuth, chromium, aluminium, iron, cobalt, and nickel. The most satisfactory theory to account for the passivity of iron assumes that it is due to the formation of a superficial film of a product of the action of oxygen on the metal. This, said M. Faraday, fits in with the general observation that the passive state is produced by oxidation processes; that iron coated with oxide is insoluble in acids; and that the passive condition disappears when the metal is polished. In 1836, in reply to a letter from C. F. Schönbein, M. Faraday wrote:

> My strong impression is that the surface of the [passive] iron is oxidized, or that the surface particles are in such relation to the oxygen of the electrolyte as to be equivalent to oxidation; and having thus their affinity for oxygen satisfied and not being dissolved by the acid under the circumstances, there is no renewal of the metallic surface and no reiteration of the attraction of the successive particles of iron on the elements of successive particles of the electrolyte.

G. T. Fechner, in 1828, tried and rejected the hypothesis that the passive state is due to the formation of a protective insoluble film; and C. F. Schönbein contested M. Faraday's explanation chiefly on the ground that the passive state persisted in dil. nitric acid which would be expected to dissolve a film of any known oxide if it were formed. M. Faraday, however, pointed out that his explanation had been misunderstood, for he meant *not an actual oxidation but a relation*; a delicate equilibrium of forces where there is association without combination. R. Borchers suggested that passivity is produced by the combination of oxygen atoms with surface iron atoms, but B. Strauss failed to obtain any evidence of the formation of such a layer. E. Ramann assumed that the film is ferrosic oxide which dissolves in dil. but not in the conc. nitric acid; H. L. Heathcote found that the reverse is true of ordinary ferrosic oxide. The nature of the blue film which forms on iron which has been heated to about 290° approximates nFeO.Fe_3O_4, as indicated elsewhere. C. E. W. Belck observed that rods heated 15 mins. in air are passive to nitric acid of sp. gr. 1·2, and to a soln. of copper sulphate. F. Haber and F. Goldschmidt suggested that the film is composed of an oxide $Fe_2O_3.2Fe_3O_4$, which is an electrical conductor. H. L. Heathcote showed that highly polished rods, kept cool during the polishing, always show a dulling of the surface when immersed in conc. nitric acid. The oxide film hypothesis was favoured by H. S. Allen, T. Andrews, W. Beetz, C. W. Bennett and W. S. Burnham, W. R. Dunstan and J. R. Hill, O. Eisenhut, U. R. Evans and co-workers, F. Flade, C. Fredenhagen, H. Freundlich and co-workers, H. Gautier and G. Charpy, F. Goldmann and E. Rupp, C. M. Gordon and F. E. Clark, G. Grube, F. Haber and co-workers, H. L. Heathcote, E. S. Hedges, N. A. Izgarischeff, W. Kistiakowsky, P. Krassa, B. Lambert, E. Liebreich and W. Wiederholt, L. McCulloch, W. Manchot, W. D. Richardson, E. Pietsch and E. Josephy, F. J. Micheli, E. Müller and F. Spitzer, W. Muthmann and F. Frauenberger, H. M. Noad, E. Ramann, E. K. Rideal, W. Rollmann, R. Ruer, E. P. Schoch, L. Tronstad, G. Wetzlar, G. Wiedemann, and H. Wieland and W. Franke.

W. J. Müller and J. G. Königsberger found that the reflecting powers of iron mirrors are always the same when they have been immersed in alkaline soln., both in their natural condition, and when polarized anodically and cathodically. This was taken to prove that the passive state is not due to the formation of a film of oxide; but A. Findlay showed that the argument breaks down because a film of molecular dimensions might suffice to produce passivity, a thickness of the order of the wave-length of light would be required to affect the reflecting power of the metal. H. Freundlich and co-workers have shown that the optical properties of passive iron are not the same as those of active iron. On admitting oxygen to the surfaces of mirrors of pure iron, a sudden change occurs in the phase relations of the two components of elliptically polarized light reflected from the metal. This is attributed to the formation of a film of oxide. The chemical activity of the iron at the same time is reduced so that the iron becomes unaffected by nitric acid of concentrations which have a marked action on iron mirrors if introduced before the admission of oxygen. H. Freundlich and co-workers, F. Förster, E. Liebreich, I. Langmuir, G. Patscheke, L. Tronstad, and H. S. Allen also showed that the surface of passive and active iron have different optical properties, although E. Becker and H. Hilberg could not find much difference. H. S. Allen found that dry active iron exhibits a considerably higher photoelectric activity than the metal which has been passivated by immersion in conc. nitric acid, or by anodic polarization in dil. sulphuric acid. He said that this is in agreement with the assumption that the cause of passivity is to be found in the condition of the gaseous layer at the surfaces of the metal. Analogous results were obtained by W. Frese. H. L. Heathcote said that the assumption that passivity is produced by a protective film of gas does not explain how dry passive iron, rubbed lightly with cotton-wool, can retain its passivity in vacuo. W. J. Müller, W. J. Müller and W. Machu, and W. Machu discussed the effect of a surface film on the potential of a metal. E. Liebreich and W. Wiederholt measured the anodic and cathodic behaviour of iron in 1·0 2N-H_2SO_4 and found discontinuities corresponding with passivity which were explained by the formation of a film of a higher oxide. C. Benedicks and P. Sederholm, and H. Hauschild made observations on surface films. E. Rupp and E. Schmid studied the reflection of electrons from passive iron but could not identify the film which is formed with films of hæmatite or magnetite. J. Gillis, and F. Krüger and E. Nähring examined passive iron by the X-ray method and concluded that films of oxide thicker than 10^{-7} cm. are not present on the surface of the passive metal. This argument is not of much weight when it is remembered, as pointed out by U. R. Evans, that it is highly improbable that films of this order of magnitude would produce the oxide lines in the X-radiograms. The formation of invisible films of oxide on the surface of iron, etc., has been demonstrated by W. H. J. Vernon, H. S. Allen, W. Frese, E. Liebreich, W. Kistiakowsky and I. V. Krotoff, A. L. Bernoulli, T. Fujihara, and F. H. Constable. L. Tronstad added that the film of oxide on passive iron is not totally destroyed on activation, but it becomes porous and spongy; on re-passivation, the holes are refilled with oxide, and the film becomes thicker. The film has an index of refraction of about 3·0, and is about 30 A. thick. The partial destruction of the film on activation is more pronounced on the grains of ferrite than on the grains of cementite. W. Boas and E. Rupp found that iron of passive state yields several electronic beams in addition to those shown by iron in the active state. F. P. Bowden and E. K. Rideal found that the true surface area of metals greatly exceeds the apparent area, especially after abrasion or similar treatment, presumably owing to the opening of innumerable fissures on the surface.

U. R. Evans and co-workers also studied the distribution of the oxide films on such surfaces. U. R. Evans said:

> The ferric oxide film usually present on iron is rapidly destroyed by dil. sulphuric acid owing to the formation of the circuit: Fe | Acid | Oxide; the ferric oxide suffers cathodic reduction to ferrous oxide which is rapidly dissolved by the acid. If the reduction is prevented by the presence of an excess of chromic acid, or by anodic treatment of the specimen as a whole, the film can remain in contact with 0·1M-H_2SO_4 for hours without change. This explains why iron can remain passive in acidic soln. during anodic treatment. The explanation of anodic passivity in acid soln. is as follows. When lead is anodically treated in sulphuric acid, the conversion of the metallic surface into sulphate will protect the metal below, but with an iron anode this will only occur when the liquid has locally become saturated with ferrous sulphate. At that stage, any further current must be expended on the production of oxygen, and although the bubbles stir the liquid, dispelling the saturated layer, the metallic surface may in the meanwhile have been converted into ferric oxide, which will protect the metal so long as the current continues to flow. Indeed, a short interruption of current can also be tolerated without resumption of activity, and this seems to depend on the presence of an oxygen supercharge, which prevents reduction to the rapidly-soluble, lower oxide.

U. R. Evans also observed that:

> The film produced by oxidizing agencies on metals necessarily ceases to thicken as soon as it becomes sufficiently protective to exclude the oxidizing agent. The considerable thickening of the film which occurs on freshly abraded iron proceeds through the production of cracks due to the internal stresses left by the abrasion; only when this cracking of the film has ceased will the thickening come to an end. Since a cracked film produces no passivity, coarsely ground metal requires a longer time to become passive than finely ground metal, and develops a thicker film, especially if substances be present in the solution which are capable of penetrating the smallest cracks (*e.g.* chlorine ions). The films obtained from abraded specimens attain thicknesses of the order 10^{-6} cm., and can be isolated from their bases and studied. In the presence of a regulated amount of penetrating anions, the thickness may come to exceed 4×10^{-6} cm., and the films will then give rise to interference tints. Great thickening is only to be obtained under conditions which render the material less perfectly protective, and there is naturally some danger that the film will break down altogether. Under suitable conditions, however, considerable thickness may be reached. Specimens were prepared showing the complete sequence of interference tints right up to the late second-order colours; although produced at room temp., the sequence of colours is the same as that of the temper colour obtained at high temp. and the tints are, on the whole, brighter.

According to W. Manchot, 3 per cent. ozone in the cold acting on the surface of a metal covered with a thin film of oxide, produces a visible deposit of oxide. This occurs with iron which has been passivated by immersion in nitric acid, or anodically in dil. sulphuric acid, which instantly reacts with the ozone showing that its surface is coated with oxide; but active iron shows no such sensitiveness towards ozone. E. Müller and F. Spitzer found that iron, cobalt, or nickel, when anodically polarized in alkali-lye, becomes coated with the respective oxides, and at the same time becomes passive. They also avoided the presence of the metal by examining the behaviour of platinum electrodes coated with the oxides of the respective metals. These electrodes, on anodic polarization, behaved like passive electrodes of the metals themselves. All this is in agreement with the assumption that the passivity of the metals is produced by a coating of oxide.

F. Haber and F. Goldschmidt showed that iron rendered passive by anodic polarization in alkaline soln. without losing its metallic lustre, becomes coated with a layer of hydroxide on adding halogen ions. F. Haber and W. Maitland found that a very conc. soln. of alkali renders passive iron active and that it acts by dissolving a superficial film of oxide. P. Krassa showed that in boiling conc. alkali soln. polarization of the iron is followed by the anode becoming passive; and the passive state is preceded by the formation of a visible coating on the metal. G. Grube found that in the electrolytic oxidation of ferrocyanides, anodes of iron, nickel, cobalt, copper, lead, and silver in neutral soln. of potassium ferrocyanide and ferricyanide, and anodes of iron, lead, silver, and zinc in alkaline soln. of the same salts, become strongly passive owing to the formation of an insoluble coating on the anode. In some other cases there was no evidence of the formation of an insoluble film, and passivity was ascribed to an oxygen charge retarding the liberation of the cations of the metal. E. S. Hedges concluded that passivity produced by anodic polarization and by chemical means is the result of the formation of a film of oxidized material.

W. Ostwald said that none of the known oxides can produce passivity, and therefore unknown oxides must be unstable because of the ease of the transition from the passive to the active state. According to C. W. Bennett and W. S. Burnham, the various objections which have been made to the oxide-film hypothesis do not apply if it be assumed that an unstable oxide is formed during the passivation of iron, and that this oxide becomes stable when it is absorbed by metallic iron. The surface film of the adsorbed unstable oxide protects the metal from the action of the acid. The increase in the stability of the oxide through adsorption is compared with the effect of sodium hydroxide on a boiling soln. of copper sulphate containing a small amount of manganese sulphate; a precipitate of blue copper hydroxide, $Cu(OH)_2$, is obtained. Cupric hydroxide is probably precipitated if the manganese salt be omitted, but it is decomposed so quickly that cupric oxide, CuO, alone appears as the product of the reaction. The manganese salt, if it be present, is absorbed by the cupric hydroxide which thereby becomes stable under conditions where it would be decomposed if alone. C. W. Bennett and W. S. Burnham said (i) a considerable amount of oxide may be adsorbed without its changing the appearance of the surface. Iron becomes passive when dipped in a soln. of potassium ferrate, and it is assumed that the unstable oxide which produces passivity cannot be higher than FeO_3, and possibly is FeO_2. C. Fredenhagen also noticed that passive iron anode yields a substance which evolves oxygen when chlorides are present. This may be due to the hydrochloric acid formed at the anode reacting with the higher iron oxide to furnish oxygen. Active chromium becomes passive in soln. of chromic acid or sodium chromate, and as in the case of iron in a soln. of potassium ferrate; it might be inferred that the oxide formed on the chromium cannot be higher than CrO_3; but CrO_3 is soluble in the liquid, and therefore C. W. Bennett and W. S. Burnham infer that the unstable oxide is CrO_2, which, on adsorption by the metal, makes the chromium passive. When lead is passivated by making it the anode in an electrolyte of dil. sulphuric acid, the film of lead dioxide, PbO_2, is stable, visible, and unquestioned. U. R. Evans and co-workers showed that the passive film after it has been separated from passive iron, consists of ferric oxide or in part of hydrated ferric oxide with some metal inclusions. W. D. Bancroft, and D. R. Hale found that iron rendered passive by anodic treatment has at first a high potential due to a surcharge of oxygen which may be present as an unstable higher oxide, but A. Smits pointed out that when the iron is allowed to stand, its potential sinks with a marked arrest at about $E_H = 0.54$ volt. Hence, added L. C. Bannister and U. R. Evans, if the original high value is due to a higher oxide, the arrest represents the formation of ferric oxide; the electrode potential is an unsatisfactory test for the oxygen-content of a solid phase; and a higher oxide is not necessary for explaining passivity. W. J. Müller and W. Machu discussed the nature of the films on passive iron. The oxide-film hypothesis of passivity was opposed by G. T. Fechner, C. Fredenhagen, W. Hittorf, F. Krüger and E. Nähring, B. Lambert, M. Martens, W. J. Müller and J. Königsberger, M. Mugdan, W. Muthmann and W. Frauenberger, J. M. Ordway, W. Rathert, and C. F. Schönbein.

In W. Hittorf's so-called *experimentum crucis* to prove that the passivity of chromium is not due to a solid film of oxide, it was shown that chromium becomes passive when made the anode in a soln. of potassium iodide. The experiment is not really decisive, because the hydrogen liberated at the cathode does not reduce the film of chromium oxide which is probably formed on the chromium anode by depolarization of the oxygen present. Adsorption is usually decreased with rise of temp., and the liberated oxide being unstable when freed, is accordingly liable to decomposition. The gradual adsorption of the oxide would give a smooth voltage-current curve free from breaks, since the corresponding e.m.f. would vary continuously from that of metallic iron to that of the adsorbed oxide. The oxide film is not reduced by air, it merely decomposes liberating oxygen, just as many substances liberate oxygen when they are oxidized to higher oxides which decompose readily back to the original oxide. The instability of wet passive iron in air or in vacuo is due to the gradual soln. of the adsorbed oxide in the liquid film; a dried piece of passive iron is comparatively stable, for it can be kept indefinitely. Instead of assuming that the passivity of iron is produced by a film of oxide, others have suggested that a film of oxygen, or a film of a solid soln., or something less definite than the oxide is formed. This view was taken by H. G. Byers and S. C. Langdon, F. Flade, C. Fredenhagen, G. Grube, E. Jordis, I. Langmuir, W. Muthmann and F. Frauenberger, G. Osann, P. de Regnon, E. Pietsch and co-workers, G. M. Schwab and E. Pietsch, I. N. Stransky and Z. C. Mutaftschieff, and G. Tammann.

According to H. O. Forrest and co-workers, the resistance of the stainless chromium steels involves the building up of an insoluble oxide film on the surface of the metal. This film is dense, adherent and not penetrated by the corroding medium, so that it protects the metal from further attack. The rate of attack by oxygenated water during the initial period before the protective film is formed, was found to be of the same order of magnitude with 18·8 per cent. chromium-nickel steel, a 14 per cent. chromium steel, and an ordinary steel. B. Strauss, and R. Borchers attributed also passivation to the union of oxygen with the surface atoms of iron.

E. St. Edme suggested that the film formed during the passivation of iron by nitric acid is iron nitride, not oxide. F. Hanaman discussed the passivity induced by nitridizing the surface of iron by heating it in ammonia gas. A. L. Bernoulli, S. W. Young and E. M. Hogg, A. Mousson, L. Varenne, and C. Fredenhagen said that a surface film of nitrous acid or nitric oxide will make iron passive. W. Beetz, C. F. Schönbein, E. Ramann, and M. Bibart did not agree.

S. W. Young and E. M. Hogg regarded the passive state as the result of a condition of equilibrium between iron and nitrogen peroxide—*vide supra.* When iron is passivated in nitrogen peroxide, a weighable amount of the gas is absorbed by the iron, and on exposure of the passivated iron to moist air, drops of acid liquor are formed on the surface. Iron is capable of absorbing nitrogen peroxide from any soln. in which it is being produced, and the rate of reaction is thereby inhibited. The degree of inhibition will therefore be determined by the concentration of nitrogen peroxide which it is itself capable of maintaining. Since iron passivated by dry nitrogen peroxide is more persistently passive than that which is passivated in nitric acid, it seems probable that the amount of nitrogen peroxide absorbed by iron from even conc. nitric acid is relatively quite small.

C. Fredenhagen said that the passivity produced by anodic polarization in sulphuric acid is different from the passivity produced by immersion in conc. nitric acid, and he suggested that the passivity in the former case is produced by a layer of oxygen gas, and in the latter case, by a layer of nitric oxide. M. Mugdan also attributed the resistance of iron to conc. sulphuric acid to the passivation of the metal; he found that when opposed to the hydrogen electrode, the potential of soft iron in dil. sulphuric acid is 0·2 to 0·3 volt, and in the conc. acid, 0·04 volt; with cast iron the potential is −0·1 volt.

M. P. Appleberg and S. H. Wilkes, and L. McCulloch attributed some cases of passivity to the presence of a sparingly-soluble sulphate film. J. A. N. Friend supposed that the passivity produced by chromic acid is due to the formation of a film of a chromate which is soluble in a soln. of sodium chloride. H. Braconnot, and M. Boutmy and M. Chateau assumed that the passivity in conc. nitric acid is due to the insolubility of iron nitrate in that menstruum, but A. Scheurer-Kestner showed that the extent of saturation of the soln. of iron nitrate in conc. nitric acid, of varying concentration, had no influence on the result. C. Tomlinson, in his work in *catharism*—or the influence of chemically clean surfaces—said that there is no apparent difference between the adhesion of gas on chemically clean surfaces, and the liquid that holds the gas in soln. Conc. nitric acid is a powerful catharizer, and by making the surface of the iron chemically clean enables the acid to adhere to it with force. The formation of a nitrate is prevented because nitrates of iron contain at least 6 eq. of water of crystallization, and this is not present in the stronger acid.

O. Sackur assumed that every electrode contains a certain amount of dissolved hydrogen formed by the interaction of H'-ions in the electrolyte. The H'-ion concentration corresponds with the equilibrium: $M+2H^{\cdot}=H_2+M^{\cdot\cdot}$ for a bivalent metal. The discharged anion—oxygen, halogen, etc.—reacts with and removes the hydrogen. To re-establish equilibrium the reaction proceeds in a direction from left to right, so that the anodic dissolution of the metal is supposed to be a chemical process. Passivity is produced by a slow rate of reaction between the hydrogen and the discharged anion, so that the latter—oxygen, etc.—accumulates on the electrode. Other forms of this hypothesis were suggested by F. Haber and J. Zawadsky, M. le Blanc, E. P. Schoch and co-workers, C. Fredenhagen, H. Kreusler, W. Muthmann and F. Frauenberger, D. Reichinstein, F. Förster, E. Grave, J. Stapenhorst, A. M. Hasebrink, and G. C. Schmidt.

A. Finkelstein attributed the active state to ferrous iron, and the passive state to ferric iron. The inference was based on the change in the electrode potential of iron in mixed ferric and ferrous chloride soln. as the relative proportions of the two salts varied. He regarded ordinary iron as a mixture of ferrous and ferric, whilst ferric iron was considered to be a noble form of the metal produced by a process of oxidation in the passivifying liquid. The ordinary contact e.m.f. measurements place iron near tin in the Volta series, and electrolytic measurements place it near tin in the electrode potential series. This makes ordinary iron appear to be in the ferrous state. According to J. G. Brown, the general chemical properties of iron are more like platinum than tin, and it is more likely that ordinary iron is essentially ferric, and passive, while active iron is ferrous, and the conditions surrounding the surface of ordinary iron are such that when dissolving, it sends ferrous ions into soln. A similar hypothesis was favoured by H. Westling, and W. J. Müller. R. Müller represented the activation of iron as involving the electronic change $Fe\rightleftharpoons Fe^{\cdot\cdot}+2\epsilon$, and the passivation, $Fe\rightleftharpoons Fe^{\cdot\cdot\cdot}+3\epsilon$, so that the change from the active to the passive state is represented by the equation: $Fe^{\cdot\cdot}\rightleftharpoons Fe^{\cdot\cdot\cdot}+\epsilon$. J. B. Senderens, A. Skrabal, J. S. de Benneville, and W. Hittorf seem to have believed that the passive state is produced by the formation of a surface layer of allotropic iron.

There are many references in which the passive state is vaguely attributed to a physical alteration of the surface of the iron. G. Wetzlar attributed the passivation of iron to the assumption of a negative electrical state by the part immersed, while the part not immersed assumes the positive state; J. F. W. Herschel, to a permanent electrical state of the surface of the metal; J. M. Ordway, " to a molecular change induced by momentary electric action set up on first contact of the acid with the metal "; J. F. Daniell, to a change in the relation of the metal to hydrogen and oxygen, possibly as a result of some difference in mechanical structures; J. H. Andrew, to the potential difference between the hydrogenized, amorphous, intercrystalline cement, and the hydrogenized, crystalline phase; and G. C. Schmidt, to the change in the surface tension of the solid metal.

In the electronic theory of A. S. Russell, it is assumed that the orientations of the electrons in the active and passive metal are different. The subject was discussed by I. N. Stransky and Z. C. Mutaftschieff, W. D. Lansing, R. Swinne, U. Sborgi, and A. Smits. M. le Blanc assumed that active iron sends ions into the electrolyte, and that in the case of metals which tend to become passive, these ions combine only very slowly with water: Ion+water⇌Ion hydrate. Accordingly, the concentration of free ions at the electrode becomes so great, and the potential difference between electrode and soln. becomes so large, that the discharge of anions or of oxygen begins. This hypothesis of passivity is based on the observation that even when the ion concentration at the electrode is sufficiently large, polarization occurs both at the anode and cathode in many cases where it was not previously suspected. To explain the facts, a difference between free and hydrated ions is postulated, and it is assumed that the hydration and dehydrations of ions is a relatively slow process.

In the so-called *internal equilibrium theory*, A. Smits assumed that in addition to uncharged atoms and free electrons, iron contains two kinds of ions of different valency—α, or base ions, and β, or noble ions which are in equilibrium. The passive state is assumed when the state of equilibrium is disturbed. During the anodic dissolution of the metal, polarization occurs because the α-ions dissolve more rapidly than equilibrium can be established, and the β-ions collect on the surface of the metal and so make it passive. It also explains why passivity is a surface phenomenon. Ordinary iron always contains hydrogen, and $H^{\cdot}$-ions, like halogen ions, greatly accelerate the change from the passive to the active states, *i.e.* they catalytically accelerate the conversion of α- into β-ions until equilibrium is established. In the anodic soln. of iron, when the current density is such that oxygen is evolved at the anode, all the hydrogen ions, normally present in ordinary iron, are expelled from the surface, and the disturbance of the state of equilibrium between the α- and β-ions reaches a maximum, and the metal becomes passive. The hydrogen soon diffuses from the interior to the surface where it catalytically accelerates the re-establishment of equilibrium, and the metal becomes active again. When iron is immersed in conc. nitric acid, the α-ions dissolve with great rapidity and $H^{\cdot}$-ions are removed from the surface of the metal so that the passive condition is established; with a soln. of ferrous chloride, α-ions dissolve rapidly but passivity is not produced because both the chlorine ions and the halogen ions catalytically accelerate the change from the passive to the active state, and β-ions never accumulate on the surface to produce the passive state. The subject was discussed by H. Gerding and A. Karssen.

§ 27. Alloys and Intermetallic Compounds of Iron.

> It was recommended by C. Hatchett (1803) that a systematic examination of all alloys of metals should be carried out, proceeding from the most simple binary ones to more complicated ternary or quaternary ones. He can hardly have been aware of the extent of his proposed inquiry. If we operated upon only thirty of the known metals, the number of possible selections of binary alloys would be 435, of ternary alloys, 4060, of quaternary, 27,405, without paying any regard to the varying proportions of the metals, and only regarding the kind of metal. If we varied all the ternary alloys by quantities not less than 1 per cent., the number of these alloys would be 11,445,600.—W. S. Jevons.

J. L. Gay Lussac and L. J. Thenard,[1] and J. H. Hassenfratz obtained an **iron-potassium alloy** in preparing potassium by the action of iron filings on potassium hydroxide, where the vapour of potassium happens to come into contact with the iron in the cooler part of the furnace. The alloy is said to be whiter than iron, malleable, and so soft that it will take an impression from the nail. It is also more fusible than iron ; oxidizes in air ; and effervesces with water and dil. acids. C. Girard and J. Poulain obtained an **iron-sodium alloy** or iron-potassium alloy by exposing molten cast iron to the vapours of the alkali metals at 5 to 6 atm. press. The same alloys were obtained by the action of sodium or potassium chloride or carbonate on heated iron ore, fuel, and flux. E. K. Smith and H. C. Aufderhaar discussed the iron-sodium alloys. F. C. Calvert and R. Johnson obtained what they regarded as **potassium triferride**, KFe_3, by heating a mixture of 12 gram-atoms of iron filings, 16 gram-atoms of potassium tartrate, and wood-charcoal in a crucible. The regulus is hard, but it may be hammered and rolled. It is difficult to file. It readily oxidizes in air, and under water. If the charcoal be omitted from the mixture, F. C. Calvert and R. Johnson said that **potassium diferride,** KFe_2, is formed. These observations all require extending and confirming. P. Oberhoffer discussed the binary alloys with the alkali metals. N. Ageeff and M. Zamotorin studied the diffusion of lithium into iron; and J. E. Hurst, the effect of sodium and potassium on cast iron.

Several reports of the analysis of ancient copper figures show the presence of appreciable quantities of iron. Thus, D. Forbes [2] obtained for a statue of Buddha, probably dating from about 900 B.C., found in the remains of a temple at Sooltangunge, on the Ganges: copper, 91·502 per cent.; iron, 7·591; silver, 0·021; gold, 0·005; traces of manganese and nickel; arsenic, 0·079; sulphur, 0·510; and slag, 0·292— sp. gr. 8·29 at 15°. The statue was probably cast from crude or unrefined copper, and was not an intentional alloy. H. Struve obtained from an ancient ornament of sp. gr. 7·224: copper, 89·7 per cent.; iron, 9·1; and tin, 0·63. R. Budelius, V. A. Skinder, and R. Hunt also described some ancient, ferruginous bronzes from Russia; and W. Flight, an ancient Egyptian, ferruginous bronze. Alloys of iron with more or less copper were examined in a desultory manner from the seventeenth through the eighteenth and nineteenth centuries; and from published work over that period, it is impossible to form a clear idea of the influence of copper on iron and steel. J. E. Stead has collected a number of statements, mainly from different metallurgical textbooks, which emphasize the extreme views held by different writers on the subject. L. Savot (1627) referred to some properties of the **copper-iron alloys**; and G. Jars (1774) mentioned alloys containing about 1 per cent. of copper. T. Bergman made experiments on some alloys of copper and iron with and without arsenic, in an attempt to synthesize nickel. C. J. B. Karsten observed that iron can take up only a very small proportion of copper, and copper, only a very small proportion of iron. M. Faraday and J. Stodart examined some alloys, and their properties were measured by R. A. Hadfield. J. Riley said that when the two metals are melted together, the copper and iron separate from one another on cooling, but a perfect alloy is formed if aluminium be also present. F. L. Garrison found that 5 per cent. of copper will alloy with steel, but he doubted if a perfect alloy could be obtained with 10 per cent. of copper. J. O. Arnold believed that free copper was present in iron containing 1·81 per cent. of copper. H. Schneider patented alloys of cast iron with 5 to 20 per cent. of copper; while D. Mushet found that malleable iron can be alloyed with any proportion of copper until it equals or even exceeds the weight of copper. When steel is alloyed with 5 per cent. of copper, he said that none could be detected on the surface or on the fracture; with 10 per cent. of copper, streaks of copper appear on the fractured surface; and with 33·3 per cent., some of the copper segregates at the bottom of the ingot. The solubility of copper, in iron, decreases as the proportion of carbon in the iron increases. D. Mushet, J. E. Stead, P. Breuil, H. Wedding, and W. Müller also noted that the presence of carbon depresses the solubility of copper in iron. W. von Lipin found that grey Swedish pig-iron could be alloyed with 5 per cent. of copper; iron with 0·13 per cent. of carbon dissolved 3·2 per cent. of copper; and iron with 0·43 per cent. of carbon dissolved less than 2 per cent. of copper. E. J. Ball and A. Wingham prepared alloys of steel with 0·8 to 7·17 per cent. of copper; and J. E. Stead and J. Evans, steel with 0·5 to 1·3 per cent. of copper. V. O. Pfeiffer stated that when mixtures of iron and copper are melted in a magnesia crucible in an electric furnace, there is no depression of the f.p. of either iron or copper. Microscopic examinations of the products indicates that iron and copper are mutually insoluble, and that the supposed alloys are really solidified emulsions; the sp. gr. of the two fused metals being nearly equal, and the viscosity of the iron considerable, separation into two layers takes place, only very slowly. When sufficient time is allowed for the separation, the copper layer is found to be free from iron. In a similar manner, copper and iron-carbon alloys are found to be mutually insoluble, although finely emulsified mixtures are readily obtained. P. Breuil said that castings containing less than 4 per cent. of copper show no segregation no matter what per cent. of carbon is present; steels with 0·103 to 0·173 per cent. of carbon showed no segregation with 32 per cent. of copper; steels with 0·282 to 0·798 per cent. of carbon gave a high segregation with 32 per cent. of copper—the lower part of an ingot contained 24·4 per cent., and the interior 74·8 per cent. A. Riche also obtained a homogeneous alloy with 4·5 per cent. of iron; but if the alloy be kept molten for some time, the iron tends to accumulate in the upper layers. T. W. Hogg observed no signs of the segregation of copper in steel containing 0·05 per cent. of carbon; and W. Müller, no signs of separation with 7·7 per cent. of copper in iron with 0·14 per cent. carbon and 0·09 per cent. of sulphur. J. E. Stead added that some of the conflicting statements on the effect of copper on iron have arisen through overlooking the effect of carbon in preventing the two metals alloying. Pig-iron alloys with only a small quantity of copper, whereas purified iron will alloy with any proportion.

Alloys of the two metals were obtained by direct fusion by J. Percy, J. E. Stead, R. Sahmen, A. Portevin, and E. Martin; F. H. Wigham, F. Dannert, P. Oberhoffer, and J. Riley obtained the alloy by the simultaneous addition of a small proportion of aluminium; C. Gautsch recommended adding 2·5 per cent. of sodium hydrocarbonate when the two metals are being alloyed. D. Mushet obtained alloys by reducing iron-copper pyrites; F. Mahla heated a mixture of cupric and ferric oxides to redness in a stream of hydrogen; H. Wedding and W. Müller reduced the mixed oxides by the aluminothermic process; J. D. Darling added a mixture of cuprous oxide and calcium carbide to molten iron, or a mixture of ferric oxide and calcium carbide to molten copper; E. Sperry added potassium ferrocyanide to molten copper; G. Wetzlar put a strip of iron in an aq. soln. of cupric tartrate and obtained brownish-black copper-iron, but F. Mylius and O. Fromm could not confirm this.

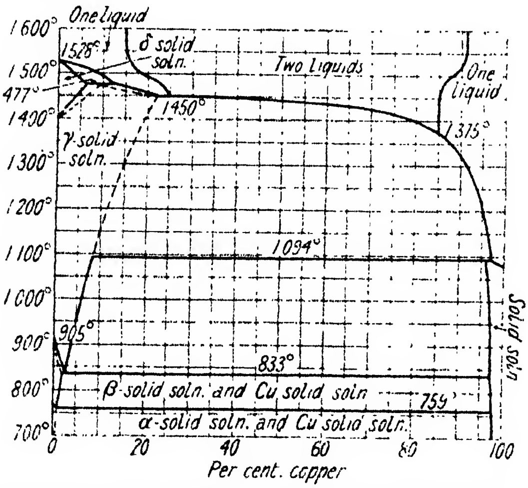

Fig. 407.—Equilibrium Diagram of Copper-Iron Alloys.

P. Siebe observed that iron has no action on electrolytic copper below 1100°, but ordinary "tough pitch" copper with cuprous oxide, is rendered brittle and porous by contact with iron at 750°. This is attributed to the reducing action of hydrogen and carbon monoxide in the iron. F. Sauerwald and E. Jänichen studied the adhesion of the particles of a compressed mixture of powdered iron and copper; and H. E. Diller, and M. I. Zakharova, the diffusion of copper in iron. G. Tammann and W. Oelsen found for the solubility, S per cent., of γ-iron in copper between 850° and 1100°, $\log S = -3792T^{-1} + 3{\cdot}392$; and for $\alpha\beta$-iron in copper between 630° and 850°, $\log S = -4003T^{-1} + 3{\cdot}574$. It was found that

	γ-iron				αβ-iron			
	1070°	980°	885°	852°	852°	770°	680°	630°
S . .	3·68	2·35	1·34	1·04	1·04	0·54	0·22	0·14

and by extrapolation at 200°, $S = 0{\cdot}0000127$, and at 20°, $5{\cdot}9 \times 10^{-11}$. W. Köster represented the solubility of copper in α-iron by Fig. 408. The solid solubility of copper in α-iron at 0° to 600° is 0·4 per cent., and it then increases in accord with log $S=-4125T^{-1}+4{\cdot}32$ to 3·4 per cent. at the eutectoid temp., 810°. P. Siebe, F. Roll, and F. P. Zimmerli studied the action of copper on iron at a high temp. According to R. Sahmen, V. O. Pfeiffer is wrong in his deductions on the nature of the alloys. The equilibrium diagram shows that there are two series of solid soln. with 0 to 3·5 per cent. and 97·3 to 100 per cent. of copper, respectively; and the break in the cooling curve of alloys with 3·5 to 97·3 per cent. of copper shows that the alloy solidifies to a conglomerate of mixed crystals. By gradually adding copper up to 4 per cent., the transition point of γ- to β-iron is lowered from 878° to 715°, and remains constant on further addition of copper. If, however, the solidified alloy is heated for some time at 900° to 1000° and again cooled, the transition takes place at 790°. The change from β- to α-iron has been followed by magnetic observations. It occurs about 790°, and is not influenced by the presence of copper, so that the latter is not miscible in the solid state with α-iron. R. Ruer and C. Fick found that the f.p. curve of the iron–copper system, Fig. 407, shows that three series of solid soln. are formed, one of which is restricted to a very small range of composition at the copper end. R. Ruer and F. Goerens observed that the f.p. curve is not horizontal but extends from 24 per cent. of copper at 1450° to 70 per cent. of copper at 1375°. R. Ruer and C. Fick observed that two liquid phases are formed, and the separation occurs as soon as carbon is added, even when the quantity is only 0·02 per cent. The action of carbon may be merely a deoxidizing one, removing the films of oxide which hinder intermixture of the two emulsified liquids. Copper retains iron in solid soln. up to between 1 and 2 per cent., whilst the iron-rich solid soln. contains about 20 per cent. copper at 1440°, and a much smaller percentage at lower temp. The magnetic change point is lowered to 760° by copper. R. Ruer and F. Goerens added that on solidification, the iron–copper system behaves as if it were a system with three or more substances and, so far as the observations go, does not fit in with the phase rule. The absorption of impurities during the process of melting, in amount sufficient to explain the phenomena, could not be established. It must therefore be assumed that a mol. complex is formed which, on account of its slow velocity of production and decomposition, plays the part of a third substance, but further confirmation of this view was not obtained. C. Benedicks discussed the apparent breaks in the liquidus curve of iron-copper alloys. L. Nowack, G. Masing, S. Kodama, I. Kotaira, A. Müller, and R. Ruer and J. Kuschmann showed that the limited range of miscibility of the two metals in the molten state cannot be explained away by assuming that it is caused by segregation during solidification. The subject was studied by H. Buchholtz and W. Köster, and E. L. Reed. D. Hanson and G. W. Ford found that solid copper dissolves about 4 per cent. of iron at 1100°, and the solubility falls to less than 0·2 per cent. at 750°. A. Müller observed that when an alloy of equal proportions of the two elements is heated at various temp., the structure of the cold product shows that the lower critical temp. for the immiscibility is about 1520°. Carbon reduces the immiscibility because it is soluble in iron only. F. Ostermann observed that the two elements are miscible in all proportions in the liquid state, that in the presence of carbon, there is a range of temp. within which the two metals are immiscible. On adding manganese,

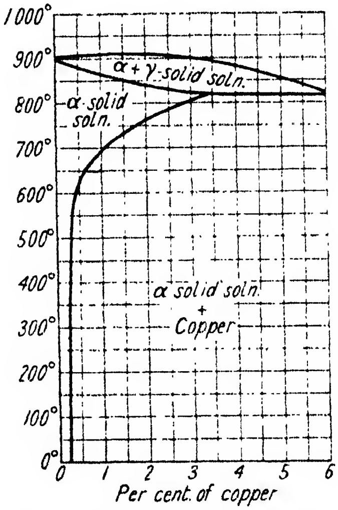

FIG. 408.—The Solubility of Copper in α-Iron.

this range of immiscibility disappears. A. S. Russell observed that where an amalgam of the two metals is exposed to an oxidizing agent, the copper is alone oxidized until the at. proportion becomes Cu : Fe, when both metals are afterwards oxidized at the same rate, in agreement with the assumption that a compound CuFe is formed. A. Müller studied the subject.

According to F. Osmond, as the proportion of copper rises, the arrest A_3 is lowered 40° to 50° in a steel containing 0·847 per cent. of copper; and in a steel with 4·10 per cent. of copper, the arrests A_2 and A_3, coincide at 730° to 720°; whilst A_1 is lowered to 625°–600°. The effect of copper on the allotropes of iron thus resembles that of carbon but to a less degree, and its influence on the recalescence is similar to that of manganese and nickel. The elements may be arranged in two groups: (i) those with at. vols. less than 7·2, the value for iron—*e.g.* C (3·6), B (4·1), Ni (6·7), Mn (6·9), and Cu (7·1); and (ii) those with at. vols. greater than that of iron—*e.g.* Cr (7·7), W (9·6), Si (11·2), As (13·2), P (13·5), and S (15·7). The elements in the first group retard the conversion of β- into α-iron, and that of temper carbon into annealing carbon. Hence, if the rate of cooling is equal, they increase the proportion of β-iron in the cooled metal, and consequently also its hardness; and they are therefore equivalent in effect to a higher or lower degree of tempering. Elements with a higher at. vol. than iron tend to raise, or keep at its normal temp., the conversion of β- into α-iron, and hence they render the reverse change more or less incomplete during heating, and, as a rule, hasten the conversion of temper carbon into annealing carbon. They therefore keep the iron in the α-state at a high temp., and also at a low temp., and their presence in iron would be one cause of softness and malleability, resembling in this respect the operation of annealing, if it were not that their own properties and those of their compounds produce strongly marked secondary effects. P. Breuil also studied the effect of copper on the critical points of steel: (i) With steels having 0·103 to 0·173 per cent. of carbon, no distinct change was observed with the Ar_3 and Ar_2 arrests, when the proportion of copper was below 8 per cent., but above that proportion, there is a long arrest at about 730°; at 740° for steels with 16 per cent. of copper; and at 675° for steels with 32 per cent. of copper. (ii) With steels containing 0·282 to 0·412 per cent. of carbon, the Ar_1-arrest is lowered from 720° to 630° with steels containing 16 per cent. of copper; and with steels containing 0·56 to 0·79 per cent. of carbon, the Ar_1-arrest points all occur between 570° and 600°. A. F. Stogoff and W. S. Messkin found that with copper steels, having 0·7 to 1·2 per cent. carbon and 1 to 5 per cent. of copper, the Ar_1-point is lowered and the temp. interval between the Ar_1- and the Ac_1-points is lowered by increasing the proportion of copper. T. Ishiwara and co-workers studied the ternary system Cu–C–Fe, for alloys with up to 30 per cent. of copper. At 1100° there is an invariant point corresponding with a concentration of 4·3 per cent. C, and 3·3 per cent. Cu at the intersection of the eutectic and monotectic lines. The maximum concentration of the γ-solid soln. is about 3·5 per cent. C and 3·8 per cent. Cu. The eutectoid line starts from the binary iron-copper eutectoid point at 2·3 per cent. Cu and 833° and gradually descends, the copper-content decreasing as the carbon increases. Addition of copper to steel lowers the A_1-transformation point 20° with 2 per cent. Cu; the eutectoid invariant point corresponds with a composition of 0·9 per cent. C, 1·75 per cent. Cu, and 97·35 per cent. Fe at 700°. Saturation of iron with copper to give a uniform solid soln. lowers the A_2-point by about 10°. H. Wedding and W. Müller, H. Buchholtz and W. Köster, A. Carnot and E. Goutal, K. G. Lewis, and M. Hamasumi also made observations on this subject. H. Sawamura, J. W. Donaldson, and F. Roll found that copper decomposes cementite. E. Piwowarsky studied the action of copper in cast iron; C. S. Smith and E. W. Palmer, the precipitation hardness; and G. Masing, the age-hardening of the copper-iron alloys.

According to H. von Jüptner, steel with 3·4 per cent. of copper and dissolved in hydrochloric acid, or an ammonium salt soln. and neutralized hydrogen dioxide, leaves fine, microscopic threads of copper. According to J. E. Stead, the micrographical study of steels containing copper leads to the conclusion that the copper retards the formation of pearlite. The same steels, differing only in copper, under like comparative rapid cooling, when cold, contain more diffused carbide when copper is present than when absent. With very slow cooling, the carbides appear to separate equally well in both the cupreous and normal steels. This peculiarity explains why annealing and slow cooling have the marked softening effect. The growth of the crystalline structure was discussed by R. Kühnel. P. Breuil concluded that the copper steels commercially capable of application are analogous to ordinary steels from the point of view of their micro-structures, but their constituents are finer. The presence of copper increases the quantity of pearlite in the steels, and to some extent it causes the steels to be more highly carburized, and consequently harder. With copper up to 4 per cent., these steels contain no free copper, that element being dissolved in the iron. When the proportion of copper is between 4 per cent. and 8 per cent., saturation occurs ; when over 8 per cent. of copper is present, free copper separates out in fibres in the case of soft or semi-soft steels, and in nodules in harder steels. Liquation is the more noticeable in the ingots in proportion as they contain a high proportion of carbon. When the ingots contain 25 per cent. of copper, liquation is strongly marked, and the ingot is found to consist of two distinct portions, clearly defined. The great hardness of some of these steels after rolling might lead to the supposition that they were martensitic ; but this is not so ; they contain fine-grained pearlite. W. Müller reported that the structure of iron containing copper and sulphide of copper is irregular with respect to the size and joining of the ferrite crystals: the crystals interlock with one another with curved junctions, and this explains the higher tensile strength of iron containing copper as compared with iron containing no copper. The sulphide of copper and the copper itself prevent the formation of pearlite; instead of pearlite, crystals of cementite are formed. The greater hardness of iron containing copper and sulphur is due to this fact. Copper and sulphide of copper distribute themselves mainly between the crystals of ferrite which they envelop, thus affording an explanation of the fact that red-shortness is prevented. In alloys of iron containing 22·2 and 61·7 per cent. of copper, the bulk of the copper is distributed in a similar form surrounding the large crystals of ferrite. In copper containing 7 per cent. of iron it is still possible to discover microscopic traces of copper sulphide, even when the percentage of sulphur is only 0·024. The subject was discussed by J. R. Cain, and W. Herwig.

According to R. Sahmen, the colour of polished surfaces passes continuously from that of iron through various tints to that of copper; and the colour of an alloy with 10 per cent. of iron can scarcely be distinguished from that of copper alone ; an alloy with 20 per cent. of iron has a grey tinge ; and the colour of an alloy with 50 per cent. of iron resembles that of iron but has a pale reddish tinge ; and the colour of an alloy with 70 per cent. of iron cannot be distinguished from that of iron. The fractured surface of an alloy with 85 per cent. of iron is red, because the red crystals of the solid soln. rich in copper are alone fractured, not those rich in iron. Observations on the colour were also made by D. Mushet, J. E. Stead, and P. Breuil. J. H. Carter studied the X-radiograms of the alloys.

W. Brown said that the addition to iron of up to 1·5 per cent. of copper reduces the sp. vol. of iron 0·0005 c.c. per 1 per cent. of copper, while additions of from 1·5 to 4·0 per cent. have no appreciable effect on the sp. vol. A steel with 0·68 per cent. C ; 0·36, Mn ; and 1·59, Cu, had a sp. gr. 7·8354, a sp. vol. 0·12763, and sp. ht., 0·1180 ; steel with 0·59 per cent. C ; 0·32, Mn ; and 2·50, Cu, had a sp. gr. 7·8366 ; a sp. vol. 0·12761, and sp. ht. 0·1180 ; steel with 0·17 per cent. C ; 1·04, Mn ; and 2·87, Cu, had a sp. gr. 7·8470, a sp. vol. 0·12744, and a sp. ht. 0·1178 ; while steel with 0·04 per cent. C ; 0·16, Mn ; 1·00, Al ; and 3·75 Cu, had a sp. gr. 7·7479, a sp. vol. 0·12907, and a sp. ht. 0·1173. J. O. Arnold made observations on the sp. gr. of the alloy. According to E. Sperry, the addition of 0·75 to 1·0 per cent. of iron hardens copper so that the metal can be sharpened to cut wood. P. Breuil obtained the results shown in Table LV for Brinell's hardness with a steel ball 10 mm. diameter and 3000 kgrms. press. H. Wedding and W. Müller observed that the presence of copper or copper sulphide hinders the formation of pearlite, and promotes the formation of cementite. This helps to explain the greater hardness observed when copper and sulphur are present, but, as C. F. Burgess and J. Aston observed, not in the absence of either copper or sulphur. The subject was discussed by G. A. Roush, A. Kussmann and B. Scharnoff, T. Isihara, G. Tammann, T. Usihara, F. Wever, R. S. Archer, E. K. Smith and H. C. Aufderhaar, K. Taniguchi, C. Pfannenschmidt, W. Buchholtz, and W. Köster; and L. Grenet discussed the hardening of the iron-copper alloys; and M. G. Corson, the ageing of the alloys. R. S. Archer observed no age-hardening with the copper-iron alloys. The viscosity of the alloys was studied by G. Drath and F. Sauerwald.

Table LV.—The Hardness of Iron-Copper Alloys.

Carbon (per cent.)	Copper (per cent.)	Rolled	Reheated	Quenched but not annealed	Quenched and annealed
0·103 to 0·173	0·000	143	124	207	192
	0·490	146	143	311	311
	1·005	146	146	311	277
	2·015	202	174	311	(345)
	3·997	255	183	351	325
0·282 to 0·412	0·000	166	166	460	418
	0·505	202	166	627	460

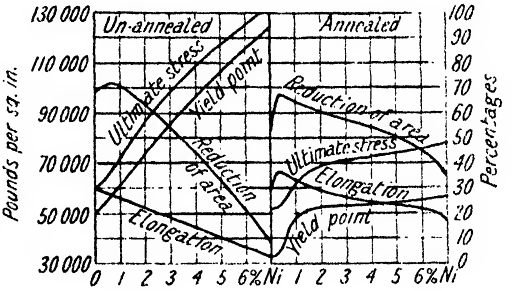
	4·009	302	212	782	782
0·560 to 0·798	0·500	255	228	no mark	555
	0·983	302	223	,,	555
	3·091	418	223	,,	600
	10·500	430	241	,,	782

In 1627, L. Savot mentioned that blacksmiths experience a difficulty in working iron containing copper, so that cupriferous iron cannot be welded; whilst in 1774, G. Jars reported that the general opinion in his time was that *le cuivre est une peste pour le fer,* but that actually small quantities of copper improve the quality of iron, and that even 1 per cent. could be added without destroying the welding power of the metal. C. J. B. Karsten stated that the addition of 1 per cent. of copper sensibly diminished its welding properties; H. H. Campbell, that 0·2 to 0·5 per cent. of copper does not affect the welding properties of wrought iron; A. Ruhfus, that ingot iron which has to be welded should not contain more than 0·3 per cent. of copper, and steel, no more than 0·4 per cent.; while A. L. Colby found that weld steel plates with 0·575 per cent. of copper passed the regulation welding and flanging tests satisfactorily. Hence, J. E. Stead concluded that if much more than 0·4 per cent. of copper is present, the metal will not weld perfectly, but smaller quantities have no detrimental influence. With respect to the effect of copper on the hot working properties of steel, S. Rinman was not very clear whether or not copper produced red-shortness. D. Mushet found that 5 per cent. of copper made steel useless for forging, and the alloy must therefore have been very red-short; C. J. B. Karsten, that 0·5 per cent. did not make malleable iron red-short, but 1 per cent. did; V. Eggertz, that 0·5 per cent. of copper in malleable iron produced only traces of red-shortness, and added that the alloys are good for nothing. M. Faraday and J. Stodart said that the quality of the metal is not improved by adding 2 per cent. of copper. J. R. Bréant added that 2 per cent. of copper makes steel brittle. J. Percy said that copper produced red-shortness; W. Longmaid, that 0·02 to 0·8 per cent. of copper hardened malleable iron without diminishing its toughness; H. H. Campbell, that best steel may contain 0·3 to 0·5 per cent. copper, but with 1 per cent., the metal cracks in rolling; S. Kern, that gun steel may contain 0·27 to 0·36 per cent. copper; A. Willis, that 0·1 per cent. of copper did not produce red-shortness, while 0·3 per cent. caused a slight cracking; M. Choubley, that steel with 0·5 per cent. of carbon and 1 per cent. of copper rolled well; A. Wasum, that steel with 0·23 per cent. carbon was not made red-short by 0·862 per cent. of copper; J. O. Arnold, that steel with 1·81 per cent. of copper rolled well; A. L. Colby, that 0·6 per cent. of copper did not make steel red-short even when the sulphur was as high as 0·08 to 0·10 per cent.; W. von Lipin, that 3 per cent. of copper in steel with 0·13 per cent. of carbon and 0·009 per cent. of sulphur did not produce red-shortness, although with 4·7 per cent. of copper, the metal cracked on hammering; A. Ruhfus, that only when the copper exceeds 0·4 per cent. in ingot iron and 0·5 per cent. in carbon steels does the metal become red-short—provided the sulphur and phosphorus do not exceed 0·05 per cent.; and G. W. Sargent, that if carbon is less than 0·1 per cent. and manganese less than 0·12 per cent., 0·5 per cent. of copper will produce red-shortness. The working properties were also discussed by C. F. Burgess and J. Aston. Hence, J. E. Stead concluded that 0·3 per cent. or even more copper does not produce red-shortness when the sulphur is low.

C. Pfannenschmidt observed that copper augments the bending strength, and the tensile strength of cast iron. C. F. Burgess and J. Aston gave the results summarized in Figs. 409 and 410 for the mechanical properties of the copper-iron alloys. With respect to the influence of copper on the mechanical properties of steel in the cold state, D. Mushet observed that alloys with 50 per cent. of copper possess great strength; steel with 10 per cent. copper is hard and brittle; M. Stengel, that the tenacity of iron is not affected by the presence of more than one-third per cent. of copper; and that the quality of steel is not improved by the addition of copper. M. Krilowsky said that cast iron with 0·25 to 2·0 per cent. of copper is well adapted for casting; it scarcely contracts on solidification; it takes a fine polish, and hardens like steel; its fracture is bright and lamellar, and after slow cooling the fracture is dull and finely granular; it can be readily turned in a lathe; and it is somewhat malleable. The castings as they leave the mould have a continuous, thin layer of copper on the surface. Observations were made by O. von Keil and F. Ebert, F. L. Garrison, A. L. Colby, J. R. Cain, and E. A. and L. T. Richardson. W. Longmaid found that small quantities of copper in malleable iron increased the hardness without decreasing the ductility; F. L. Garrison, that copper in steel sensibly diminishes its tensile strength, but in some cases the metal is improved; E. J. Ball and A. Wingham, that copper increases the tenacity of steel; and H. Schneider, that copper improves the quality of steel. J. O. Arnold found with purified iron, and with steel having 1·81 per cent. of copper and 0·1 per cent. of carbon, the **elastic limit** and tenacity are as follow:



FIGS. 409 and 410.—The Mechanical Properties of Copper-Iron Alloys.

	Elastic limit (tons per sq. in.)	Tensile strength (tons per sq. in.)	Elongation (per cent.)	Reduction of area (per cent.)
Fe	14·39	21·77	47·00	76·50
Cu, 1·81 per cent. .	30·8	34·8	30·5	62·2

H. H. Campbell, for steel with

Cu, 0·10 per cent. . . .	27·4	19·7	27·52	56·30
Cu, 0·35 ,, . . .	26·9	19·6	27·88	59·01

A. L. Colby, for steels with 0·39 and 0·25 per cent. of carbon, and respectively

Cu, 0·553 per cent. . .	17·16	29·25	31·12	51·92
Cu, 0·565 ,, . .	20·64	35·11	24·92	44·67

Observations on cast iron and steel were also made by O. Bauer and A. Sieglerschmidt, H. Buchholtz and co-workers, G. H. Clamer, J. Evans, H. J. French and T. G. Digges, R. Genzmer, R. C. Good, L. Guillet and M. Ballay, D. Hanson and G. W. Ford, J. E. Hurst, F. Johnson, H. B. Kinnear, W. Köster, E. Kothny, F. C. Lea, W. von Lipin, G. Masing, E. Mauer and W. Haufe, W. Mauksch, H. Müller, I. Musatti and G. Calbiani, F. Nehl, Z. Nishiyama, A. L. Norbury, C. Pfannenschmidt, F. Rapatz and H. Pollack, O. Smalley, E. K. Smith and H. C. Aufderhaar, W. H. Spencer and M. M. Walding, J. E. Stead, K. Stobrawa, and A. F. Stogoff and W. S. Messkin. M. Hamasumi found that the addition of up to 1 per cent. of copper increases the strength of cast iron containing 1·87 per cent. of silicon, but proportions between 1 and 4 per cent. had very little influence. A. F. Stogoff and W. S. Messkin found that the hardness, yield-point, and tensile strength of copper steels—with 1 to 5 per cent. Cu and 0·7 to 1·2 per cent. of carbon—increase with increasing proportions of copper with annealed steels, but the elongation, impact strength, and reduction of area reach a maximum with about 3 per cent. of copper. In the case of hardened and tempered copper steels, the tensile strength increases with the copper-content when the structure is hypereutectoidal. Quenched and tempered steels have a high yield-point, and ultimate strength combined with a good elongation and reduction in area. J. E. Stead and J. Evans concluded that between 0·5 and 1·3 per cent. of copper has no deleterious effect on either the hot or cold property of steel; that a large proportion—2 per cent.—makes steel liable to be over-heated; and that on small proportions it raises its tenacity and the elastic limit, but, unlike phosphorus, it does not sensibly make the steel liable to fracture under sudden shock. Like carbon, it reduces the power of steel to extend under stress, but this is not pronounced when the proportion is small. The effect is more marked when large proportions are present. P. Breuil found that the tensile strength of copper steels, as rolled, appears to be greater in proportion as they contain more copper, and the difference is more manifest in proportion as the carbon is lower. Annealing leaves the steels with the same characteristics, but greatly reduces the differences observed in the case of the untreated steels. Quenching restores the differences encountered in the case of cast steels. Copper steels with a tensile strength equal to nickel steels can be obtained. The resistance of copper steels to shock shows that they are no more brittle than nickel steels containing eq. percentages of nickel. The torsion tests give results similar to the tensile strength tests. Copper steels are capable, under torsional stresses, of undergoing a considerable degree of deformation. F. Abbolito studied the resistance to wear.

O. Bauer and H. Sieglerschmidt observed no effect with 0·55 per cent. of copper on the thermal expansion of cast iron, but it reduced the permanent elongation. As indicated above, W. Brown found that copper has very little effect on the sp. ht. of steel with a high proportion of carbon—*vide supra*. J. T. Littleton found for light of wave-length 5893, and alloys with 27·6, 53·4, and 77·6 per cent. of iron, the respective reflecting powers R=52·8, 51·8, and 57·5; the coeff. of absorption k=2·71, 2·96, and 3·41; and the indices of refraction 1·77, 2·24, and 2·62. A. Matthiessen and M. Holzmann observed that the electrical conductivity of copper goes from 93·08 to 34·56 by the addition of 0·48 per cent. of iron, and to 26·95 with 1·06 per cent. of iron; and A. Matthiessen and C. Vogt, that a hard-drawn wire with 0·46 vol. per cent. of iron had a conductivity of 38·852–0·06034θ

$+0{\cdot}0000081280\theta^2$, and between 0° and 100° it falls 13·44 per cent. Observations were made by G. A. Roush, V. O. Pfeiffer, H. Buchholtz and W. Köster, and G. Tammann. The results of C. F. Burgess and J. Aston for the resistance, *R* microhms per cm. cube, are as follow:

Cu .	0·09	0·20	0·42	0·80	1·51	2·01	3·99	5·07	7·05	94·34 per cent.
R .	12·2	12·0	13·6	13·6	14·7	7·0	12·7	12·5	15·8	3·9

P. R. Kosting's results for the sp. resistance, in microhms per cm. cube at 20°, and the temp. coeff. in ohms per ohm per degree, are summarized in Fig. 411. G. Dillner observed that the electrical resistance of iron and steel is augmented by alloying it with copper, but, added M. Fric, the increase extends up to a maximum, expressing the sp. resistance in microhms per sq. cm.:

Copper .	per cent.	0·01	0·05	1·0	2·0	3·0	4·0	10·0
Carbon 0·15	,,	13·81	15·06	16·69	17·46	—	16·71	—
0·35	,,	16·95	17·69	18·78	19·01	—	17·76	—
0·70	,,	20·55	22·03	21·13	—	20·90	—	19·81
1·00	,,	22·58	24·86	24·72	—	24·24	—	—

C. Benedick's rule that the electrical resistance of a steel at ordinary temp. is roughly $R=7{\cdot}6+26{\cdot}8\Sigma C$, where, representing the percentages of the contained elements by their symbols, $\Sigma C=C+(12/28{\cdot}4)Si+(12/63{\cdot}4)Cu+$etc., was found by P. Breuil not to be applicable to copper steels. G. K. Burgess and J. Aston found an increase of 3 to 4 microhms per cm. cube, and R. Ruer and K. Fick, 4·0 microhms for additions of 1 per cent. of copper to iron. W. H. Keesom and co-workers measured the thermoelectric force of the alloys against an alloy of silver and gold; and A. Pepe, against iron and copper. P. R. Kosting studied the thermoelectric force against platinum. A. W. Smith studied the Hall effect. L. C. Bannister and U. R. Evans discussed the electrode potential of these alloys.

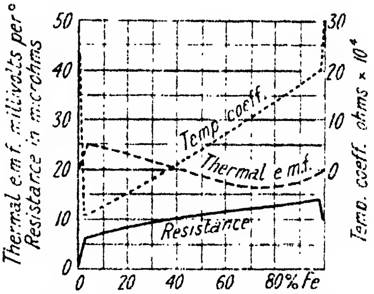


FIG. 411.—The Electrical Resistance of Iron-Copper Alloys.

G. Dillner found that 0·64 per cent. of copper had no effect on the magnetic properties of iron. R. Sahmen observed that an alloy with 98·7 per cent. of copper is magnetizable at room temp., and that the magnetism of alloys with 1 to 10·7 per cent. of copper vanishes at 795°. D. Mushet observed that alloys with 90 per cent. copper are magnetic; and P. Breuil, that steel with 32 per cent. copper is magnetic in the cold; and G. Tammann, that the magnetizability of the alloys rich in copper is possibly conditioned by the presence of crystals of a solid soln. rich in iron; and that the temp. of magnetizability of iron is lowered 27° by 2·5 per cent. of copper. G. Tammann and W. Oelsen measured the sp. magnetization (gauss) of copper-iron alloys containing the following proportions of dissolved and total iron:

	250°	418°	560°	770°	885°	1070°
Dissolved Fe . . .	0·14	0·14	0·14	0·54	1·34	3·68
Gauss 0·502 per cent. Fe .	0·694	0·694	0·713	0·001	0·001	0·002
2·00 ,, ,, .	3·64	3·72	3·72	2·85	1·238	0·019
4·50 ,, ,, .	8·76	8·73	8·82	7·96	6·04	1·18

C. F. Burgess and J. Aston measured the magnetization, or magnetic induction, *B*, of alloys of electrolytic iron and copper—unannealed, annealed at 675° and 1000°, and quenched from 900°—for magnetic fields of intensity *H* gauss, and the results are summarized in Table LVI; while the results for the coercive force ($H_{max.}=200$), and retentivity ($H_{max.}=200$) are summarized in Table LVII. The subject was studied by H. Buchholtz and W. Köster. A. F. Stogoff and W. S. Messkin found that with steels having 0·7 to 1·2 per cent. of carbon and

1 to 5 per cent. of copper, the coercive force, and the product of the coercive force and the remanence are increased more or less proportionally to the copper-content. Observations were also made by E. Gerold, A. Kussmann and co-workers, G. Tammann, A. D. Ross, E. Take, W. Köster, and W. Krings and W. Ostmann, while A. Kussmann and B. Scharnoff observed no relation between the coercive force and hardness.

TABLE LVI.—MAGNETIZATION OF COPPER-IRON ALLOYS.

Copper (per cent.)	$H=10$				$H=100$			
	Not annealed	Annealed at 675°	Annealed at 1000°	Quenched from 900°	Not annealed	Annealed at 675°	Annealed at 1000°	Quenched from 900°

94·34	None	200+	200+	200+	None	500	300	400

According to J. E. Stead, the surface of alloys of 8 to 97·2 per cent. of copper readily tarnished because of the presence of crystallites of iron; and alloys with 0 to 8 per cent. of copper oxidize when melted more rapidly the more copper they contain. C. J. B. Karsten reported that copper is an undesirable element in steel because it makes the metal corrode more rapidly; but later observations have shown that this is not always a valid deduction, since the early cupriferous steels seem to have had sulphur associated with the copper. I. Kotaira found that when a cupriferous steel is oxidized at 1000° for 22 hrs., the surface oxide has only 10 to 20 per cent. of the original copper, and the copper-content of the unoxidized steel increases 5 to 10 per cent. H. Kirscht studied the effect of copper on the oxidation of iron. According to C. Carius and co-workers, the high resistance to rusting of steels with 0·2 to 1·0 per cent. of copper, when exposed to a damp atmosphere, is due to the formation of a tenacious layer of cupric oxide below the iron scale which first forms. This layer is a secondary deposit produced by oxidation of the copper set free when the outer layer of iron oxide is formed. It is possible to arrange conditions to show that the copper liberated is first converted by the ferric ions into cuprous ions, which are immediately reduced so that the steel becomes covered with a film of copper, which then oxidizes to cupric oxide. In the presence of chloride ions the deposited copper is spongy and is rapidly converted into cupric hydroxide, which then accelerates rusting of the iron by the formation of local cells. P. Kötzschke found that 0·3 to 0·4 per cent. of copper decreased the corrosion of cast iron in the atmosphere, and that further additions of copper had no appreciable effect. The resistance to acids was not improved by the addition of up to 0·9 per cent. of copper. F. H. Williams found that soft Bessemer steel containing variable proportions of copper, on exposure to the atmosphere for a month during which the samples were wetted several times daily, the losses by corrosion were:

Copper . . .	0	0·078	0·145	0·263 per cent.
Loss by corrosion .	1·85	0·89	0·75	0·74 ,,

Observations were also made by J. E. Stead and F. H. Wigham, who found the corrosion, during 9 weeks' immersion in a stream of tap-water, for steel with approximately 0·990 C, 0·463 Mn, 0·168 Si, 0·034 S, 0·021 P, and 0·010 and 0·460 copper, to be respectively 12·7 and 10·1 per cent.; steels with 0·430 C, 0·940 Mn, 0·065 Si, 0·030 S, 0·063 P, and 0·250 and 0·480 copper, to be respectively 10·6 and 8·9 per cent.; steels with 0·480 C, 0·933 Mn, 0·070 Si, 0·047 S, 0·084 P, and 0·033 and 0·889 copper, to be respectively 12·0 and 13·5 per cent.; steels with 0·330 C, 1·090 and 0·640 Mn, 0·028 Si, 0·118 and 0·055 S, 0·049 P, and 0·012 and 1·286 Cu, to be respectively 19·0 and 11·5 per cent.; and 0·310 C, 0·676 Mn, 0·084 Si, 0·0475 S, 0·084 P, and 0·012 and 2·000 copper, to be respectively 14·7 and 4·7 per cent. The results with tidal river-water were similar. H. Wedding and W. Müller observed the reduced tendency of copper steels to corrosion or separation of copper sulphide and copper in the form of protective shells around the ferrite grains. D. M. Buck stated that the addition of 0·15 to 0·30 per cent. of copper to mild steel greatly increases its resistance to corrosion in air without interfering with its tenacity or ductility; he also added that the addition of copper helps to neutralize the favourable effect of sulphur on corrosion; S. L. Hoyt also found 0·20 to 0·25 per cent. of copper enhanced the resistance of steel to atm. corrosion; A. S. Cushman said that a small percentage of copper restrains the corroding influence of the acidic atm. of manufacturing towns; but copper is not beneficial under all conditions, for corrosion by immersion in neutral, acidic or alkaline water is either not influenced or influenced detrimentally by copper. He said: if it is desired to make a roof of sheet metal for a building in a smoky atm., and not intended to galvanize or paint it, it would probably be best to select copper steel; but if it is intended to galvanize it or keep it painted with a good paint, pure iron would no doubt give the best results. O. Bauer concluded that in the presence of carbon dioxide and sulphur dioxide, in air, a slight percentage of copper or of nickel seems to have a beneficial influence, but the addition of copper to steel for the purpose of preventing or mitigating corrosion is not generally advisable. J. A. Aupperle and D. M. Strickland, M. Ballay, O. Bauer, O. Bauer and co-workers, F. K. Bell and W. A. Patrick, P. Breuil, C. Carius, H. Cassel and F. Tödt, E. L. Chappell, G. H. Clevenger and B. Ray, W. H. Creutzfeldt, A. S. Cushman and co-workers, K. Daeves, J. A. N. Friend, M. Grison and E. Lepage, R. A. Hadfield, H. Hebberling, W. Herwig, S. L. Hoyt, H. T. Kalmus and K. B. Blake, V. V. Kendall and F. N. Speller, W. Marzahn and A. Pusch, P. B. Mikailoff, F. Nehl, J. V. Neubert, H. S. Rawdon, E. A. and L. T. Richardson, W. D. Richardson, R. T. Rolfe, J. E. Stead, S. S. Steinberg, O. W. Storey, W. H. Walker, and H. Wedding made some observations on this subject. M. Faraday and J. Stodart, and R. Mallet stated that alloys of iron with copper are less corrodible than iron alone. M. Ballay, D. M. Buck, C. Carius, E. Crowe, G. Dillner, H. T. Kalmus and K. B. Blake, W. Müller, J. V. Neubert, C. Pfannenschmidt, E. A. and L. T. Richardson, J. E. Stead and F. H. Wigham, S. S. Steinberg, W. H. Walker, H. Wedding, and F. H. Williams found copper made the alloy more resistant to corrosion: (i) copper increases the resistance of iron and steel to atmospheric corrosion, and its influence is apparent when the copper reaches only 0·03 per cent.; its maximum effect is produced when only 0·05 per cent. is present, and the best amount for commercial steel is about 0·25 per cent. (ii) Steels with 0·05 and with 0·25 per cent. of copper outlast iron containing 0·04 per cent. of copper. (iii) Sulphur in steel accelerates corrosion very markedly, and sulphur oxides in the air accelerate the corrosion of steel, but copper counteracts or retards both these effects. O. Bauer, R. A. Hadfield, and J. A. N. Friend found the differences to be too small to be able to state definitely that there is any improvement; whilst A. S. Cushman said that copper is deleterious. According to F. K. Bell and W. A. Patrick, the rate of dissolution of the alloys in 28·7 per cent. hydrochloric acid decreased below the value for iron alone; the first 0·5 per cent. of copper had the greatest effect since further additions of copper only increased the resistance to attack very slightly. Mere contact with copper wire reduces the rate of dissolution of iron in the acid, whilst platinum and silver are without effect. The results with 57 per cent. sulphuric acid were erratic. It is assumed that the retarding influence of copper is due to the dissolution of some of that metal which is at once re-precipitated in a finely-divided state on the surface of the iron; it is then re-dissolved. The intermittent dissolution and re-precipitation of copper is said to be responsible for the retardation. J. A. N. Friend found that the addition of small quantities of copper to steel exerts a minor influence upon the corrodibility of the metal in neutral corroding media. In tap-water and in salt-water there is nothing to choose between the cupriferous steel and the wrought irons, all of which possess a slight advantage over the steels; in the alternate wet and dry tests the non-cupriferous metals proved slightly superior. In all cases, however, the differences are relatively small, being but slightly greater than the usual eccentricities manifested between different specimens of apparently similar metals. O. Kötzsche and E. Piwowarsky observed that the addition of 0·3 to 0·4 per cent. of copper increases the resistance of grey cast iron to weather by 25 per cent., but up to 0·9 per cent. of copper, the resistance to acid attack is unaltered, and the resistance to salt soln. is reduced. L. Aitchison found that the corrosion of copper steels represented by the loss in weight per 100 sq. cm. when left in the dark in 3 per cent. sodium chloride soln. and 1 per cent. sulphuric acid for 77 days, and 45 hrs. in 10 per cent. sulphuric acid, were:

C	1·18	0·59	0·38	0·30 per cent.
Cu	0·48	1·06	2·52	4·78 ,,
NaCl	1·86	2·13	2·31	2·07
H_2SO_4 1 per cent.	15·1	0·58	9·45	3·22
H_2SO_4 10 ,,	58·3	0·69	0·92	1·02

Y. Utida and M. Saito measured the loss in weight, in grams per sq. cm., suffered when the alloy with about 0·05 per cent. of carbon, is exposed for 24 hrs. to 10 per cent. soln. of the different acids:

Copper	0	0·55	1·06	1·60	2·10	2·88 per cent.
HNO_3	0·9380	0·2410	0·3820	0·4355	0·4875	0·5875
HCl	0·0712	0·0025	0·0027	0·0037	0·0031	0·0026
H_2SO_4	0·0990	0·0220	0·0162	0·0117	0·0098	0·0107

H. Endo's results, during 5 hrs.' action at ordinary temp., are plotted in Fig. 412. In all cases there is a minimum corrosion with alloys containing 1 to 2 per cent. of copper. According to J. E. Stead and F. H. Wigham, steels free from copper dissolved in dil. acids more quickly than those containing copper. C. F. Burgess and J. Aston found that with alloys of electrolytic iron and copper, containing :

Copper	. .	0	0·089	0·422	0·804	1·510	3·990	6·160	7·050 per cent.
Acid corrosion	.	1·300	0·178	0·059	0·104	0·147	0·093	0·143	0·186
Atm. corrosion	.	0·449	0·254	0·268	0·259	0·225	0·171	0·200	0·161

where acid corrosion refers to the loss in grams per sq. dm. when immersed for an hour in 20 per cent. sulphuric acid ; and atm. corrosion refers to the loss in kgrms. per sq. metre per year when exposed for 162 days from July to February. L. Schneider observed that with 10 per cent. sulphuric acid, soft basic steel with 0·01 per cent. of copper had a relative rate of corrosion of 120; pig-iron with 0·12 per cent. copper, 32 ; soft open-hearth steel with 0·14 per cent. copper, 26 ; and soft basic steel with 0·2 per cent. of copper, 19. P. Breuil observed that with dil. sulphuric acid, and different steels, the losses in weight taken as a measure of corrosion were those indicated in Table LVIII. There is a minimum corrosion with the steels with 0·156 to 0·168 per cent. carbon when about 1 per cent. of copper is present, and with steels with 0·336 to 0·400 per cent. carbon, when about 2 per cent. of copper is present. The subject was discussed by P. Bardenhauer and G. Thanheiser, O. Bauer and co-workers, F. K. Bell and W. A. Patrick, C. Carius, C. Carius and E. H. Schulz, J. H. Carter, J. A. N. Friend, V. V. Kendall, V. V. Kendall and E. S. Taylerson, C. Pfannenschmidt, and A. R. Surface ; and O. P. Watts and H. C. Knapp found that the action of sulphuric acid is in some cases accelerated by the presence of silver and copper salts. V. K. Pershke and co-workers studied the action of phosphoric acid.

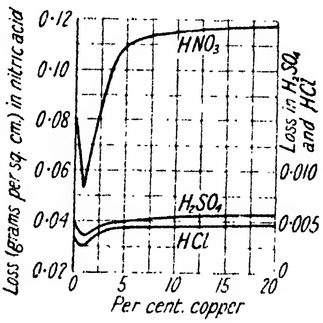

FIG. 412.—Corrosion of Copper Steels by Acids.

TABLE LVIII.—THE CORROSION OF CUPRIFEROUS STEELS.

Composition of steel						Percentage corrosion
C	Mn	Si	P	S	Cu	
0·168	0·100	0·214	0·023	0·013	0·0	5·23
0·158	0·092	0·223	0·016	0·017	0·490	4·40
0·156	0·072	0·209	0·022	0·016	1·005	2·80

L. B. G. de Morveau [3] prepared a **silver-iron alloy.** He said that when the two metals are fused together, two layers are formed. The lower layer contains 0·31 per cent. of iron, and it is affected by a magnet ; while the upper layer, containing 1·25 per cent. of silver, is very hard, and has a denser texture than iron. C. J. B. Karsten observed that the presence of 0·034 per cent. of silver made the iron red-short ; and diminished its tensile strength very considerably. C. F. Burgess and J. Aston discussed the working qualities of iron-silver alloys. G. Barruel obtained a hard, white alloy, by melting silver with 0·35 per cent. of iron.

C. A. Coulomb said that silver can retain no more than 0·0067 part of iron, and that if 0·003 part is present, the alloy acts on a magnetic needle. W. Longmaid patented iron alloys with minute proportions of silver. M. Faraday and J. Stodart said:

> If steel and silver be kept in fusion together for a length of time, an alloy is obtained, which appears to be very perfect while the metals are in the fluid state, but on solidifying and cooling, globules of pure silver are expressed from the mass, and appear on the surface of the button. If an alloy of this kind be forged into a bar, and then dissected by the action of dil. sulphuric acid, the silver appears, not in combination with the steel, but in threads throughout the mass; so that the whole has the appearance of a bundle of fibres of silver and steel, as if they had been united by welding. The appearance of these silver fibres is very beautiful; they are sometimes one-eighth of an inch in length, and suggest the idea of giving mechanical toughness to steel, where a very perfect edge may not be required. At other times, when silver and steel have been very long in a state of perfect fusion, the sides of the crucible, and frequently the top also, are covered with a fine and beautiful dew of minute globules of silver; this effect can be produced at pleasure. Less than one part of silver in 500 of the steel is present in the buttons. The alloys were later examined by R. A. Hadfield.

G. Tammann and W. Oelsen discussed the solubility of iron in silver and found 0·0004 and 0·0006 per cent. respectively at 1000° and 1600°; and N. Agéeff and M. Zamotorin studied the diffusion of silver in iron. G. J. Petrenko said that the two metals do not alloy at temp. below 1600°; for on cooling the mixtures, there are always two arrests corresponding with the f.p. of iron and silver respectively. M. Faraday and J. Stodart found that hammered steel with 2 per cent. of silver had a sp. gr. of 7·808. C. F. Burgess and J. Aston observed that electrolytic iron with:

Silver . . .	0	0·281	0·492	0·581	0·691 per cent.
Acid corrosion .	1·300	1·021	1·760	1·340	1·170
Atm. corrosion .	0·499	0·317	0·430	0·356	0·450

where the acid corrosion refers to the loss in grams per sq. dm. when the alloy was immersed in 20 per cent. sulphuric acid for 1 hr.; and the atm. corrosion refers to loss in kgrms. per sq. metre per year with alloys exposed to the weather for 162 days from July to February. Iron can be separated from silver by cupellation, by fusion in air, or by fusion with borax and nitre. E. Lüder prepared a series of **silver-iron-copper alloys** and found a miscibility gap extending over most of the diagram, Fig. 413. The alloys separate into two layers of which the upper consists mostly of iron, and the lower of silver and copper with very little iron. Homogeneous liquid alloys of iron and copper are broken up into two layers when silver is added.

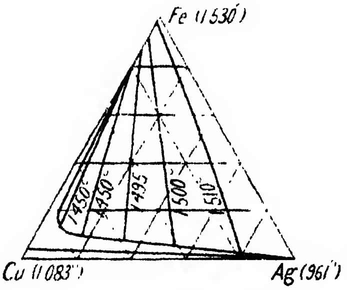

FIG. 413.—The Ternary System: Copper–Silver–Iron.

W. Lewis[4] said that **gold-iron alloys** are readily formed. Gold dissolves twice or thrice its own weight of iron at a temp. far less than that at which the iron melts; so that if molten gold be stirred with an iron rod, it corrodes a part of the iron, and gold adheres to the rod. Hence, J. A. Cramer said that it is not advisable to stir molten gold with an iron rod. Gold is thus an excellent solder for iron. W. Lewis concluded that the colour of gold is made pale by iron, and if there is 3 or 4 times as much iron as gold present, the alloy has a whiteness approaching that of silver. C. Hatchett said that the alloy with equal parts of gold and iron forms a yellowish-grey, hard alloy of sp. gr. 16·885; and M. Faraday and J. Stodart, and C. J. B. Karsten observed that gold and iron can be alloyed in all proportions, and that 8 to 9 per cent. of iron does not diminish the toughness of gold. Richter and Co. obtained white gold-iron alloys; and the subject was discussed by A. H. Hiorns, W. Bersch, and W. T. Brannt. R. A. Hadfield examined some of M. Faraday and J. Stodart's alloys. An alloy with one-sixth of iron is used in jewellery as *grey gold,* and with one-fourth of iron, *blue gold.* E. Isaac and G. Tammann found iron and gold to be miscible in all proportions in the fused state and to form an uninterrupted series of solid soln. on solidification. The break, Fig. 414, extends from 28 to 63 per cent. of gold. At lower temp., partly owing to the change of iron into another form, the break extends from 18 to 85 per cent. of gold. At 1168°, the sat. solid soln. with 28 per cent. of gold, reacts with the fused mass to form a second series of solid soln. At 95 per cent. of gold, the f.p. curve, Fig. 414, shows a minimum at about 1040°. The transition point of iron is not affected by the presence of gold. The alloy with 10 per cent. of gold is harder than iron; and beyond this point the hardness slowly diminishes, and the alloys with more than 70 per cent. of gold are considerably softer than iron. Observations on this subject were made by W. Guertler, L. Nowack, P. Oberhoffer, and W. Wahl. E. Jänecke observed that at 1168° there is a transition point. N. Agéeff and M. Zamotorin studied the diffusion of gold in iron; and H. Sawamura, the effect of gold on the graphitization of cast iron. G. Borelius and co-workers, and M. Faraday and J. Stodart found that hammered steel with 1 per cent. of gold had a sp. gr. 7·870. G. Wertheim measured the elasticity of some gold-iron alloys; A. Matthiessen, and W. Guertler, the electrical conductivity, finding about 1·1 microhms increased resistance per cm. cube for an addition of 1 per cent. of gold. W. Guertler and A. Schulze found that A. Matthiessen's rule to the effect that the absolute increase of the resistance on raising the temp. from 0° to 100° is independent of the increase of resistance brought about by the presence of mixed crystals, and has the same value as that calculated from the increase of resistance of the pure components when raised through the same temp. interval, that is $dW_m/dt = dW/dt$, is not only true over the temp. range 0° to 100°, but also over any other temperature range. It may therefore be also stated in the form that within the range of a given state the differential quotient of the resistance and the temp., dW/dt, increases in a given series of binary alloys proportionally to the vol. conc. of the components. The resistance between 20° and −190° was studied by J. O. Linde. C. G. Knott and J. G. MacGregor measured the thermoelectric force. J. W. Shih found alloys with 10 per cent. of iron to be ferromagnetic, and the magnetic susceptibilities of alloys with smaller proportions of iron to be:

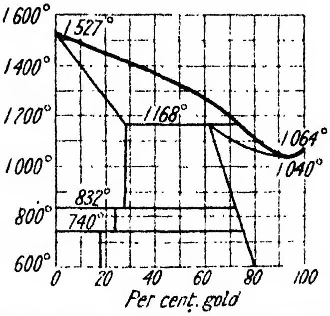

Fig. 414.—Equilibrium Diagram of Iron-Gold Alloys.

Fe	0·07	0·085	0·1	0·5	1·0	2·0	3·5	5·0
$\chi \times 10^6$	−0·041	−0·023	+0·01	0·559	1·52	4·33	12·72	29·76

According to J. L. Gay Lussac and L. J. Thénard,[5] by heating to whiteness a mixture of baryta, strontia, or lime with iron, with or without carbon, no alloy of iron with the alkaline earth metal is formed. W. A. Lampadius, however, heated baryta with iron and charcoal dust, obtained a **barium-iron alloy,** which on exposure to air, formed baryta and iron oxide. E. D. Clarke heated a mixture of barium and iron (2 : 1) in the oxyhydrogen flame, and obtained a brittle alloy the colour of lead. A. Stavenhagen and E. Schuchard obtained the alloys by the thermite process. P. Oberhoffer discussed these binary alloys; and N. Agéeff and M. Zamotorin, the diffusion of barium in iron. J. L. Gay Lussac and L. J. Thénard obtained negative results in the attempt to prepare **strontium-iron alloys** by the method employed for the barium-iron alloys; and they were also unsuccessful in preparing **calcium-iron alloys.** G. Tammann and K. Schaarwächter found that the attack of iron by calcium begins at about 380°, and increases rapidly as the temp. rises. J. J. Berzelius did not succeed in preparing alloys. C. J. B. Karsten stated that iron with 0·1774 per cent. of calcium was deficient in weldability and tenacity, though neither cold-short nor red-short. This iron was produced by adding an excess of limestone to the charge for converting cast iron into malleable iron on the charcoal hearth. According to L. Stockem, calcium dissolves in molten cast iron with great development of heat, but when large quantities are used the metal is rapidly coated with a crust of calcium carbide which prevents further action. Some calcium carbide always remains mechanically entangled in the iron. Ferric oxide reacts vigorously with an excess of metallic calcium; the iron formed is pure and ductile, and does not contain a trace of calcium. O. P. Watts observed no alloying of the two elements fused together in a carbon crucible, but the iron became richer in carbon and silicon—the latter was derived from the silica in the lining of the crucible. C. Quasebart also said that calcium does not alloy with iron whether containing carbon or not. A hollow, iron cylinder filled with calcium was heated at 1400° for 3½ hrs., but no absorption of calcium by the iron was observed. N. Agéeff and M. Zamotorin studied the diffusion of calcium in iron. E. K. Smith and H. C. Aufderhaar observed that up to 0·2 per cent. had no perceptible effect on the shrinkage, strength, or fluidity of cast iron. Calcium has been tried for the deoxidation of iron. O. P. Watts succeeded in removing all the sulphur from iron by means of calcium, but the phosphorus was reduced from 1·96 only to 1·56 per cent. W. Hessenbruch and J. E. Hurst discussed these alloys.

H. Davy[6] prepared an **iron-beryllium alloy** by heating to whiteness a mixture of beryllia, iron, and potassium; and also by bringing slightly moistened beryllia in an atm. of hydrogen, in the circuit of a voltaic battery with an iron wire as cathode. The iron becomes brittle and white, and when dissolved in acids, yields a beryllium and an iron salt. According to F. Stromeyer, if a mixture of beryllia, iron and lampblack is heated to whiteness, an alloy is formed which is whiter and more ductile than iron. When dissolved in acids, it forms a double salt of iron and beryllium. I. Fetchenko-Tchopiwsky studied the cementation of iron with beryllium. G. Oesterheld examined the f.p. of the alloys with up to 21 per cent. beryllium, and the results are summarized in Fig. 415. There is a eutectic point at 1155° and 9·2 per cent. of beryllium. The β–α transformation of iron is lowered by beryllium from 790° to about 647°. There is evidence of the formation of a compound **iron diberyllide,** Be_2Fe; and on polished sections it is darkened by soda-lye. R. H. Harrington also studied the phase diagram; and F. Wever, the effect of beryllium on the range of the γ-phase; the results of F. Wever and A. Müller are summarized by dotted lines in Fig. 415, showing the range of stability of the γ-phase. G. Masing, and W. Kroll found the hardness of some alloys, on Brinell's scale, with a 1000-kgrm. load, a 10-mm. sphere acting for one minute, to be:

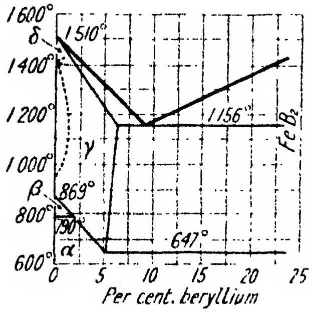

FIG. 415.—Equilibrium Diagram of Iron-Beryllium Alloys.

Beryllium		1·21	2·25	2·97	3·00	3·88 per cent.
Hardness	quenched from 1100°	212	241	221	230	263
	aged at 520°	221	289	353	335	467
	annealed at 950°	212	241	231	252	335

W. R. Whitney found that beryllium improved the mechanical properties and electrical resistance of steel. O. von Auwers observed that the electrical resistance, R ohms per cm. cube:

Beryllium	0·5	1·0	1·5	2·0	3·0	4·0 per cent.
$R\times10^4$	0·193	0·494	0·460	0·475	0·646	0·541

with steel having 1 per cent. each of beryllium and carbon, $R=0{\cdot}0_4248$; 1 per cent. beryllium and 2 per cent. silicon, $0{\cdot}0_4595$. The saturation, value of the magnetization, the remanence, the coercive force, and the maximum permeability of beryllium iron alloys are—Q denotes quenched, and A, annealed :

	Per cent.	0·5	1·0	1·5	2·0	3·0	4·0	1Be, 1C	1Be, 2Si
Saturation	Q .	16,400	16,000	13,000	15,200	8,300	1,120	14,900	10,800
	A .	16,400	12,000	14,200	17,800	10,800	13,300	17,500	15,100
Remanence	Q .	5,400	6,150	4,300	6,000	3,200	4,400	8,800	3,350
	A .	8,500	5,700	5,250	7,800	4,700	7,600	13,200	3,800
Coercive force	Q .	3·05	4·5	6·75	6·75	18·3	10·1	21·3	7·7
	A .	1·6	2·5	2·5	4·75	4·3	23·3	7·1	0·9
Permeability	Q .	16,450	27,650	32,300	40,500	58,500	44,500	187,300	25,800
	A .	13,600	14,230	13,100	37,000	20,200	17,700	93,800	3,420

According to E. D. Clarke,[7] when magnesia moistened with oil is melted along with iron before the oxyhydrogen blowpipe, a brittle, metallic mass is produced supposed to be an impure **iron-magnesium alloy.** F. Stromeyer thought that he had obtained an impure alloy by the method he employed for the beryllium-iron alloy. C. R. Fresenius said that the magnesium in iron is not in an oxidized state. J. J. Berzelius obtained indications of the formation of an alloy of magnesium and iron when a mixture of magnesia, iron filings, and powdered charcoal is heated ; but C. J. B. Karsten never obtained any evidence of the existence of such an alloy ; and J. Parkinson could not prepare magnesium-iron alloys. E. K. Smith and H. C. Aufderhaar, J. E. Hurst, and P. Oberhoffer discussed these alloys. F. C. Lea and L. T. Wills studied the ternary aluminium-magnesium-copper alloys.

The **zinc-iron alloys** are difficult to prepare. Many have assumed that alloys cannot be obtained ; but J. F. Gmelin[8] melted zinc in contact with iron in a closed crucible and noted that the iron became steel-grey in colour, did not become malleable, did not rust, preserved its lustre, etc. G. Tammann and K. Schaarwächter found that the attack of iron by zinc begins at about 420°, and increases rapidly with rise of temp. A. F. Gehlen observed that when cuttings of zinc and iron are heated together, part of the zinc evaporates, and the remainder penetrates the iron making it denser and brittle. C. J. B. Karsten found that in reducing zinciferrous iron ores, the greater part of the zinc volatilized during the operation. The iron *eine bemerkbare Quantitätzink aufnimmt nicht.* C. F. Hollunder found that if a mixture of iron filings and zinc oxide, without charcoal, is heated under a layer of powdered glass, the iron takes up much zinc. P. Berthier, F. C. Calvert and R. Johnson, A. Laurent and C. Holms, A. Erdmann, H. Bablick, W. G. Imhoff, and L. Elsner observed that a vessel of wrought iron or cast iron, in which zinc is continuously melted, becomes corroded by an alloy of zinc and iron ; and P. Berthier, that in galvanizing iron by immersing it in molten zinc, with frequent additions of ammonium chloride, an alloy of zinc and iron is deposited at the bottom of the fused zinc. N. Agéeff and M. Zamotorin, and G. Tammann and H. J. Rocha studied the diffusion of zinc in iron. W. Guertler found that sections of galvanized iron cut obliquely through the outer layers show that the zinc and iron are separated by an intermediate layer of crystals of trizincide, $FeZn_3$. This compound is more electronegative than either iron or zinc, and thus accelerates corrosion if exposed. The zinc layer contains isolated crystals of the monozincide, FeZn, which is also electronegative. Zinc deposited from vapour by the dry process, or from soln. by the electrolytic process, is porous, and also contains minute crystals. C. W. Stillwell and G. L. Clark studied the subject. A. F. W. von Escher investigated the simultaneous deposition of iron and zinc electrolytically—***vide supra.***

A. von Vegesack studied the equilibrium diagram of alloys of iron with up to about 24 per cent. of zinc. This diagram includes the observations of P. T. Arnemann, and S. Wologdine, as well as those of U. Raydt and G. Tammann, who extended the observations over the whole range of the alloys, and prevented the loss of zinc by volatilization, by working at a press. of 110 to 130 atm. The results are summarized in Fig. 416. A. von Vegesack observed that with alloys having between 11 and 24 per cent. of iron, there is a primary separation of crystals which react with the fused mass at 777° to form **iron trizincide,** $FeZn_3$. The crystals of the trizincide separate primarily from alloys with 4 to 11 per cent. of iron, but when the temp. falls to 662°, the compound reacts with the fused mass to form **iron heptazincide,** $FeZn_7$. These two compounds show an inclination to form a solid soln. The heptazincide forms a series of mixed crystals which are saturated when 7·3 per cent. of iron is present. Below 422°, the sat. solid soln. reacts with the fused mass to form another series of solid soln. extending from 0·7 to 7·3 per cent. of iron. U. Raydt and G. Tammann observed the formation of no compound other than those just indicated, but a series of solid soln. of zinc in iron occurs with a saturation point near 80 per cent. iron. A. S. Russell and co-workers, W. M. Peirce, P. Oberhoffer, and S. Wologdine studied the subject. F. Roll found that zinc favoured the decomposition of cementite.

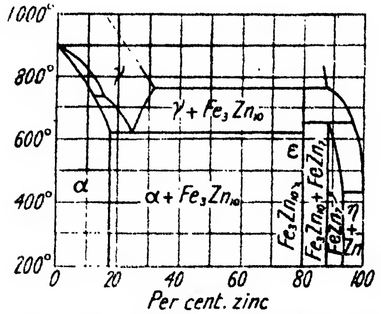

FIG. 416.—Equilibrium Diagram of Zinc-Iron Alloys.

Although only the existence of the trizincide and heptazincide has been established by the thermal process, H. le Chatelier, and S. Wologdine inferred the existence of *iron enneadecazincide*, $FeZn_{19}$; and E. Vigouroux and co-workers, from their study of the e.m.f. of the cell Zn | 0·05*N*-$ZnSO_4$ | $FeZn_x$, the existence of the tri- and hepta-zincides as well as of *iron tritazincide*, Fe_3Zn, and of *iron pentitazincide*, Fe_5Zn. F. C. Calvert and R. Johnson also thought that the crystals obtained in an iron galvanizing bath were those of *iron dodecazincide*, $FeZn_{12}$, but F. Taboury showed that they are identical with the crystals of a solid soln. with 7·3 per cent. of iron, observed by A. von Vegesack. A. S. Russell observed that when an amalgam of zinc and iron is treated with oxidizing agents, zinc is oxidized until definite proportions of the two metals are present when both are oxidized at the same rate, indicating that definite proportions of the two elements are present. The results indicate that compounds with the at. proportions Zn : Fe and Zn : Fe_8 are formed.

A. Osawa and Y. Ogawa obtained Fig. 416 for the equilibrium diagram of the iron-zinc alloys. The X-radiograms of the alloys were determined. Two compounds appear: **iron tritadecazincide,** Fe_3Zn_{10}, is the same as that formerly assumed to be $FeZn_3$. The crystals are cubic with the lattice parameter a=8·93 A., and there are 52 atoms per unit cube. The other compound is iron heptazincide, $FeZn_7$; it furnishes hexagonal crystals with the axial ratio approximating 1·60. The **zinc pentitahenicosizincide,** Fe_5Zn_{21}, alloy; and also the relation between the crystal structure and the atomic properties of the zinc-iron alloys, were studied by A. Westgren.

The observations of C. F. Hollunder, L. Elsner, and P. Berthier showed that the alloys have the general appearance of zinc, but some are whiter; they are also harder and more brittle; in some cases the alloy can be rubbed into crystalline grains by the fingers. A. Westgren, and W. Ekman studied the X-radiograms. A. Osawa and Y. Ogawa noted the similarity of the crystal structure of the zinc–iron system with those of the binary systems of zinc with copper, silver, and gold. The β-phase of the Cu–Zn system corresponds with the α-phase of the Fe–Zn system, and in both the phase forms a body-centred cubic lattice. The γ-phase of the Cu–Zn system corresponds with Fe_3Zn_{10} in the zinc–iron system, and in both, cubic crystals are formed. The ε-phase of the copper–zinc system corresponds with the compound $FeZn_7$, and both have a hexagonal form. The α-phase of the copper–zinc system corresponds with the γ-phase in the iron–zinc system, and both have a face-centred cubic lattice and the latter is stable at a high temp. The cubic lattice of Fe_3Zn_{10} or $FeZn_3$ has a=8·93 A., and has 52 atoms per unit cube. The close-packed, hexagonal lattice of $FeZn_7$ has an axial ratio of about $a : c = 1 : 1·60$, and $a = 2·788$ A. A. J. Bradley discussed this subject. P. T. Arnemann said that the crystals of the solid soln. with up to about 3·3 per cent. iron are harder and more resistant to acids than zinc alone. As the proportion of iron increases, the alloys become harder and more brittle, so that those with 8 to 9 per cent. of iron are extraordinarily brittle and friable. U. Raydt and G. Tammann observed that the alloy with 96 per cent. iron is malleable when cold, but is more brittle than iron, though the alloy with 80 per cent. iron is brittle, and not malleable at ordinary temp. J. E. Hurst, E. K. Smith and H. C. Aufderhaar, and O. Smalley studied the tensile properties of the alloys. K. J. Bayer observed that the alloys are difficult to melt before the blowpipe, and they colour the flame greenish-white. U. Raydt and G. Tammann found that the recurrence of the magnetic permeability occurs :

Fe . .	26·6	43·6	50·0	60·5	67·2	76·0	82·0	87·6	96·0 per cent.
Temp. .	638°–643°	642°	650°	653°	648°	676°	684°	747°	771°

E. Lehmann studied the magnetic properties of the alloys. M. Faraday and J. Stodart, and R. Mallet noted that alloys with copper and zinc are less corrodible than iron. In 1779, W. Keir patented an **iron-copper-zinc alloy** (10 : 100 : 75), and in 1860, J. Aich patented a similar alloy, sometimes called *Aich-metal*. The alloy was recommended as a substitute for copper and brass in shipbuilding and sheathing. It was said to be stronger than copper, and to resist satisfactorily the action of sea-water. H. M. St. John studied these alloys. A related alloy, called *sterro-metal*, contains rather less iron, and a small proportion of tin. Some properties of sterro-metal were described by J. Percy. E. Sorel called an alloy of iron, copper, and zinc (10 : 10 : 80) *unoxidizable cast iron*, or *white brass*. It was said to have the appearance of zinc; the hardness of copper; to be more tenacious than cast iron; and to be susceptible of turning, filing, and tapping. H. N. Warren said that **magnesium-zinc-iron alloys** are used in pyrotechny; and that they are produced by the electrolysis of sodium and magnesium chlorides in the presence of ferrous chloride and zinc, and also by the action of an alloy of sodium and zinc on a mixture of sodium and magnesium chlorides, and then on ferrous chloride.

E. Isaac and G. Tammann examined the **iron-cadmium alloys,** and concluded that cadmium is insoluble in fused iron, and when iron is brought in contact with fused cadmium, it is either insoluble, or forms a compound insoluble in fused cadmium. The temp. of volatilization of cadmium, 770°, limits the range of temp. possible under ordinary press. G. Tammann and W. Oelsen found that cadmium at 400° and 700° dissolves respectively 0·0003 and 0·0002 per cent. of iron. Observations were also made by G. Tammann and K. Kollmann, W. H. Spencer and M. M. Walding, and P. Oberhoffer. N. Agéeff and M. Zamotorin studied the diffusion of cadmium in iron. C. F. Burgess and J. Aston found that an alloy with 5 per cent. of added cadmium forged, welded, and machined easily. A. S. Russell observed no evidence of the presence of a compound of cadmium and iron when an amalgam containing the two metals is treated with oxidizing agents. The cadmium is first removed, then the iron.

It is difficult to form **mercury-iron alloys** or **iron-amalgams** directly from the elements. J. Nicklès [9] said that iron does not take up mercury; P. Casamajor considered that it does. According to T. W. Richards and R. N. Garrod-Thomas, the solubility of iron in mercury is about 0·00135 per cent.: that is, about a milligram of iron in 100 grms. of mercury. E. Palmaer observed 0·00007 per cent. between 20° and 200°; G. Tammann and co-workers gave $1·1 \times 10^{-17}$ grm. per 100 grms. of mercury at 18°; and N. M. Irvin and A. S. Russell, $< \times 10^{-5}$ grm. per 100 grms. of mercury. N. M. Chuiko said that the iron amalgams are colloidal soln.

V. Colvin said that steel can be directly amalgamated by direct contact with mercury and by magnetizing soft steel filings, and dissolving the filings in mercury, a magnetic iron-amalgam is formed. E. H. Amagat observed that at a press. of 4000 atm., mercury will pass through cast iron, 8 cm. thick, and appear like "fine rain," the mercury passes through the intramolecular pores; L. P. Cailletet and co-workers also observed that at a high temp., and a relatively low press., mercury can pass through steel; and P. W. Bridgman observed that surfaces of steel, broken under mercury, are readily amalgamated, but not if the broken surface has had the slightest contact with air. He said:

> When the amalgamation is once started, the rapidity with which it spreads through the metal is greatly increased by hydrostatic press. The spread of mercury through the mass of the steel and the subsequent destruction of the hollow cylinders is produced by two causes, both of which must act together. One is the natural chemical affinity between mercury and steel, shown by the ready amalgamation of freshly broken surfaces. But the amalgamation is never started by the action of press. alone. In all those cases in which amalgamation occurs, there is in addition to the chemical affinity a strain of such a nature as to distend the pores of the metal. This allows the entrance of mercury into the pores so that amalgamation may begin, and also facilitates its further growth, which is most rapid in the direction in which the pores are most distended. In all cases in which rupture occurs the strain is of such a type as to distend the metal, and, on the other hand, in all those cases in which amalgamation is not produced by press., the strain is such as to compress the metal, closing up the pores.

H. Davy showed that an iron-amalgam is produced by the action of an amalgam of an alkali metal on iron; but E. Ramann observed that dry sodium-amalgam does not react when it is heated with powdered iron. L. P. Cailletet observed that iron may be superficially amalgamated by contact with sodium-amalgam and water. V. Colvin, R. Böttger, E. Ramann, J. Schumann, W. Kettembeil, P. Oberhoffer, and P. Casamajor obtained the amalgam in a somewhat similar manner. The last-named observed that:

> If the sodium-amalgam has sodium enough in it to make it pasty, it will cover iron with a silvery coat. This coat may be rubbed off, leaving the oxidized surface unaltered. If brought in contact with water, or, still better, with a soln. of ammonium chloride, the sodium-amalgam is decomposed and the mercury will sink into the iron. If the sodium-amalgam is liquid it will adhere in little drops all over the surface of a piece of iron shaken up in it; by the action of water, of acids, or of ammonium chloride, the droplets will spread on the iron, which will become amalgamated. The coat of mercury left on iron by the various agencies I have mentioned is not a superficial layer, for the mercury sinks into the metal, modifying its physical and chemical properties. In the case of pure soft iron it is difficult to notice any decrease of tenacity after amalgamation. With hard-tempered steel, however, the increased brittleness is very marked. In the case both of iron and steel a fresh fracture shows that mercury has penetrated deeply into the metal.

V. Colvin also obtained iron-amalgam by the action of an amalgam of the alkaline earths on iron. L. P. Cailletet, and P. Casamajor also found that ammonium-amalgam will give up its mercury to iron when rubbed up with it very persistently. Even then there are in every piece of iron certain spots where the mercury will not adhere. The intervention of acidulated water, by decomposing ammonium-amalgam with great energy, facilitates the amalgamation of iron in these difficult portions. P. Casamajor also observed that to amalgamate iron with zinc-amalgam, mercury should be placed in a vessel and covered with dil. sulphuric or hydrochloric acid. If, now, a piece of iron is agitated, in contact with the mercury and the acid, no combination will take place; but if pieces of zinc are placed in the mercury, in a few minutes iron placed in the above conditions will become coated with mercury. If after a while the power of the mercury seems to decline, more zinc must be added. The zinc is only attacked when iron, or some other metal more electronegative than zinc, is brought in contact with the zinc-amalgam and the acid, so that the expense in zinc is very slight.

According to C. Klauer, when sodium-amalgam is immersed in a sat. soln. of ferrous sulphate, a silvery, tenacious mass of iron-amalgam is formed, the separate globules of which readily follow the magnet, and when exposed to air become covered with flakes of hydrated ferric oxide. C. F. Schönbein observed that the amalgam is formed by rubbing a conc. soln. of ferrous chloride with 1 per cent. sodium-amalgam, and washing the product with water. H. Moissan employed a somewhat similar process. A. Aiken triturated zinc-amalgam with an aq. soln. of ferrous chloride, and kneaded the heated product to ensure the union of the 2 elements—A. A. Damour added that the amalgam cannot be obtained in this way. R. Böttger prepared iron-amalgam by rubbing together in a porcelain mortar, a mixture of mercuric chloride and finely divided iron (2 : 1), then add 2 parts of cold water, and when the mass begins to get hot, adding a few drops of mercury. H. Reinsch added iron to a soln. of copper sulphate mixed with a little hydrochloric acid; brushed off the copper deposit, and dipped the metal in a soln. of mercuric chloride acidified with hydrochloric acid. H. A. von Vogel recommended mixing together iron filings and alum (1 : 2); adding two or three parts of mercury and half a pint of water; triturating for an hour at a gentle heat; and finally washing the product with water.

According to J. P. Joule, the electrolysis of a soln. of ferrous sulphate with a mercury cathode, and an iron wire as anode, furnishes iron-amalgam. Using a Daniell's cell, the iron wire gradually dissolved, and an equal portion was taken up by the mercury, which in so doing lost its fluidity, and at length formed a mass of greyish-white crystals with a metallic lustre. The time required is about a day. J. F. W. Herschel previously obtained the iron-amalgam. The amalgam was also prepared by the electrolysis of a soln. of a ferrous salt with a mercury cathode, by J. Schumann, R. E. Myers, T. M. Drown and A. G. McKenna, L. P. Cailletet, P. Casamajor, and A. Zamboni.

E. Palmaer said that X-radiograms of iron-amalgam show that particles of iron are suspended in mercury; and the subject was discussed by R. Brill and W. Haag. According to J. P. Joule, the amalgam with 100 of mercury and 0·143 of iron was quite liquid; with 1·39 of iron it was also liquid; with 2·97, semi-fluid; with 11·8, soft, and of sp. gr. 12·19; with 18·3, solid and greyish-white; with 47·5, solid with a metallic lustre; with 127·6, solid, friable, and of sp. gr. 10·11. According to J. Schumann, E. Ramann, and J. P. Joule, if the amalgam be allowed to stand for some time, or if it be shaken violently, or rapidly stirred, it is decomposed, and the iron floats as a black powder on the liberated mercury; if the soft amalgam be compressed, some black powder also separates out. If amalgamated and ordinary iron are placed in acid and connected by a wire, the amalgamated metal is attacked, and the unamalgamated metal acts as cathode, and, added J. P. Joule, the amalgamation of iron produces a contrary effect to the amalgamation of zinc. Amalgamated iron is positive towards iron, and negative towards copper. H. Reinsch said that when used in a galvanic battery, it gives a stronger and more uniform current than ordinary iron. C. Hockin and H. A. Taylor observed that the e.m.f. of amalgamated iron to amalgamated zinc in a conc. soln. of zinc sulphate, is about 0·486 volt; with a solid iron-amalgam, 0·407; and with mercury containing only a trace of iron, 1·258 volts. According to J. P. Joule, R. Böttger, C. Klauer, C. P. Steinmetz, and A. Zamboni, the iron in the amalgam retains its magnetic qualities, for the amalgam is attracted by a magnet, and it can be permanently magnetized. H. Nagaoka observed that the magnetization increases proportionally with the iron content; the coercive force is high, being 240 gauss with an amalgam with 1·78 per cent. of iron, and 370 gauss with 2·3 per cent. of iron. G. Tammann and W. Oelsen found for amalgams with 0·062 per cent. of iron, the sp. magnetization 0·280 gauss. L. Stjepanek studied the electromagnetic induction. J. Férée observed that iron-amalgam is stable if kept away from contact with air, but in dry air it forms ferrous oxide and mercury; and A. Zamboni said that the dry amalgam is stable in dry air, but it forms a black powder in moist air. C. Klauer, R. Böttger, and H. Reinsch observed that the amalgam in air acquires a yellow film of ferric oxide. M. Krouchkoll said that iron-amalgam is more stable than aluminium-amalgam. J. P. Joule said that when heated to the b.p. of mercury, the liberated iron oxidizes, throwing off red sparks, and leaving a hard lump of oxide. R. Böttger obtained finely powdered iron by distilling the amalgam out of contact with air. M. Faraday and J. Stodart, and R. Mallet noted that alloys with mercury are less corrodible than iron. J. P. Joule observed that if the amalgam be left under water for a few days, it becomes covered with rust, and C. F. Schönbein added that if the amalgam be shaken in air with dil. sulphuric acid, ferrous sulphate and hydrogen dioxide are formed. A. S. Russell and co-workers studied the order of removal of metals from amalgams by oxidizing agents and found Zn, Mn, Cu, Cr, Fe, Mo, Co, Hg, Ni, and W. M. Rabinovich and P. B. Zywotinsky found that iron is dispersed in mercury, above the solubility limits to form colloidal soln. An electromagnet removes no iron from a soln. with 0·0018 to 0·0035 gram-atom per gram-atom of mercury, hence it is inferred that these soln. are colloidal. P. Casamajor added that in dil. sulphuric acid, the amalgam loses only two-thirds of its contained iron. H. A. von Vogel added that if the amalgam be triturated with argentite or silver glance, the mercury is transferred to the silver. A. S. Russell and H. A. M. Lyons studied the **zinc-iron-mercury system.**

The **boron-iron alloys** have been discussed from the point of view of the borides **5.** 32, 4. L. Troost and P. Hautefeuille[10] prepared an alloy with 11 per cent. of boron and found that it could be forged; while an alloy with 23 per cent. of boron was brittle and could not be forged. H. N. Warren obtained alloys by reducing ferrous borate with charcoal; and W. R. Hulbert obtained them by the thermite process. A. Binet du Jassonneix, S. Curie, W. Guertler, L. Guillet, H. W. Gillett and E. L. Mack, T. Miyaguchi, H. Moissan, P. Oberhoffer, N. Parravano and C. Mazzetti, J. W. Richards, and J. M. Weeren also prepared these alloys; and they were discussed by A. Campion, I. Fetchenko-Tchopiwsky, E. Lievenie, J. Ohly, and N. Parravano and C. Mazzetti; and T. P. Campbell and H. Fay studied the cementation of iron by boron.

G. Tammann and K. Schaarwächter said that the attack of iron by boron begins at about 440° and increases rapidly with rise of temp. J. Laissus, and N. Agéeff and M. Zamotorin discussed the diffusion of boron in iron. N. Tschieschewsky and A. Herdt's equilibrium diagram is indicated **5.** 32, 4; and that of G. Hannesen is shown in Fig. 417. This diagram also includes the effect of boron on the critical temp. from the f.p. down to 500°. The transformation of γ- to β-iron decreases from about 895° for pure iron down to 710° for alloys with over 0·8 per cent. of boron. During the solidification of the molten alloy, δ-iron crystallizes out first, until the soln. contains 1·38 per cent. boron, and γ-iron then separates until the soln. has 4 per cent. boron. After that, the pentitadiboride separates out. The eutectic, boron-pearlite, has a f.p. of 1164°. The δ-iron changes into γ-iron at 1414°. The regions of solid soln. of $\beta+\gamma$-iron and of $\alpha+\gamma$-iron are indicated in the diagram. F. Osmond observed that the presence of boron lowered the γ-transformation temp. R. Walter stated that a small proportion of boron promotes the graphitization of cast iron; H. A. Schwartz, that a large proportion inhibits graphitization; and F. Roll, that boron partly preserves and partly decomposes cementite.

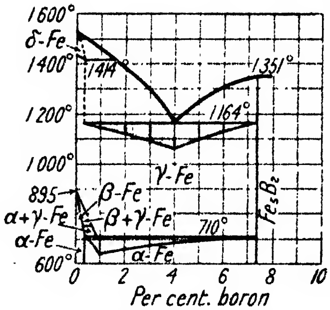

FIG. 417.—Equilibrium Diagram of the Iron-Boron Alloys.

The eutectic system has Fe–C at 1150°, Fe–B at 1165°, Fe_3C–Fe_2B at 1155°, and Fe–Fe_3C–Fe_2B at 1100°. The system at the end of the crystallization of the molten alloy has zones of solid soln. and iron hemiboride. Measurements were also made of the hardness of the alloys. F. Wever studied the effect of boron on the domain of the γ-phase—*vide* **5.** 32, 4, and G. Hägg, the X-radiograms of the hemiboride.

H. Moissan and G. Charpy found that an alloy with 0·58 per cent. of boron and 0·17 per cent. of carbon can be rolled; and is readily worked at a dull red-heat, but crumbles under the hammer if too strongly heated. A. Campion did not observe the excessive brittleness and hardness reported by N. Tschieschewsky and A. Herdt. R. Wasmuht, and N. Tschieschewsky discussed the hardening of steel by boron. L. Guillet observed that boron steels with 0·215 to 0·844 per cent. boron have (i) a solid soln. of ferroboron with a small proportion of boron; (ii) pearlite; and (iii) a substance which was regarded as iron borocarbide. This third constituent produces the brittleness of boron steels; this brittleness disappears on tempering owing to the borocarbide passing into soln. The general effect of boron is to increase the tensile strength, especially after tempering; but a maximum effect is obtained with 0·8 per cent. of boron with low-carbon steels. Observations were also made by P. Blum, the Elektrochemische Werke Bitterfeld, J. E. Hurst, E. Kothny, J. V. McCrae and R. L. Dowdell, T. Miyaguchi and I. D. K. Kaisha, J. Ohly, J. Scott, M. Vasvari, F. C. Weber, and by P. Marsich, and E. K. Smith and H. C. Aufderhaar. A. M. Portevin said that the resistance to shear, and, in particular, the elastic limit on shearing, increase rapidly with the percentage of boron in steel with 0·25 per cent. of carbon. G. Hannesen found that rapidly cooled alloys have the martensitic structure, and the alloys as well as the boride are ferromagnetic. The quenched alloys are softer than those which are slowly cooled. Alloys with primary pentitaboride are hard, and scratch corundum. G. Hägg, and S. B. Hendricks and P. R. Kosting studied the X-radiograms of iron borides. R. Wasmuht, and W. R. Whitney found that boron improves the mechanical properties and electrical resistance of steel. The effect of boron on the electric at. resistance, and the magnetic properties were likewise observed by T. D. Yensen, and the results are summarized in Fig. 419. With increasing proportions of boron, the electrical resistance, the hysteresis loss, the coercive force, and the retentivity all decrease slightly until the amount of added boron becomes appreciable, when all these qualities increase; but even then, boron has a deteriorating effect on the magnetic properties of iron. C. Matignon tested the acid-resisting properties of the ferroborons. E. D. Gleason studied the **iron-carbon-boron-copper alloys.**

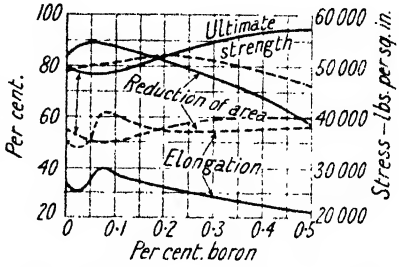

FIG. 418.—The Mechanical Properties of Boron Steels.

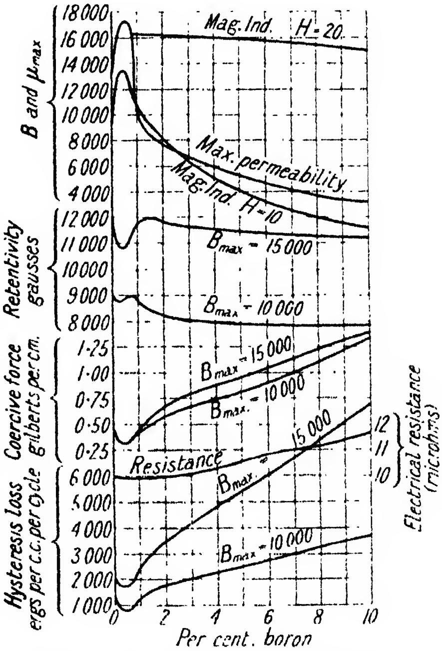

FIG. 419.—Electrical and Magnetic Properties of Boron-Iron Alloys.

H. Davy[11] prepared an **iron-aluminium alloy** by the same method as that which he employed for the alloy of iron and beryllium; and H. St. C. Deville, by passing the vapour of aluminium chloride over iron at a high temp.; G. Tammann and K. Schaarwächter observed that the attack of iron by aluminium begins at about 660° and increases rapidly with rise of temp., as well as by the direct alloying of the two elements; and W. R. Hulbert obtained them by the thermite process. Alloys were also prepared by F. R. Michel, P. Oberhoffer, E. T. Richards, J. Escard, J. W. Richards, W. Guertler, J. Czochralsky, W. Venator, J. Ohly, A. Wahlberg, S. Kern, O. I. Vher and co-workers, J. M. Weeren, and F. C. Calvert and R. Johnson. M. Faraday and J. Stodart obtained alloys which when forged into bars and the surface polished and treated with dil. sulphuric acid, exhibited the damasked surface peculiar to *wootz* or *Indian steel;* but neither C. J. B. Karsten, nor T. H. Henry could find any aluminium in wootz. C. F. Burgess and J. Aston found that alloys with about 2 per cent. aluminium forge and machine easily.

J. Cournot discussed the cementation of iron with aluminium; R. Kremann and co-workers, and R. Irmann, the solubility of aluminium in iron; and A. Hauttmann, G. Grube, N. Agéeff and M. Zamotorin, and N. Agéeff and O. I. Vher, the rate of diffusion of aluminium in iron. F. C. Calvert and R. Johnson obtained what they regarded as *iron tetritaluminide*, Fe_4Al, by heating for 2 hrs. at a white-heat a mixture of 3 mols. of aluminium chloride, 40 gram-atoms of iron, and 8 mols. of lime; *iron tritadialuminide*, Fe_3Al_2, occurs in silver-white beads in the slag from the previous operation; and F. Wöhler obtained *iron dialuminide*, $FeAl_2$, by melting together a mixture of aluminium ferrous chloride, and sodium potassium chloride (10 : 5 : 20). W. C. Roberts-Austen, and L. Guillet made a partial study of the equilibrium diagram; and A. G. C. Gwyer showed that the f.p. curve of iron falls rapidly in passing from 100 to 50 per cent. iron, and at this point there is a distinct break after which the f.p. curve falls slowly from 50 to 30 per cent. of iron, and then rapidly to the f.p. of aluminium. There are two series of solid soln. respectively with 40 to 48 per cent. and 66 to 100 per cent. of iron. The end-member of the first series is thought to be **iron trialuminide,** $FeAl_3$. Alloys with 60 to 65 per cent. of iron show eutectic breaks in the cooling curve at 1087°, and the breaks occur at a higher temp. with from 50 to 57 per cent. of aluminium. Alloys with 52 to 65 per cent. of iron have a eutectic of the same structure, but the latter differs from the eutectic with 50 per cent. iron. The curve *ef*, Fig. 420, represents the lowering of the temp. at which the magnetic permeability disappears on the heating curve as the proportion of aluminium is increased. N. Kurnakoff and co-workers found that in the interval between 32·1 and 39·5 at. per cent. of iron, iron trialuminide, $FeAl_3$ (or possibly Fe_2Al_6), crystallizes from the fused mass, but below 1100°, this compound decomposes into the α- and γ-solid soln. of aluminium in iron. Between 24·2 and 34 at. per cent. of iron, a stable δ-phase is formed having properties different from those of the adjoining phases. This phase shows a minimum electrical conductivity and temp. coeff., and a maximum hardness. It is also very

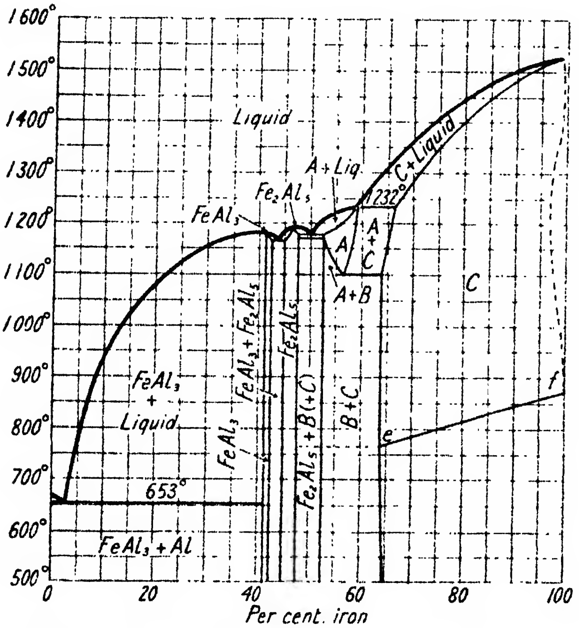

Fig. 420.—Equilibrium Diagrams of Fe-Al Alloys.

brittle. It is considered to be a chemical individual of variable composition. A. G. C. Gwyer and H. W. L. Phillips' study of the system is summarized in Fig. 420. Alloys with 0 to 40 per cent. of iron form a eutectiferous series, the eutectic alloy contains 1·89 per cent. of iron, and freezes at 653°. The liquidus rises to a slight maximum with 40·6 to 41·1 per cent. of iron, and above this range, the alloys are homogeneous. This establishes the existence of iron trialuminide, $FeAl_3$, not N. Kurnakoff and co-workers' Fe_2Al_3. There is a second maximum with about 45·3 per cent. of iron, where over a small range the alloys are homogeneous, and probably contain **iron hemipentaluminide,** Fe_2Al_5, which forms a eutectiferous series with a limited solid solubility with $FeAl_3$. The trialuminide before etching is Chinese white, and the hemipentaluminide is pale lavender; both are attacked by soda-lye; the trialuminide is alone attacked by hydrofluoric acid. All the alloys with 40 to 50 per cent. of iron are brittle, and spontaneously disintegrate in a few days. The liquidus gradually slopes from the Fe_2Al_5 maximum at 45·19 per cent. to a minimum at 49·5 per cent., and beyond that point rises steeply to 58 per cent. where a break occurs. The alloys in the range form a eutectiferous series with appreciable solid solubility. The constituents are Fe_2Al_5, and a solid soln. *A*, which is unstable and breaks up below the solidus. The eutectic line is at 1165°, and *A* breaks up at 1158°, into Fe_2Al_5 and the solid soln. *B*. At 1232° there is a peritectic reaction resulting in the formation of another compound with 59 per cent. of iron. The magnetic transformation occurs at *ef*, Fig. 420. G. Tammann and W. Salge studied the residues left after treating the alloy with an acidified soln. of ammonium persulphate. W. Biltz and C. Haase gave 3·896 for the sp. gr. of Al_3Fe at 25°/4, 35·2 for the mol. vol.; and 25 Cals. for the heat of formation. The subject was studied by L. Grenet, V. N. Svechnikoff, and F. Wever and A. Müller, whose results for the range of stability of the γ-phase are summarized by the dotted line in Fig. 420. F. Roll found that aluminium partly preserves and partly decomposes cementite—*vide* cast iron. O. von Keil and O. Jungwirth also investigated the influence of aluminium on the iron and iron–carbide system. The eutectic composition of the iron–carbon system is reduced by 0·16 per cent. carbon by the addition of 1 per cent. of aluminium; and the pearlitic transformation is slightly reduced by the addition of up to 3·5 per cent. of aluminium, but, as the proportion of aluminium is increased from 3·5 to 8 per cent., it is raised again; and with more than 8 per cent. of aluminium, the intensity of this transformation is very small; and the γ-field ceases to exist with hypoeutectic alloys having less than 5 per cent. of aluminium; the finely-granular distribution of graphite, which corresponds with metastable freezing and spontaneous decomposition, is rendered more prominent; with 5 to 9·5 per cent. of aluminium, the edges of the primary, solid soln. crystals have a decreasing tendency to decompose, and these zones become more readily soluble in acids; and with over 9·6 per cent. of aluminium, the solid soln. becomes stable and readily soluble in acids. The addition of 2·3 per cent. of aluminium to iron with a high proportion of carbon results in the complete separation of the carbon as graphite; with 11 per cent. of aluminium, the graphite completely disappears; and with 18 per cent. of aluminium, the graphite is again completely precipitated. E. Söhnchen and E. Piwowarsky found that aluminium raised the eutectoid temp. and reduced the solubility of carbon in iron. The subject was discussed by J. W. Donaldson, W. L. Fink and K. R. van Horn, and E. L. Reed.

The use of aluminium as a deoxidizing and solidifying agent in the manufacture of steel ingots is so general that its employment is regarded as almost indispensable. E. Adamson, H. M. Boylston, J. E. Carlin, G. F. Comstock, W. F. Darch, W. Eilender and H. Diergarten, C. af Geijerstam, L. Grabau, G. Guzzoni, R. A. Hadfield, C. H. Herty and co-workers, K. Hilgenstock, H. O. Hofman, W. J. Keep, O. von Keil and F. Ebert, J. W. Langley, F. W. Lürmann, J. V. McCrae and R. L. Dodwell, P. Marsich, G. Melland, J. R. Miller, N. Petinot, E. Piwowarsky, M. C. Smith, A. Spiral, S. Sirovich, K. Styffe, T. Swinden,

T. Turner, U. le Verrier, and M. H. Wickhorst studied the effect; and T. D. Yensen and W. A. Gatward thus summarize the action: When aluminium is added to molten iron, it will reduce iron oxide to metallic iron. Furthermore, it will reduce CO or CO_2 gases to free carbon and thus degasify, quiet the bath, and prevent blowholes during solidification and cooling. If the iron is sufficiently liquid, the Al_2O_3 formed will pass to the surface; if it is not, the Al_2O_3 will become entangled in the iron, increase the viscosity, and cause the iron to be more or less unsound. When added in sufficient quantities, 2 to 5 per cent., aluminium will cause carbon to be completely precipitated as graphite and thus transform, for example, white cast iron into grey iron. If 10 to 20 per cent. aluminium is added, however, the carbon may all be in the combined form Fe_3C. As the heat of combustion liberated by the oxidation of aluminium is much greater than that absorbed by the reduction of iron oxides, clearly illustrated by the use of thermite in welding iron, the addition of aluminium to oxidized iron or steel causes a rise in the temp. of the bath. This fact, and not any appreciable lowering of the melting-point, is the cause of the higher fluidity noticed when a small percentage of aluminium is added to the bath. Aluminium is a more powerful deoxidizer than silicon for it does not commence to combine with iron until all oxides present are reduced. F. Osmond showed that aluminium dissolves in iron with the absorption of heat, although an evolution of heat usually attends the phenomenon. This is attributed to the heat liberated by the decomposition of oxides of iron by the aluminium. G. Masing and O. Dahl discussed the expression of the alloys and the formation of warts during the cooling of the alloy owing to the liberation of occluded gases; and W. E. Remmers, the effect of aluminium on the growth of cast iron. For the cementation of these steels, *vide supra.*

A. Westgren and co-workers, K. Schäfer, W. L. Bragg, and A. J. Bradley and A. H. Jay discussed X-radiograms of the iron aluminides. Z. Nishiyama studied the X-radiograms of these alloys, and found for the *a* lattice parameter; the sp. gr.; and the elastic modulus, *E* kgrms. per sq. cm., at 23·0° to 23·2°:

Al . .	2	4	6	8	10	14 per cent.
a . .	2·874	2·884	2·886	—	2·897	2·904 A.
Sp. gr. .	7·6932	7·4619	7·2196	7·0418	6·8848	6·6443
$E\times10^{-6}$.	2·113	2·165	2·090	2·106	1·929	1·826

The microstructure of the alloys was studied by R. A. Hadfield, A. G. C. Gwyer, L. Guillet, and T. D. Yensen and W. A. Gatward; and with the smaller proportions of aluminium, they consist of solid soln. of the constituent elements. J. E. Johnson, F. Wever and A. Müller, A. Borsig, W. J. Keep, and T. W. Hogg studied the action of aluminium in causing the separation of graphite from the carbide in cast iron. E. Piwowarsky found that grey cast iron is appreciably softened by less than 0·10 per cent. of aluminium; and G. Melland and H. W. Waldron, that with rapidly cooled cast iron, with about 0·24 per cent. of silicon, up to 0·25 per cent. of aluminium is needed before any influence on the graphite separation can be detected; with 0·50 per cent. of aluminium, most of the carbon occurs in the graphitic state, and larger proportions of aluminium seem to cause a reversion to combined carbon—possibly owing to the formation of a complex carbide. With slowly cooled samples, the presence of the element is more marked and is more sensitive to varying conditions—*e.g.* casting temp., proportion of silicon, etc. At least 0·9 per cent. of carbon is retained in the whole series whether slowly or rapidly cooled. In general, aluminium decreases the solubility of carbon in iron, and, like silicon, it has a softening influence. A. B. Everest obtained rather different results with iron-carbon alloys free from silicon. Soft, machinable grey irons are produced by adding up to 8 per cent. of aluminium. Aluminium acts less powerfully than silicon as a softener since 2 to 3 per cent. of aluminium are needed to produce an iron comparable with one containing 1 per cent. of silicon. The maximum percentage of carbon graphitized is

61 in the presence of 4 per cent. of aluminium, against 70 per cent. in the presence of 3 per cent. of silicon. The graphite formed with aluminium is finer than in the case of silicon. With aluminium between 8 and 18 per cent., the alloys are hard and brittle, and the carbon is all combined; with between 18 and 25 per cent. of aluminium, the alloys are soft, and graphite is precipitated. Alloys with over 25 per cent. aluminium are not stable in the atmosphere.

L. Guillet observed that the presence of aluminium prevents the pearlite from assuming its ordinary forms; it is in a manner contorted, and it forms little nodules which are more easily coloured by picric acid, and the more closely resemble troostite as the proportion of aluminium increases. With a high proportion of aluminium it is even possible to have free cementite formed in a hypo-eutectoidal steel. The effect of quenching is to transform only the nodules of the pre-existing pearlite giving place to martensite, generally encircled round its edges by troostite. The iron-aluminium soln. is incapable of dissolving carbon. So long as the amount of aluminium is below 3 per cent., the quenching has no effect, but with higher proportions of aluminium, while quenching has no effect on the tensile strength, the elastic limit, or the resistance to shock, whilst the elongation and reduction in area are reduced. Annealing develops the nodular structure of the special form of pearlite without changing the microstructure in any other way; and during the operation all aluminium steels are softened. The presence of aluminium delays case-hardening, and when the proportion of aluminium attains 7 per cent., case-hardening becomes impracticable, and only nodules of cementite are found. H. Sawamura gave the constitutional diagram of aluminium and cast iron alloys. The effect of aluminium on the graphitization of cast iron is indicated above.

F. Wever and A. Müller found the sp. gr. of alloys with 8·64, 13·60, and 21·24 at. per cent. of aluminium to be respectively 7·38, 7·10, and 6·78, values rather lower than those calculated by the mixture rule. T. W. Hogg observed that the sp. gr. of an alloy with 9·62 per cent. aluminium is 6·99 when the calculated value is 6·54 to 6·65—assuming the sp. gr. of steel is 7·80 or 7·88, and that of aluminium 2·60 or 2·70. An alloy with 20 per cent. of aluminium has a sp. gr. 6·31 when the calculated value is 5·59 to 5·69. Hence, the observed sp. gr. are higher than the calculated values. G. Melland and H. W. Waldron gave for the sp. gr. of cast iron at 20°:

Al . .	0	0·024	0·527	1·78	4·24	8·31	11·80 per cent.
Sp. gr. .	7·64	7·58	7·12	7·11	6·88	6·53	6·69

Z. Nishiyama's values are indicated above. W. Brown obtained the following values for the sp. gr. and sp. vol.:

C	Si	Cr	Al	Sp. gr.	Sp. vol.	Sp. ht.
0·67	2·25	--	0·50	7·5930	0·13170	0·1158
0·24	0·18	--	2·25	7·5132	0·13310	0·1165
0·22	--	1·5	4·50	7·1582	0·13970	0·1195

The results show that up to 4·5 per cent. aluminium increases the sp. vol. by 0·0025 per 1 per cent. aluminium. The subject was discussed by B. Simmersbach, and J. O. Arnold. R. A. Hadfield, and G. Tammann and V. Caglioti measured the hardness of some of these alloys. Representing the percentage proportions of C : Al in the alloys, R. A. Hadfield's data for the sp. gr. are:

C : Al . .	0·20 : 0·61	0·17 : 0·72	0·21 : 1·60	0·24 : 2·29	0·26 : 9·14
Sp. gr. . .	7·781	7·755	7·624	7·554	6·672

E. Gumlich represented the sp. gr., D, of the alloys with p per cent. of aluminium by $D = 7·865 - 0·1166p$. C. Benedicks and N. and G. Ericson studied the sp. vol.; and L. Losana, the viscosity of the molten metal; and A. Kussmann and B. Scharnoff, the hardness. E. Söhnchen and E. Piwowarsky found that additions of aluminium up to 1 per cent. halve the hardness of iron-carbon alloys; from 1 to 8 per cent. has little effect, and further additions of aluminium increase the hardness to its original value with 11 per cent. aluminium. The subject was studied by K. Taniguchi, and O. Meyer and R. Hobrock; and the corrosion fatigue, by P. Brenner.

W. Brown found that the presence of up to 2 per cent. of aluminium has little effect on the sp. ht. F. Wüst and co-workers gave for the mean sp. ht. of aluminium steel between 0° and 1000°, $102\cdot39\theta^{-1}+0\cdot21870+0\cdot0000024\theta$; and for the true sp. ht., $0\cdot21870+0\cdot0000048\theta$. The mechanical properties of the alloys were studied by W. W. Christie, C. A. Edwards, F. L. Garrison, R. C. Good, L. Guillet and co-workers, R. A. Hadfield, W. J. Keep, E. Kothny, W. Kroenig, I. Musatti and G. Calbiani, A. L. Norbury, P. Ostberg, S. A. Pogodin, A. M. Portevin, A. Schulze, A. E. M. Smith, E. K. Smith and H. C. Aufderhaar, and K. Styffe, who found that up to 5 per cent. aluminium has very little effect; but with more than 5 per cent. of aluminium, the alloys are stronger in tension, but they become brittle. R. A. Hadfield observed that if 0·2 per cent. of carbon is present, the limits of forgeability are between 5·6 and 9·14 per cent. aluminium, while L. Guillet found the limits to be 7·18 and 9·25 per cent. for alloys with 0·8 per cent. carbon. T. D. Yensen and W. A. Gatward observed that with alloys prepared in vacuo, the tensile strength increases in direct proportion to the aluminium-content up to at least 6 per cent., the ultimate strength of the latter being 60 kgrms. per sq. mm. in the unannealed state, and 50 kgrms. per sq. mm. in the annealed state. The corresponding figures for purified iron are 34 kgrms. and 25 kgrms. per sq. mm. The toughness is only slightly affected by the aluminium-content. A selection from the results for iron with no more than 0·02 per cent. of carbon is summarized in Table LIX. The alloys, annealed at 1000°, were cooled at the rate of 30° per hour. M. Wählert found for alloys of iron with:

TABLE LIX.—MECHANICAL PROPERTIES OF SOME AL-FE ALLOYS.

	Al (per cent.)	Yield-point (lbs. per sq. in.)	Ultimate strength (lbs. per sq. in.)	Elongation (per cent.)		Reduction area (per cent.)
				Before necking	Ultimate	
Unannealed	0·00	50,700	54,700	4·0	26·0	84·3
	0·02	40,200	46,400	5·0	28·0	93·4

Elongation	38·5	30·0	24·2 per cent.

G. Melland and H. W. Waldron found the crushing load in tons per sq. in. to be for iron with aluminium:

Al	0	0·25	0·389	0·722	1·250	2·375	3·82
Crushing load .	101·2	42·5	50·63	45·3	45·18	51·0	50·10

Z. Nishiyama's values for the elastic constants are indicated above. Observations were made by H. Bohner, and R. L. Templin and D. A. Paul. R. A. Hadfield observed that at liquid air temp., −182°, the tenacity increases, and the ductility decreases. E. E. McCollough studied the thermal expansion of some alloys; and A. Schulze found that the values of the coeff. of thermal expansion $\times 10^6$ were as follow:

Aluminium	0·52	2·17	5·66	10·52 per cent.
20°–100°	11·60	11·74	11·96	12·20 $\times 10^{-6}$
100°–300°	13·19	13·21	13·42	13·70 $\times 10^{-6}$
300°–500°	14·42	14·50	14·88	15·12 $\times 10^{-6}$

W. F. Barrett and co-workers found that as the proportion of aluminium increased up to 5·50 per cent., the electrical resistance increased from 10·9 to 70·0 microhms. Observations were made by S. A. Pogodin, and G. Tammann, and V. Caglioti. J. H. Partridge found that aluminium raises the electrical resistance of cast iron. T. D. Yensen and W. A. Gatward's results for the electrical resistance, given in Table LX, show that this property increases about 12 microhms for each per cent. of aluminium added. When the aluminium-content exceeds 3 per cent., the rate of increase falls off more gradually. N. Kurnakoff and co-workers observed the singular points indicated in Fig. 421 for the electrical conductivity and the temp. coeff. of the conductivity of these alloys; A. Schulze, the electrical resistance. G. Tammann and E. Sotter found that the potential of the iron-aluminium alloys in 0·1N-H_2SO_4 slowly falls with time when cathodically polarized, and rises when anodically polarized. A film of oxide is formed as passivity develops. A. M. Portevin observed that with steel containing approximately 0·13 per cent. of aluminium, with different percentages of carbon, the electrical resistance, R microhms per cm. cube at 20°–23°, is:

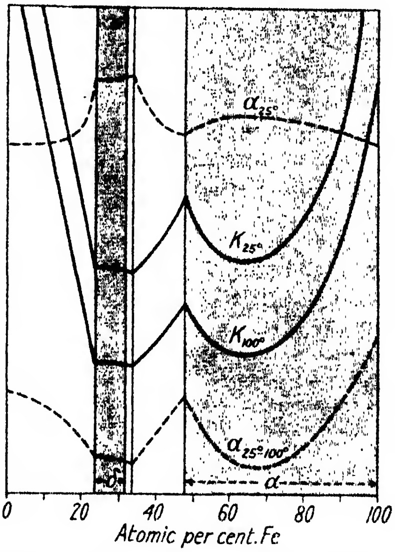

Fig. 421.—The Electrical Conductivity and Temperature Coefficient of the Conductivity for Iron-Aluminium Alloys.

Al		0·51	1·08	2·04	3·05	5·08	7·18 per cent.
R	Normal . .	17·1	26·3	35·9	50·7	63·6	76·6
	Hardened .	17·5	27·2	35·5	51·4	65·4	77·3

and for steels with approximately 0·75 per cent. of carbon:

Al		1·05	2·09	2·89	4·65	9·15	14·90 per cent.
R	Normal . .	30·3	47·4	53·0	65·6	92·6	87·8
	Hardened .	41·8	57·2	60·9	76·5	100·6	99·6

W. F. Barrett and co-workers gave 11·1 microhms per cm. cube for the increase in the resistance of iron produced by 1 per cent. of aluminium; A. M. Portevin gave 11·7 microhms; T. D. Yensen and W. A. Gatward, and E. Gumlich, 12·0 microhms. C. Benedicks' formula for the conductivity—*vide supra*, Fe-Cu alloys—is not generally applicable. Observations were also made by E. Gumlich, and M. Kuroda. E. L. Dupuy and A. M. Portevin measured the thermoelectric force of aluminium steels against copper over a range of temp. from −80° to 100°. The results expressed in millivolts with steel annealed at 1000°, and quenched from 1000°, are as follow:

C		0·17	0·13	0·08	0·81	0·66	0·67	0·86	per cent.
Al		2·04	3·04	7·18	4·65	7·00	9·15	14·90	,,

	100°	−12·65	—	—	−14·65	−16·05	—	−13·15	
Hardened	−80°	−8·10	−11·70	−16·80	−13·60	−15·60	−14·60	−12·80	
	100°	−11·50	−10·05	—	−16·30	—	—	−14·05	

Observations were made by E. Sedström. J. H. J. Daggar stated that the addition of above 5 per cent. of aluminium rapidly destroys the magnetic properties of iron. The magnetic qualities of the alloys were examined by M. E. Thompson and co-workers, S. W. Richardson and L. Lownds, S. W. Richardson, R. L. Wills, W. M. Hicks, T. D. Yensen and W. A. Gatward, J. H. Partridge, E. Gerold, C. Eickmeyer, W. F. Barrett and co-workers, L. Guillet, A. Schweitzer, E. Gumlich, and G. Dillner and A. F. Enström. T. D. Yensen and W. A. Gatward found that aluminium, like silicon, has a beneficial effect when added in small quantities. The results for alloys with no more than 0·02 per cent. of carbon are summarized in Table LIX. The best alloys obtained, contained about 0·40 per cent. of aluminium, annealed at 1100°, and cooled at the rate of about 30° per hour, had a maximum permeability above 35,000. The hysteresis losses, for $B_{\text{max.}}=10,000$ and 15,000, are 450 and 1000 ergs per c.c. per cycle, respectively. For higher aluminium-contents the magnetic quality decreases gradually, so that the alloy containing 3·5 per cent. aluminium has a maximum permeability of 20,000 and hysteresis losses for the given densities of 1000 and 2200 ergs, respectively. This loss is only one-half that of the 3·5 per cent. commercial silicon steel. A. Kussmann and B. Scharnoff observed no relation between the coercive force and hardness. E. Gumlich studied the magnetic saturation of iron-aluminium alloys; and A. Schulze the magnetostricture in different magnetic fields. Observations were also made on the effect of the magnetic intensity, and magnetic concentration on the magnetostricture.

G. Tammann and G. Siebel found that the introduction of aluminium results in a marked reduction in the rate of oxidation of iron. J. E. Stead stated that the presence of aluminium increases the liability of steel to corrosion. G. Tammann and E. Sotter discussed the passivity of the alloys. A. Hauttmann observed that the increases in weight, in grms. per sq. m. per hour, due to oxidation which occurs when the iron-aluminium alloys are heated for 48 hrs. in air, are:

Al	0	1·84	3·72	9·44	22·34	38·32	per cent.
Oxidation	45·7	36·2	31·5	0·57	0·29	0·14	

F. C. Calvert and R. Johnson observed that dil. sulphuric acid will extract the iron from the alloys and leave the aluminium; and F. Wöhler, that soda-lye extracts the aluminium and leaves the iron. The alloys are soluble in hydrochloric acid. C. F. Burgess and J. Aston observed that the corrosion of alloys of electrolytic iron with 0, 0·067, and 1·333 per cent. of aluminium is represented by a loss of respectively 1·300, 0·628, and 0·760 grms. per sq. dm. when immersed for an hour in 20 per cent. sulphuric acid; or by loss of respectively 0·499, 0·513, and 0·390 kgrm. per sq. metre per year when exposed to the weather for 162 days from July to February. S. Satoh studied the nitridizing of these steels by heating them in ammonia at 560° to 580°; and O. Bauer, and A. von Zeerleder, the effect of aluminium on the resistance of steel to dil. sulphuric acid. H. Gruber found that with alloys 60×13×12 mm. after an hour's exposure to hydrogen sulphide:

	Al : Fe	700°	800°	900°
Gain in weight	0 : 100	0·76	5·51	10·0
	5 : 95	1·37	4·89	12·8
	10 : 90	0·33	2·38	19·1
	15 : 85	0·05	0·15	25·0

The study of light aluminium alloys for aeronautical and other work involved observations on alloys containing preponderating proportions of aluminium.

TABLE LX.—MAGNETIC AND ELECTRICAL PROPERTIES OF FE-AL ALLOYS.

	Al (per cent.)	Permeability (max.)	Density (gausses)	Permeability		Hysteresis loss (ergs) (c.c. per cycle)		Retentivity (gausses)		Coercive force (per cm.)		Sp. elect. resistance (micr-ohms) (at 20°)

	6·24	16,050	3,200	7,400	259	922	2,830	8200	9,100	0·27	0·31	70·4

R. J. Anderson said that no binary alloy of aluminium and iron is employed commercially. C. A. Edwards studied the mechanical properties of the binary alloys with up to 5 per cent. of iron; and H. Schirmeister, alloys with up to 12·5 per cent. of iron. S. A. Pogodin, O. L. Kowalke, C. A. Edwards, W. Rosenhain, J. Ohly, F. C. Lea, N. A. Ziegler, M. Ballay, E. T. Richards, A. V. Farr, S. F. Herman and F. T. Sisco, V. Fuss, K. Yamaguchi and I. Nakamura, and L. J. Wills also studied the properties of some ternary **aluminium-copper-iron alloys**; V. Fuss, of some ternary **aluminium-magnesium-iron alloys**, and of some **aluminium-zinc-iron alloys**; C. A. Edwards, L. J. Wills, some quaternary Al–Cu–Fe–Mg and Al–Cu–Fe–Zn alloys.

W. Kroll[12] studied some **gallium-iron alloys.** According to E. Isaac and G. Tammann, **thallium-iron alloys** were not obtained because the b.p. of thallium, 1515°, is below the m.p. of iron. J. G. Gahn[13] heated to whiteness a mixture of ceric and ferric oxides, and charcoal, and obtained a green, porous, brittle, magnetic mass, which appeared to be metallic when filed. Observations were made by P. Oberhoffer.

H. C. Kremers and R. G. Stevens found that the **lanthanum-iron alloy** (85 : 15) is hard, but is not pyrophoric when scratched with a file. A 30 per cent. alloy is much harder, and shows no increase in pyrophoric qualities. The alloy is resistant to tarnishing in air. N. Agéeff and M. Zamotorin studied the diffusion of cerium in iron. The **cerium-iron alloys** were investigated by R. Vogel, H. Suchanek, L. W. Spring, A. Trillat, and A. Hirsch. Starting from 95·6 per cent. cerium, free from neodymium and praseodymium, but with lanthanum and traces of iron, melting at 775°, R. Vogel found that the f.p. falls to a eutectic at 635° and 5 per cent. of iron. The rising branch of the curve shows the existence of **iron hemiceride,** $CeFe_2$, which changes at 773° into **iron pentitadiceride,** Fe_5Ce_2—or, according to F. Clotofsky, into **iron ceride,** CeFe. L. Guillet studied the hemiceride. The second break in the curve is at 1085°, where this ceride breaks up into solid soln. rich in iron, and liquid. The solid soln. contains up to 15 per cent. of cerium at 1085°, diminishing on cooling to about 11 per cent. cerium at 850° and lower temp. It undergoes two polymorphic changes due to those of iron at 840° and 795°. The latter is recognized by the appearance of magnetic properties on cooling. The change in the saturation of the solid soln. at these transition points is too small to be observed; the two cerides do not form solid soln. The reactions in the solid state take place slowly, and there is a difficulty in obtaining equilibrium. The hemiceride is magnetic at ordinary temp. but becomes non-magnetic at 116°. It is uncertain how far the second compound is magnetic since the alloys contain the magnetic solid soln. which becomes non-magnetic at 795°. The hardness is a maximum at 60 per cent. cerium. F. Clotofsky found that the curve showing the variation of the potential difference with composition with a soln. of 0·3N-cerium chloride and 0·2N-ferrous chloride has breaks corresponding with the existence of iron ceride, CeFe, and with **iron hexitaceride,** $CeFe_6$, but the composition of the latter is not certain. H. Beck said that at 800°, molten cerium takes up considerable amounts of iron ultimately forming what he regarded as **iron decitaceride,** $CeFe_{10}$. A. B. Schiotz obtained alloys approximating Ce_2Fe_3 by the electrolysis of soln. of ferrous and cerous salts. R. Vogel found that the sat. solid soln. of cerium and iron is more resistant to oxidation than pure iron; the compounds are readily oxidized. The pyrophoric properties of the alloys reach a maximum with 70 per cent. of cerium, and depend on the presence of one or other of the compounds. Pyrophoric cerium alloys usually consist of a hard compound embedded in a softer, readily oxidizable ground mass. The pyrophoric alloys obtained by alloying mischmetall with about 30 per cent. of iron were patented by A. von Welsbach; and the subject was discussed by H. Kellermann— **5.** 38, 10. P. Martin studied Kerr's effect. The mechanical properties of alloys with cast iron were examined by R. Moldenke, E. Kothny, E. K. Smith and H. C. Aufderhaar, J. E. Hurst, etc.; and the magnetic properties by G. Rassat. H. W. Gillett and E. L. Mack thus summarize the effects of cerium:

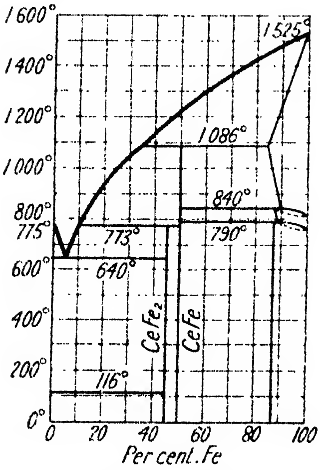

FIG. 422.—Equilibrium Diagram of the Ce-Fe Alloys.

> Cerium is readily oxidizable and, like uranium, is difficult to introduce into steel without segregation and loss. Cerium can combine with sulphur and act like manganese in preventing the formation of iron sulphide. Some sulphur may be eliminated by the use of cerium, but cerium steels retain some of the sulphur compounds or some oxidation products of cerium as inclusions and are prone to excessive dirtiness. Up to amounts which can be introduced without too much difficulty, the effect of cerium on the critical points, the propensity for hardening and the mechanical properties seems to be very small. Tests on certain steels are generally vitiated as far as showing the alloying action of cerium by the multitude of non-metallic inclusions present. Cerium is probably present in steel, at least in part, as carbide. A steel containing 0·25 per cent. cerium gives a strong acetylene-like odour on exposure of a fresh fracture. After giving various tests in detail and analyzing the results, they conclude that cerium appears to have no true alloying effect in steel and does no good. Since it gives rise to inclusion, it probably does harm. There is a possibility that it might be used as a scavenger to eliminate or control sulphur if means could be found to eliminate the accompanying inclusions.

The **iron-silicon alloys,** and *ferrosilicon* were discussed in connection with the iron silicides—**6.** 40, 13. G. Tammann and K. Schaarwächter [14] found the attack of iron by silicon begins at about 1000°. R. Walter observed that when soft iron together with silicon or a high percentage ferrosilicon is heated to 1250°, a vigorous reaction occurs, the temp. rises above 1800°, and the mass melts. The early samples of siliceous iron contained up to about 6 per cent. of silicon; and the siliceous cast iron known as *glazed pig,* or *burnt pig,* formerly rejected as useless, may now be manufactured deliberately. J. Percy, and C. J. B. Karsten obtained highly siliceous iron by heating iron and silica in the presence of carbon; the silica is not reduced if carbon be absent. Alloys were made by E. Riley in 1872; and by A. Pourcel in 1878. T. E. Holgate gave a number of analyses showing that the proportion of carbon decreases as the silicon-content increases; and in 1862, H. Caron had observed that silicon transforms combined carbon into the graphitic state. G. J. Snelus, in 1871, and C. Wood also, in 1885, observed silicon converted combined carbon into free carbon and so transformed white cast iron into grey cast iron. The alloys were discussed by J. Ohly, W. Schut and J. D. Jansen, J. Arnott, G. Kothny, H. D. Hibbard, R. P. Hudson, H. Buchholtz, H. Koppenberg, C. Wallmann, K. von Kerpely, J. Silberstein, H. Jungbluth, M. Debar, C. A. Heise, W. Guertler, R. Walter, F. Peters, A. T. Lowzow, J. Escard, J. W. Richards, J. Härden, E. Piwowarsky, R. Namais, E. Donath and M. Hailsig, P. Girod, A. Ledebur, G. P. Scholl, J. Ohly, B. L. Vanzetti, W. Pick and W. Conrad, F. M. Becket, H. C. H. Carpenter, M. G. Corson, P. H. Brace, W. G. Merten, H. Delomenie, and E. Lievenie. Some of the trade-names of the corrosion-resisting iron-silicon alloys are: *duriron, tantiron, corrosiron, thermisilid, elianite, ironac,* and *métillure*. They carry from 13·5 to 16·9 per cent. of silicon, 81 to 85·5 per cent. of iron, 0·2 to 1·25 per cent. carbon, 0·06 to 0·78 per cent. of phosphorus, 0·01 to 0·15 per cent. of sulphur. Métillure has 0·25 per cent. of aluminium, and elianite, 2·23 per cent. of nickel. T. D. Yensen found that carbon is more effective as a deoxidizer than silicon, and that 2 to 3 per cent. of silicon is about as effective as 0·3 per cent. of carbon. Silicon can dissolve in iron in all proportions, but only 4 to 5 per cent. of carbon dissolves in the absence of special impurities or metalloids. The control of the proportion of silicon in pig-iron was discussed by W. H. Morris; and J. W. Thomas showed the variations in the proportions of silicon in pig-iron as the iron flows from the blast-furnace. The deoxidizing powers of silicon were discussed by C. H. Herty and G. R. Fitterer. The behaviour of silicon in cast iron, etc., was studied by I. L. Bell, C. F. Joseph and A. L. Boegehold, O. von Keil and F. Ebert, G. Jüngst, P. Oberhoffer, M. H. Wickhorst, A. Smith, J. M. Weeren, J. S. Kennedy, P. Girod, W. Venator, and B. Neumann. T. Turner, and W. J. Keep and E. Orton observed that white cast-iron which gives porous and brittle castings yields a metal free from honeycombing, and possesses greater strength when it is associated with a little silicon. With up to 2 per cent. silicon, the iron becomes grey, and possesses a maximum strength. With more silicon, the iron remains grey, but becomes weaker, and closer grained. C. F. King observed that in pig-iron the carbon liberated on cooling is proportional to the proportion of silicon, and he also estimated the rate of elimination of the metalloids in the Bessemer process. F. Gautier said that some of the alleged ill-effects of silicon, by C. J. B. Karsten, etc., may be due to the presence of silica, which, as H. von Jüptner emphasized, may accumulate between the crystal grains, and lower the tenacity of the metal. R. A. Hadfield also favoured this view, for he observed that the presence of up to 2 per cent. silicon imparted a remarkable ductility and toughness in the bending and tenacity tests. L. Guillet said that the only silicon steels capable of being rolled are those with less than 5 per cent. silicon and 0·20 per cent. carbon, and with 2 per cent. silicon and 0·80 per cent. carbon. According to R. A. Hadfield, a specimen with 0·24 per cent. silicon did not forge well since it cracked while being hammered; but samples with 0·79 to 5·53 per cent. of silicon forged at a yellow-heat. Samples with higher proportions of silicon are red-short and crumble at a low red-heat even when there is only 0·25 per cent. of carbon; with a higher proportion of carbon, the metal becomes red-short with a lower proportion of silicon. The red-shortness is not removed by further additions of silicon, or of manganese. The fractures with 2·18 per cent. silicon are silky, and with higher proportions they are coarsely crystalline. T. D. Yensen found that the limit of forgeability of iron-silicon alloys lies between 7 and 8 per cent. silicon. A critical range occurs between 2·55 and 2·60 per cent.

silicon in which the alloys are very brittle, being in some cases unforgeable. According to R. A. Hadfield, neither annealing nor water-quenching has any effect on the structure of cast or forged silicon steel. There is a striking change in the fracture on exceeding 2·5 per cent. silicon. The crystals become large, have a glazed appearance, and cleave after the manner of speigeleisen. As this crystalline structure becomes more marked, the metal becomes very brittle, approaching silicon cast iron, and is non-malleable. The presence of silicon in steel is fatal to welding. C. F. Burgess and J. Aston discussed the working qualities of the silicon-iron alloys.

F. Osmond found that silicon combines with iron with the evolution of heat, but the resulting compound is decomposed by an excess, and it can exist only if sufficient silicon be present. A. Fry, N. Agéeff and M. Zamotorin, M. Dubowicky, and L. Guillet discussed the diffusion of silicon in solid iron; and W. F. Holbrook and co-workers, in liquid iron. The equilibrium diagrams of the iron–silicon system, and of the iron–carbon–silicon system were discussed in connection with the iron silicides **6.** 40, 13. There is not yet general agreement in all parts of the equilibrium diagram—particularly below 15 per cent. silicon. B. Stoughton and E. S. Greiner's summary is indicated in Fig. 423. The curve of magnetic transformation, *FKG*, occurs at 760° with an alloy having 1·76 per cent. Si, drops to 450° as the silicon increases to 17·04 per cent., and remains at 450° with alloys having up to 25 per cent., it is perceptible with alloys having 27·30 per cent. but not with alloys having a higher proportion of silicon. The curve *FKG* thus represents the effect of silicon on the A_2-transformation of iron. N. B. Pilling observed a sharp line of demarcation between brittle and ductile alloys—probably the dotted line, Fig. 423; and B. Stoughton and E. S. Greiner observed confirmatory evidence on the temp.—electrical resistance curve. Alloys with less than 33 per cent. of silicon undergo a complex series of transformations on cooling; the line *AB* is supposed to represent the peritectic formation of Fe_3Si at 1255°, because T. Murakami observed no evidence of heat corresponding with *CD* in alloys with less than 18 per cent. of silicon, and because on extrapolating N. B. Pilling's results, the curve *AB* connects with the peritectic reaction at *B*. It may be that the curve *AB* connects with *CD* at *C* instead of the peritectic reaction at *B*. T. Murakami regards the magnetic transformation *FK*, and *KG* as changes of phase, and the line *HI* represents a transformation of Fe_3Si_2. The lines separating the γ- from the α-phase have been traced by F. Wever and P. Giani, R. Frilley, H. Esser and P. Oberhoffer, M. Bamberger and co-workers, and A. Sanfourche. Fig. 423 is based on the assumption that four silicides are formed. M. G. Corson considered that his photomicrographs demonstrate the existence of **iron tritasilicide,** Fe_3Si, formed by a peritectic reaction between the melt and the solidus at *B*; then a peritectic reaction sets in at 1020°, the line *DE*, between Fe_3Si and FeSi, to form **iron tritadisilicide,** Fe_3Si_2, thus $Fe_3Si + 3FeSi \rightleftharpoons 2Fe_3Si_2$. The ditritasilicide is decomposed at temp. exceeding *DE*, and the tritasilicide is decomposed when heated to *BN*.

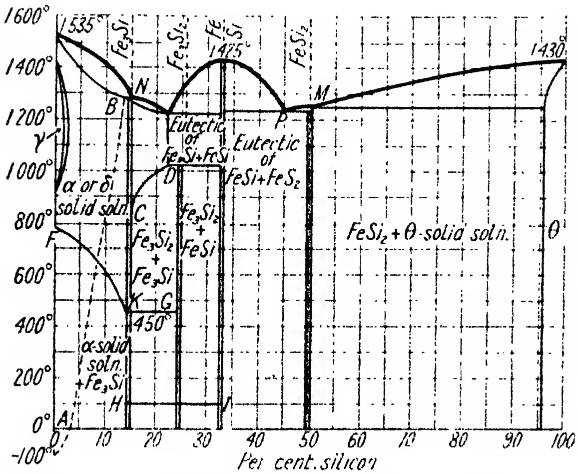

Fig. 423.—Equilibrium Diagram of the System: Iron–Silicon.

There is a maximum in the m.p. curve corresponding with **iron monosilicide,** FeSi, and a hidden maximum in its m.p. curve corresponding with **iron silicide,** $FeSi_2$. F. Wever and H. Möller found that the monosilicide has 4 mols. in a unit cell, and $a=4{\cdot}467$ A. Whilst there is a doubt, the probabilities are in favour of the existence of Fe_3Si, Fe_3Si_2, and $FeSi_2$. Alloys with over 33·3 per cent. of silicon are comparatively simple; there is a eutectic at 45 per cent. silicon, and the disilicide at *M*. There is only 5° difference of temp. between the eutectic at *P* and the m.p. of the disilicide at *M*. The θ-phase is a solid soln. of the disilicide in silicon. According to J. L. Haughton and M. L. Becker, the liquidus and solidus curves of the α-solid soln. lie close together and fall at 35 per cent. silicon to 1198°; the eutectic temp. with the ϵ-phase—FeSi. The maximum of the liquidus curve in the ϵ-region is at 1410°, and falls at 51 per cent. silicon to the eutectic with the ζ-phase at 1213°. The ζ-phase is thought to be **iron hemipentasilicide,** Fe_2Si_5, which forms a eutectic with 59 per cent. of silicon at 1208°. Iron is but slightly soluble in silicon, but the solubility of silicon in iron at the eutectic point is 18·5 per cent. and it falls to 15 per cent. at about 800°. In agreement with T. Murakami, the arrest on the cooling curve, at about 1030°, is attributed to the formation of iron tritadisilicide, Fe_3Si_2. There is another arrest at 950°, which has not yet been interpreted. Silicon lowers the $\beta\alpha$-transformation until it meets the boundary of the η-phase at 490° and 14·5 per cent. of silicon, after which the curve is horizontal up to 25 per cent. silicon. The magnetic transformation at 82° is due to a change in the η-phase. R. T. Haslam and L. E. Carlsmith, and A. Fry studied the diffusion of silicon in iron—*vide* cementation—and A. Sanfourche, the cementation of iron with silicon by means of silicon tetrafluoride. F. Wüst and O. Petersen, and G. Charpy and A. Cornu-Thénard showed that the solubility of carbon in iron decreases as the proportion of silicon increases. The solubility of carbon in iron was discussed by W. Gontermann, K. Honda and T. Murakami, D. Hanson, H. Voss, F. Roll, A. Merz, T. F. Pearson, A. L. Norbury, J. H. Andrew, M. L. Becker, H. Moissan, F. Poboril, and J. E. Stead. F. Wüst and O. Petersen found that the presence of silicon causes the ledeburite point to occur with a lower proportion of carbon, or at a higher temp.; and, as indicated above, it renders the formation of cementite more difficult, and favours the production of graphite. M. L. Becker found that as the silicon increases up to 4 per cent., the solubility of carbon at any constant temp., between 940° and 1100°, decreases, whilst the effect of temp. in raising the solubility becomes less marked. Below 940°, probably in the neighbourhood of 920°, the solubility drops to zero. The effect of silicon on the Ar_4-arrest was also discussed **6.** 40, 13, and in connection with the equilibrium diagram of the carbon-iron alloys. F. Osmond, W. Gontermann, T. D. Yensen, L. Grenet, T. Naske, K. Honda and T. Murakami, and G. Charpy and A. Cornu-Thénard showed that the effect of silicon is to raise the temp. of the A_3-arrest, and to diminish its intensity; whilst R. Ruer and R. Klesper, A. Sanfourche, F. Wever and P. Giani, G. Phragmen, and D. Hanson have shown that the A_4-arrest occurs at decreasing temp. and gradually disappears. This, coupled with the fact that A. Westgren and G. Phragmen found that the space-lattice of δ- and α-iron are the same, led P. Oberhoffer, D. Hanson, and T. D. Yensen to suggest that with silicon above, say, 1·5 to 2·5 per cent., the A_3- and A_4-arrests merge into one another, and γ-iron is no longer present in the system. F. Wever and H. Möller studied the X-radiograms of the monosilicide. F. Wever and P. Giani also found that the $\alpha\rightarrow\gamma$ transition temp. is raised and the $\gamma\rightarrow\delta$ transition temp. is lowered by increasing proportions of silicon, and no transition occurs when more than 1·8 per cent. of silicon is present. The subject was studied by J. H. Andrew, R. S. Archer, A. Carnot and E. Goutal, G. de Chalmot, W. Claus and R. Hensel, W. Haufe, A. Hayes and co-workers, K. Honda and T. Murakami, A. Jouve, A. Kriz and E. Poboril, P. Lebeau, A. L. Norbury and E. Morgan, P. Oberhoffer and C. Kreutzer, G. Phragmen, N. B. Pilling and G. P. Halliwell, C. Schols, H. A. Schwartz and co-workers, H. Scott, E. Vigouroux, and F. Wever. F. Körber described the "etching colours" of the iron-silicon alloys.

H. A. Schwartz and A. N. Hird observed that in the freezing of the eutectic for the ternary system, the silicon will be rejected to the liquid and will be found – possibly as a silicocementite—in the eutectic cementite if the cooling is slow enough for equilibrium conditions. G. Charpy and A. Cornu-Thénard thus summarized their observations on this subject. The A_3-point rapidly decreases as the proportion of silicon increases. The A_2-point falls gradually in the temp. scale when the percentage of silicon rises; it loses little by little its intensity, but still persists when 7 per cent. of silicon is present. In this case, the A_2-point is the only anomaly appearing on the thermal diagram of alloys containing a low proportion of carbon even when the rate of variation in temp. is sufficiently accelerated. The effect of silicon on the eutectic temp. of the pearlite precipitation was examined by F. Wüst and O. Petersen, A. P. Hague and T. Turner, and W. Gontermann. D. Hanson also studied this subject. E. Söhnchen and E. Piwowarsky observed that silicon reduces the solubility of carbon in iron, and 5·7 per cent. of silicon raises the eutectoid temp. to 940°. F. Wever and P. Giani, E. Gumlich, and K. Honda and T. Murakami studied the effect of silicon on the temp. of the β- to α-magnetic change. W. Guertler and G. Tammann found that with the following atomic proportions of silicon, the Ar_2-point was but little affected:

Silicon . .	0·06	10·40	20·00	29·10	38·60	47·50 at.
Ar_2-arrest . .	760°	750°	745°	735°	720°	720° per cent.

According to G. Charpy and A. Cornu-Thénard, the individuality of the A_2-point is more clearly indicated by the fact that it is possible, at will, to retain in or eliminate from its vicinity the *A_1-point*, by bringing into play the precipitation of graphite. The temp. at which the A_1-point occurs rises with increasing proportions of silicon, reaches and finally passes the A_2-point, and at the same time it becomes fainter. After reaching a given proportion of silicon and a given rate of variation of temp., the A_1-point completely disappears, and all the carbon in the metal is then graphite. The effect of silicon on the critical temp. of iron was discussed by E. Gumlich, W. E. Ruder, A. P. Hague and T. Turner, F. Osmond, J. O. Arnold, G. Charpy and A. Cornu-Thénard, R. Ruer and R. Klesper, B. Kjerrman, F. L. Meacham, T. Baker, P. Debye, H. Faxen, L. M. Brillouin, I. Waller, F. Wever and P. Giani, H. Esser and P. Oberhoffer, P. Oberhoffer and H. Heger, E. H. Schulz and F. Bonsmann, A. Sanfourche, F. Wüst and O. Petersen, T. D. Yensen, W. Gontermann, and K. Honda and T. Murakami—*vide* **6**. 40, 13.

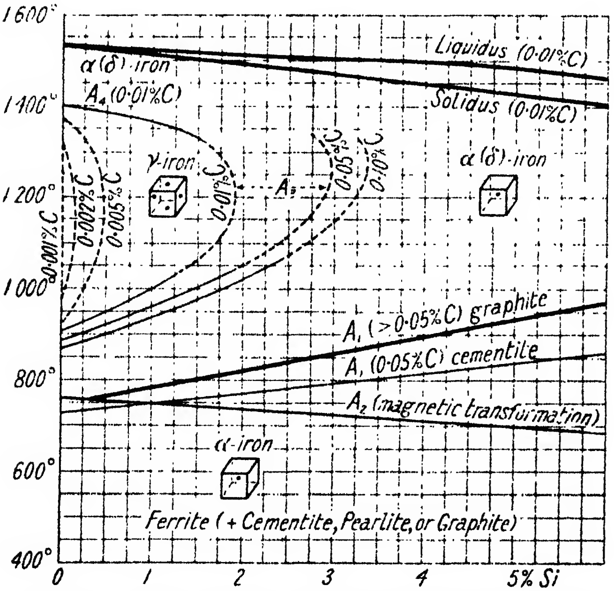

FIG. 424.—The Constitutional Diagram of Alloys of Iron with Small Proportions of Silicon.

The results of C. Kreutzer with the X-radiograms are summarized in Fig. 424. With up to 2·2 per cent. of silicon, α-iron changes into δ-iron through γ-iron; with 2·2 to 2·5 per cent. of silicon there is a region where α- and γ-iron can co-exist, but above 2·5 per cent. of silicon, the α-phase changes directly into the δ-phase. Accordingly, T. D. Yensen represented the constitution of the low-silicon alloys of iron, with 0·001 to 0·1 per cent. of silicon, by Fig. 424. The dotted lines have not been established experimentally. The A_3-arrest increases rapidly with a decrease of carbon, below 0·05 per cent., when the proportion of silicon is constant, and this leads to the conclusion that the A_3- and A_4-transformations depend on the carbon-content in such a way that the lower the carbon, the less the proportion of silicon needed to eliminate these points. Hence, the 1·5 to 2·5 per cent. of silicon reported to be needed to efface the A_3-arrest is really dependent on the proportion of carbon, and with no carbon no silicon would be required to obliterate the A_3-arrest provided oxygen and other interstitial impurities can be kept out. A. Westgren and G. Phragmen observed that the γ to δ-transformation is a reversion of the α to γ-transformation, and P. Oberhoffer, and G. Phragmen found that with 2·5 per cent. silicon steel, the α- and δ-ranges form one common domain; and E. C. Bain made a similar observation with respect to chromium steel.

The silicon is presumably present as silicide in molten cast iron; and during solidification when the eutectic breaks up into solid cementite and austenite, the silicide was thought by W. Gontermann to divide itself between the cementite and austenite. J. E. Stead observed that in low silicon irons, the austenite retains the silicon in solid soln. as silicide, but as the proportion of silicon in the iron increases, some unites with the carbide to form iron carbosilicide—silicocementite, possibly $Fe_3(Si,C)$. Indeed, he observed that two different cementites crystallize from high silicon irons—one, comparatively free from silicon, becomes red on heat-tinting, and the other, comparatively rich in silicon, remains white during the heat-tinting. The highly silicified cementite is unstable, and J. E. Stead considered that it is responsible for the graphitic condition of cast irons. The carbon in the iron carbide may be precipitated at high temp. by the diffusion of the silicide from the austenite. In the cooling of solid, high silicon irons, the austenite, remaining after the separation of the primary graphite, deposits more cementite associated with more or less silicide, and the silicocementite will be less likely to persist the higher the proportion of silicon in the iron. At the temp. of the pearlitic change, there is still present the solid soln. of cementite containing much silicide. As the solid soln. is resolved into pearlite, and if the proportion of silicon is high, the whole of the pearlitic carbide dissociates into a ferritic matrix with the silicon in solid soln. as silicide. The cooling curve of grey cast iron with a trace of combined carbon; graphite, 3·30 per cent.; manganese, 0·676; silicon, 4·321; sulphur, 0·025; and phosphorus, 1·660, has an arrest at 1118°, the primary f.p., and freezing is extended to 1030° as the iron carbide, containing the bulk of the silicon, dissociates; the arrest at 943° is due to the freezing of the iron-phosphorus-carbon eutectic; the arrest at 850° is due to the formation of pearlite, and the arrest at 690° is probably due to the formation of pearlite in the eutectic of iron and phosphorus, and it points to the conclusion that silicon is not a constituent of the austenite of the ternary eutectic. P. Bardenheuer and M. Künkele, and P. Oberhoffer and C. Kreutzer studied the effect of silicon on the arrests. D. Hanson studied the effects of 0·4 and 1·9 per cent. of silicon on annealed and quenched iron-carbon alloys. T. F. Pearson also examined the effect of silicon in hastening the graphitization of carbon-iron alloys—*vide supra*, cast iron. K. Schichtel and E. Piwowarsky found that the solubility of carbon in liquid iron is lowered by the presence of silicon, and the effect on the carbon solubility curve is shown in Fig. 425. The effect on the proportion of carbon in the eutectic, and on the eutectic temp. is shown in Fig. 426. Observations

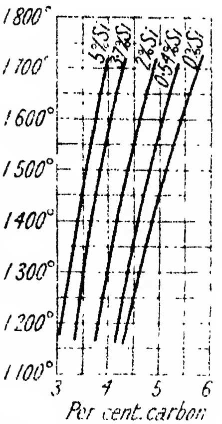

FIG. 425.—The Effect of Silicon on the Solubility of Carbon in Iron.

were also made by F. E. Bachman, W. Gontermann, A. L. Norbury, K. Honda and T. Murakami, B. S. Summers, and F. Wüst and O. Petersen. The reduction per unit of silicon, up to 3 per cent., is smaller the higher the proportion of silicon, and with over 3 per cent. of silicon, the reduction is proportional to the content of silicon, but increases from 0·28 to 0·40 unit of carbon per unit of silicon as the temp. rises from 1200° to 1700°. The addition of 1·2 to 6 per cent. of silicon to hypoeutectic alloys of carbon and iron causes graphite to separate in a very finely divided form, but with hypereutectic alloys, the graphite separates in needles—*vide supra*, graphitization. With ternary, iron-carbon-phosphorus alloys, the addition of 1·2 to 2·8 per cent. of silicon displaces the porphyritic line, *CE*, towards the iron end of the diagram, and as the proportion of silicon increases, the solidification range becomes smaller and smaller, and the proportion of molten metal which solidifies in primary crystals is larger. Hence, with composition almost up to the eutectic, the graphite separates completely from the primary crystals, in a finely dispersed form. P. Oberhoffer found that the range of existence of the γ-phase becomes smaller as the proportion of silicon increases, and disappears with alloys having over 5 per cent. silicon. D. G. Anderson concluded that with 1·1 per cent. of silicon, the combined carbon in cast iron rose sharply as the total carbon dropped below 3·4 per cent., and the strength rose sharply as it dropped to about 2·9 per cent.; with higher proportions of silicon, the combined carbon rose as the total carbon fell below 2·5 per cent.; with 2 per cent. of silicon, the maximum strength corresponded with about 1·9 per cent. of carbon; and with 2·2 per cent. of silicon, with about 1·95 per cent. of carbon. G. Tammann and W. Salge studied the residues left after treatment with an acidified soln. of ammonium persulphate. L. Guillet said that the constitution of silicon steels is virtually independent of the percentage of carbon, so that the lines separating the different zones are nearly parallel to the carbon axis. The subject was investigated by A. B. Albro, H. Birnbaum, M. G. Corson, L. Grenet, J. L. Haughton and M. L. Becker, B. Kjerrman, A. Kriz and F. Poboril, E. Lissner, A. Merz and F. Fleischer, N. B. Pilling, T. Sato, and T. D. Yensen. B. Stoughton and E. S. Greiner, and H. Sawamura gave Fig. 427 for the constitution of silicon cast iron. Field I contains cementite, silicoferrite, and temper carbon; while field II contains silicoferrite and temper carbon. The solid soln. Fe–C–Si was not observed. H. Scott found that silicon has a marked effect on the temp. of transformation of martensite to troostite. O. von Keil and F. Kotyza studied the effect of silicon on the solidification of iron-carbon alloys.

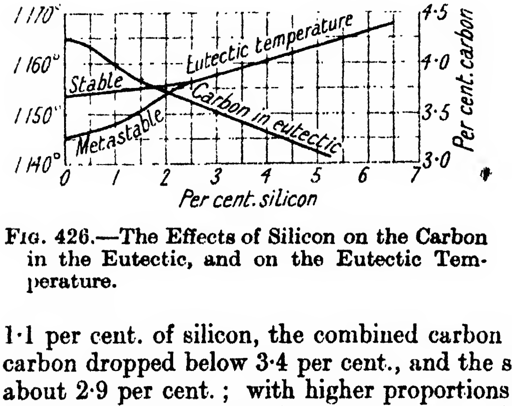

FIG. 426.—The Effects of Silicon on the Carbon in the Eutectic, and on the Eutectic Temperature.

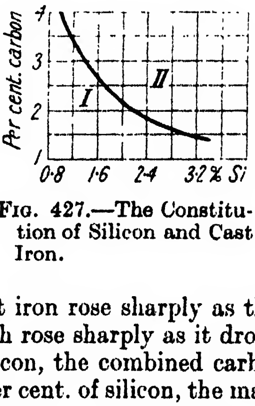

FIG. 427.—The Constitution of Silicon and Cast Iron.

P. Oberhoffer and W. Oertel examined the re-crystallization of a 4 per cent. silicon steel showing the grain-size as a function of the annealing temp. W. H. Hatfield, and E. Piwowarsky discussed the influence of the size of casting, the rate of cooling, and the casting temp. on the properties of a silicified cast iron; and V. N. Krivobok, the re-crystallization of the cold-worked alloy. E. Adamson, A. E. Allison, O. Bauer and K. Sipp, S. J. E. Dangerfield and co-workers, D. Hanson, F. C. Nix and E. Schmid, R. T. Rolfe, H. Sawamura, and A. Stadeler studied the action of silicon on malleable cast irons, etc. The deoxidizing action of silicon was discussed by E. Adamson, H. M. Boylston, G. K. Burgess and G. W. Quick, J. E. Carlin, A. L. Feild, C. H. Herty and co-workers, H. M. Howe, O. von Keil and F. Kotyza, F. W. Lürmann, E. G. Mahin and F. J. Mootz, E. Oughterbridge, N. Petinot, E. Piwowarsky, W. E. Remmers, H. Schenck, A. E. M. Smith, T. Swinden, E. Thews, and others—*vide supra*. For the cementation of these steels, *vide supra*. The effect of phosphorus and silicon was studied by W. Hummitzsch and F. Sauerwald, O. von Keiland, R. Mitsche, and B. Kjerrman.

T. D. Yensen, H. Möller, and Z. Nishiyama studied the X-radiograms of these alloys, and obtained for the lattice parameter, *a*; the sp. gr. at 15·1°; and the elastic modulus, *E* kgrms. per sq. cm.:

Si . . .	0	1	2	4	6	8 per cent.
a . . .	2·869	2·868	2·866	2·864	2·858	2·847 A.
Sp. gr. . .	7·8610	7·7933	7·7344	7·5677	7·5053	7·4258
$E \times 10^{-6}$.	2·157	2·164	2·194	2·175	2·205	2·103

H. Möller, E. R. Jette and E. S. Greiner, and F. Wever and H. Möller studied the crystal lattice of FeSi. F. C. Nix, and A. T. Lowzow studied the microstructure and the texture of the alloys; F. Körber, the etching colours; and T. A. Wilson, the orientation of the crystals.

The sp. gr. of the iron-silicon alloys was previously discussed. W. Brown gave for a steel with 0·028 C and 0·07 Si, the sp. gr. and sp. vol. respectively 7·8771 and 0·12695; with 0·020 C and 2·50 Si, respectively 7·6934 and 0·12998; and with 0·26 C and 5·50 Si, 7·5100 and 0·13315, so that an increase up to 5·5 per cent. silicon increases the sp. vol. by 0·0011 c.c. per 1 per cent. silicon. P. Paglianti said that the sp. gr. decreases 0·058 per 1 per cent. increase of silicon. J. Rothe, and B. Simmersbach made observations on this subject. E. Gumlich represented the relation between the sp. gr., *D*, and the per cent., *p* contents, by $D=7·874-0·0622p$. According to W. J. Keep, and R. A. Hadfield, high percentages of silicon in the cast or forged metal cause a considerable increase in shrinkage or contraction. P. Paglianti observed that the Brinell's hardness increases about 3·5 units for even 0·1 per cent. rise in the proportion of silicon. F. Robin studied the acoustic properties and found that the metal becomes aphonic when 1 per cent. silicon has been added. In addition to the observations of R. A. Hadfield on the mechanical properties of the iron-silicon alloys, mentioned in connection with the iron silicides, observations were also reported by L. Guillet. T. Turner measured the sp. gr. of silicon-iron-carbon alloys, and the results are indicated below. Observations were also made by A. Abraham, J. O. Arnold, C. Bedel, R. A. Hadfield, E. Heyn, K. von Kerpely, A. T. Lowzow, A. L. Norbury and E. Morgan, J. Rothe, E. H. Schulz and F. Bonsmann, A. Schulze, M. von Schwarz, and A. Wahlberg. C. Benedicks' results are summarized in Fig. 186. M. von Schwarz gave for the iron-silicon alloys, at 18°:

Silicon .	0·2	2·0	15·0	29·3	40·2	51·8	65·9	79·4	93·4	100 per cent.
Sp. gr. .	7·883	7·784	7·032	6·198	5·378	4·406	3·367	2·787	2·363	2·309

E. Widawsky and F. Sauerwald found that the introduction of 1 per cent. of silicon raises the sp. vol. of the iron-carbon alloys 0·0010 c.c. per gram. The subject was studied by C. Benedicks and N. and C. Ericson, and W. Denecke. O. Hengstenburg found:

Silicon . .	25	33·4	50·1	61·5	95·0 per cent.
Sp. vol. . .	0·155	0·165	0·213	0·254	0·419

T. Turner measured the hardness of the iron-silicon-carbon alloys and he found, on the sclerometer scale:

Silicon .	0·19	0·45	0·96	1·96	2·51	3·92	4·74	7·83	9·80 per cent.
Graphite .	0·38	0·10	0·24	1·62	1·19	1·81	1·66	1·48	1·12 ,,
Comb. C .	1·00	1·90	1·85	0·56	0·68	0·20	0·37	0·38	0·69 ,,
Hardness .	72	52	42	22	22	27	32	42	57
Sp. gr. .	7·719	7·670	7·630	7·350	7·388	7·218	7·170	7·138	6·924

Observations on the hardness were also made by A. Ledebur, R. A. Hadfield, A. Wahlberg, G. Tammann and V. Caglioti, K. Taniguchi, and H. O'Neil. E. Söhnchen and E. Piwowarsky found that the hardness of iron-carbon alloys is almost halved by the addition of 1 per cent. of silicon, but further additions reduce the hardness more slowly. According to T. D. Yensen, if N denotes Brinell's hardness of alloys with [Si] per cent. of silicon, $[\mathrm{Si}]=0{\cdot}092(N-86)\ 0{\cdot}777$ at 20°. A. Krüger discussed the age-hardening of silicon steels; H. O'Neil the effect of annealing on cold-worked single crystals of the alloys. The elastic limit, and tensile strength are expressed in kilograms per sq. mm.; and the elongation, and reduction in area in percentages. Observations were also made by A. Abraham, T. Baker, G. A. Bisset, P. Blum, F. Bonsmann, G. Charpy and A. Cornu-Thénard, L. M. Clark, H. I. Coe, A. L. Colby, S. J. E. Dangerfield and co-workers, F. Delaroziere, E. Diepschlag and F. Eggert, P. Eyermann, I. Fetchenko-Tchopiwsky, J. E. Fletcher, F. L. Garrison, H. W. Gillett, N. G. Girshovich and E. K. Vidin, R. C. Good, W. Haufe, R. H. Holbrock, G. R. Johnson, J. A. Jones, A. Jouve, K. von Kerpely, P. Kleiber, F. Körber and A. Pomp, H. Koppenberg, E. Lemaire, J. V. McCrae and R. L. Dowdell, T. Meierling and W. Denecke, J. Meiser, A. L. Norbury, F. Rapatz and H. Pollack, W. E. Ruder, F. Sauerwald, E. H. Schulz and H. Buchholtz, E. H. Schulz and co-workers, E. K. Smith and H. C. Aufderhaar, K. Tamaru, A. le Thomas, T. Turner, A. Wahlberg and E. Heyn, C. Wallmann, and R. Wasmuht; while P. Paglianti's results for soft iron are summarized in Table LXI. T. D. Yensen's results with silicon-iron alloys containing only 0·01 per cent. of carbon, melted in vacuo, are shown in Figs. 428 and 429. There is in all cases a critical point with about 2·60 per cent. of silicon, when the alloys are comparatively brittle. The maximum tensile strength, 10,500 lbs. per sq. in., occurs with a silicon-content of 4·5 per cent. W. Giesen observed that silicon steel of pearlitic structure with up to 6 per cent. of silicon has an exceedingly low tensile strength, elastic limit, elongation, and hardness—only the breaking strength and brittleness increase with the silicon-content. Silicon steels with 6 to 8 per cent. of silicon and with a pearlitic and graphitic structure, and silicon steels with over 8 per cent. of silicon with a graphitic structure have no useful industrial applications, but the non-graphitic steels have a limited application. In the case of iron, the toughness increases until the silicon has attained 4·5 per cent., and any excess beyond that decreases the toughness. With over 4·5 per cent. of silicon, the hardness increases rapidly, and the metal has a tendency to fracture. Every increase of the elastic limit and tensile strength decreases the elongation; and with 4·5 per cent. of silicon, the

TABLE LXI.—MECHANICAL PROPERTIES OF SILICON-IRON ALLOYS.

Silicon (per cent.)	Elastic limit (kgrms. per sq. mm.)	Tensile strength (kgrms. per sq. mm.)	Elongation (per cent.)	Reduction of area (per cent.)
0·001	11·53	25·38	61	80·9
0·010	11·28	24·53	53	81·5
0·090	10·05	24·88	64	94·8
0·230	10·48	24·95	60	84·7
0·400	18·28	29·53	55	91·0
0·673	18·66	31·80	45	88·2
0·822	18·42	31·74	50	91·6

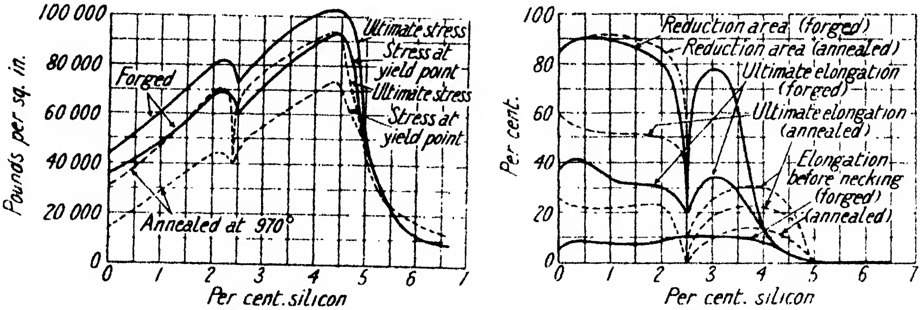
4.44	51·26	64·38	24	25·1
4·90	33·53	33·53	0	0
6·57	9·13	9·13	0	0

elongation and reduction of area fall to zero. Z. Nishiyama's values for the elastic constant are indicated above. J. J. Porter discussed the effect of silicon on the fluidity of the molten alloy.



FIGS. 428 and 429.—Mechanical Properties of Silicon-Iron Alloys Melted in Vacuo—Forged and Annealed at 970°.

G. Charpy and A. Cornu-Thénard found that the dilation curves of iron-silicon alloys show that the addition of silicon to iron does not appreciably affect the coeff. of expansion between 0° and 700°; while with 3·9 per cent. of silicon, the metal shows no dilational anomaly. A. Schulze's values for the coeff. of thermal expansion $\times 10^6$ are as follow:

Silicon	0·08	1·03	2·40	8·37 per cent.
20°–100°	12·51	12·29	12·03	$11·31 \times 10^{-6}$
100°–300°	13·64	13·41	13·32	$12·73 \times 10^{-6}$
300°–500°	15·01	15·00	14·76	$14·19 \times 10^{-6}$

A. L. Norbury and E. Morgan studied the effect of silicon on the growth of cast iron. W. Brown observed that the sp. ht. of the alloys with 0·028 C and 0·07 Si is 0·1134; with 0·20 C and 2·50 Si, 0·1200; and with 0·26 C and 5·50 Si, 0·1194. This shows that an increase of up to 2 per cent. of silicon raises the sp. ht. 0·003 per 1 per cent. Si, and that further additions have very little effect. Observations were made by M. Padoa, and G. Tammann and V. Caglioti.

In addition to the observations on the electrical resistance indicated in connection with the iron silicides, A. Schulze, and E. Kolben made some measurements; J. H. Partridge observed that silicon raises the electrical resistance of iron; and T. D. Yensen found for the resistance at 20°, R microhms:

Si . .	0·001	0·010	0·068	0·148	0·472	1·74	3·55	4·92 per cent.
R . .	9·83	9·89	10·75	11·8	16·2	31·2	51·5	66·5

so that the sp. resistance increases about 13 microhms for the first per cent. of silicon added; and about 11 microhms for each additional per cent. added. H. le Chatelier, and E. Gumlich found an increase in the resistance of 14·0 microhms per cm. cube for 1 per cent. of silicon; W. F. Barrett gave 10·3; C. F. Burgess and J. Aston, 12·0; P. Paglianti, and T. D. Yensen, 13·0; and A. L. Norbury, 13·5 for the best representative value. According to T. D. Yensen, if R microhms per cm. cube be the resistance at 22°, and [Si] the percentage of silicon in the alloy, $[\mathrm{Si}]=0·0544(R-9·6)$ if R be 16·05 or less, and in other cases $[\mathrm{Si}]=0·35+0·09(R-12·16)$. E. L. Dupuy and A. M. Portevin found the thermoelectric force of silicon steel against copper, expressed in millivolts, to be:

		Annealed		Hardened	
		−80°	100	−80°	100°
0·2 Carbon	0·41 . .	+2·10	−0·30	+1·10	−0·90
	0·93 . .	−2·90	−6·10	−1·30	−5·00
	1·06 . .	−4·80	−8·28	−5·00	−8·40
	5·12 . .	−6·80	−10·80	−6·90	−10·40
0·8 Carbon	1·16 . .	−3·40	−6·00	—	—
	5·54 . .	−8·20	−12·00	−8·90	−10·79

Observations were made by E. Sedström. T. C. Mackay found the increment in the Hall effect to be proportional to the percentage of contained silicon up to 5 per cent. A. W. Smith studied the effect of temp. on the Hall effect. T. D. Yensen gave for purified iron, and iron with 4 per cent. of silicon: initial permeability, 700 and 440 respectively; maximum permeability, 26,000 and 15,500; saturation value, 22,600 and 25,000; hysteresis loss (ergs per c.c. per cycle for B=10,000), 600 and 500; retentivity, 8600 and 5200; coercive force, 0·20 and 0·15 gilberts per cm.; electrical resistance, 10 and 55 microhms at 20°; and sp. gr., 7·9 and 7·6.

The magnetic properties of the silicon-iron alloys were discussed in connection with the iron silicides. Observations were also made by E. Kolben, R. Pohl, A. Jouve, F. E. Raven, K. Daeves, H. Scott, W. F. Barrett, F. C. Caldwell, J. H. Hruska, M. Otto, J. C. Stearns, T. D. Yensen, W. E. Ruder, J. D. Ball and W. E. Ruder, T. Spooner, W. A. Wood, R. Cazaud, E. Peterson, H. D. Hibbard, H. de Nolly and M. Veyret, M. Fallot, M. A. Hunter and J. W. Bacon, E. Gerold, M. von Moos and co-workers, S. R. Williams, C. H. Willis, H. F. Parshall, P. Reusch, H. Nathusius, F. Goltze, J. H. Partridge, O. von Auwers, C. F. Burgess and J. Aston, G. J. Sizoo, P. Paglianti, R. Becker and H. F. W. Freundlich, C. Bedel, etc. The results of T. D. Yensen are summarized in Fig. 430, where the magnetic permeability is expressed in terms of $\mu=B/H$; the flux density and retentivity in gausses; the coercive force in gilberts per cm.; and the hysteresis loss in ergs per c.c. per cycle. The best alloys contained 0·15 and 3·40 per cent. of silicon, and were annealed at 1100°. The maximum permeability for both alloys is over 50,000, and the hysteresis loss for $B_{\max.}$, 10,000 and 15,000, is about 300 and 1000 ergs per c.c. per cycle respectively. This hysteresis loss is respectively one-eighth and one-third of the corresponding loss for silicon steel. E. Gumlich found that alloys with p per cent. silicon—for values of p up to 5 per cent.—the saturation value $4\pi I_{\max.}=21,600-480p$. A. Schulze studied the magnetostriction, and also the effect of the intensity and concentration of magnetization; T. Spooner studied the effect of temp. on the induction; E. P. T. Tyndall, the Barkhausen effect; L. Néel, the Curie point; O. von Auwers, the influence of grain-size on the magnetic properties; and J. D. Bell, the magnetic reluctivity, that is, the inverse of the metallic permeability, $\mu-1$, of silicon steel.

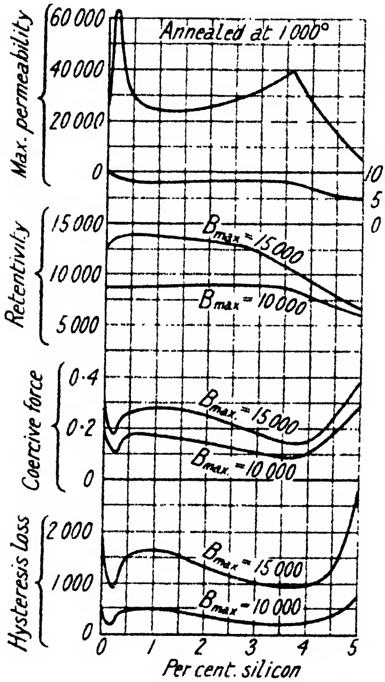


FIG. 430.—Magnetic Properties of the Iron-Silicon Alloys.

E. Martin studied the absorption of hydrogen and nitrogen by silicon steels and found that there is a small rise in the solubility of the gases in molten iron for small quantities of silicon, but with higher proportions the solubility is less than it is for purified iron. With nitrogen in α-iron, however, the solubility of nitrogen is greater than it is for iron alone. L. B. Pfeil observed that a three-layer scale—*vide supra*—is formed when silicon steel is heated in air for some hours at 1000°; no silicon appears in the two outer layers, but all is concentrated in the innermost layer where it occurs about three times more concentrated than in the original steel. Probably some ferrous silicate was formed in the inner layer. In 1838, R. Mallet found that iron rich in silicon is not readily attacked by acids; a protective skin of silica may be found. T. Turner found that pig-iron containing 18 per cent. of silicon was not appreciably rusted after a few years' exposure to the air of the laboratory. J. A. N. Friend and C. W. Marshall observed that if allowance be made for the tendency of silicon in cast iron to throw out carbon as graphite, the presence of 1·24 to 2·28 per cent. of silicon exerts no appreciable influence on the corrodibility of the metal either in neutral or acidic media. On the other hand, the presence of 0·12 to 0·13 per cent. of silicon in mild steel enhances its resistance to atmospheric corrosion, and to sea-water. Observations were also made by F. Ulzer and E. Baderle, M. von Schwarz, and by C. F. Burgess and J. Aston, who found that with iron alloyed with silicon:

Silicon . . .	0	0·233	1·190	1·897	2·826
Acid corrosion . .	1·300	1·630	1·190	1·800	1·270
Atm. corrosion . .	0·499	0·509	0·307	0·606	0·635

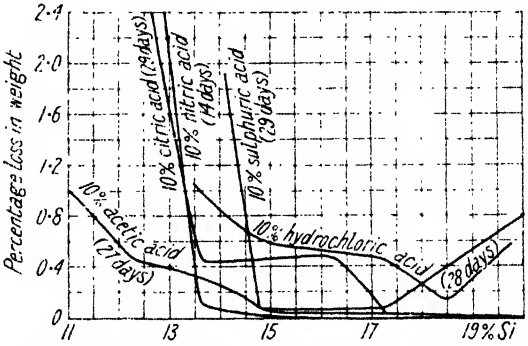

FIG. 431.—The Action of Acids on the Iron-Silicon Alloys.

where the acid corrosion refers to the loss in grams per sq. dm. when immersed for an hour in 20 per cent. sulphuric acid; and the atm. corrosion refers to the loss in kgrms. per sq. metre per year when exposed 162 days from July to February. H. Fromm studied the scaling of silicon steels. P. Askenasy noted the resistance of silicized iron to steam at 1000°. P. Kötzschke found that 1·5 to 3·0 per cent. of silicon in cast iron does not influence the rate of corrosion in hydrochloric acid; in conc. alkali-lye, silicon in cast iron is strongly attacked. O. L. Kowalke said that 16 to 20 per cent. of silicon gives the maximum resistance to corrosion by sulphuric, hydrochloric, nitric, acetic, and citric acids, and his results are summarized in Fig. 431. The resistance of silicon-iron alloys to acids was discussed by A. Jouve, J. Hoffmann, S. J. Tungay, P. Bres, A. Mangin, W. Schreck, P. Kötzschke, P. Kötzschke and E. Piwowarsky, H. G. Haase, H. Endo, W. Denecke, M. G. Corson, E. Piwowarsky, G. Krebs, E. Leuenberger, M. Spanner and M. Goltermann, T. F. Banigan, C. Matignon, E. Becker, and J. W. Hinchley. E. H. Schulz and F. Bonsmann found that the resistance of silicon steels to acids and acidified water is small, but it can be improved by the addition of 0·3 per cent. of copper. According to W. D. Richardson, and W. H. Hatfield, cast iron containing silicon is less readily attacked by nitric acid, and more readily attacked by hydrochloric acid than is the case with iron of a higher degree of purity. A. Jouve observed that iron with 20 per cent. of silicon is not readily attacked by acids. Thus, with 20 per cent. nitric acid, the alloy lost 0·6 per cent. in 12 hrs., and 0·9 per cent. in 48 hrs. With 12 and 24 hrs.' exposure to conc. nitric acid, the losses were respectively 0·0215 and 0·0142 per cent.; nitric acid (1 : 1), 0·0243 and 0·0168 per cent.; conc. sulphuric acid 0·1174 and *nil* per cent.; sulphuric acid (1 : 1), 0·0975 and *nil* per cent.; tartaric acid, *nil* per cent.; acetic acid, 0·0958 and 0·460 per cent.; and oxalic acid, 0·0676 and *nil* per cent. Hydrofluoric acid was the only satisfactory solvent. Y. Utida and M. Saito measured the gain in weight in grams per sq. cm. when alloys with about 0·05 per cent. carbon are heated for an hour at 1100°; and also the loss in weight in grams per sq. cm., when the alloys are immersed in 10 per cent. acids for 24 hrs. They found:

Silicon	0	1·33	4·16	7·00	9·88	13·02 per cent.
At 1100° in air	0·0212	0·0405	0·0025	0·0019	0·0012	0·0009
HNO_3	0·9380	0·6830	0·4775	0·4485	0·2818	0·1897
HCl	0·0712	0·1115	0·1038	0·0648	0·0397	0·0274
H_2SO_4	0·0990	0·1762	0·1256	0·1041	0·0513	0·0167

H. Endo measured the losses in weight in grams per sq. cm. during 5 hrs.' action, at ordinary temp., of alloys with 0·45 to 0·55 per cent. of carbon, and different proportions of silicon. E. H. Schulz and W. Jenge represented by Fig. 433 the loss in grams from a silicon-iron alloy 20 mm. diameter by 125 mm. length in 5 per cent. boiling hydrochloric acid. The corrosion of these alloys was studied by H. H. Abram, P. Askenasy, J. A. Aupperle, T. F. Banigan, W. C. Carnel, M. G. Corson, H. E. Diller, G. M. Enos, J. Escard, F. Espenhahn, A. B. Everest and co-workers, H. G. Haase, R. A. Hadfield, W. H. Hatfield, F. Körber O. L. Kowalke, W. Mason, C. Matignon, B. Neumann, W. Oertel and K. Würth, W. E. Pratt and J. A. Parsons, W. D. Richardson, P. D. Schenck, E. H. Schulz and W. Jenge, G. Tammann, J. G. Thompson, and R. Walter. A. M. Portevin and A. Sanfourche studied the action of phosphoric acid. F. Körber studied the etching films produced by an alkaline picrate soln. P. Kötzschke and E. Piwowarsky observed that the percentage of silicon should be kept as low as possible (below 1·5 per cent.) for grey cast iron to have the best resistance to corrosion by acids and salt soln.—*vide supra*. T. F. Banigan examined the action of sulphuric acid on iron. M. Wunder and B. Jeanneret studied the action of phosphoric acid on ferrosilicon; and W. Hummitzsch and F. Sauerwald studied the ternary system: iron-phosphorus-silicon. J. G. Thompson and co-workers studied the action of soln. of urea and of ammonium carbonate; W. G. Imhoff, the action of molten zinc; and J. A. Hedvall and F. Ilander, the action of calcium oxide.

The average composition of the iron-silicon alloy *tantiron* is said to contain:

Silicon	Total Carbon	Manganese	Phosphorus	Sulphur
14 to 15	0·20 to 0·60	0·20 to 0·35	0·16 to 0·20	0·05 per cent.

to have a tensile strength about 25 per cent. less than cast iron; an impact test of 8 to 10 ft. lbs. for ¾-in. bars; not to rust except at the skin; and to be but little affected by sulphuric, nitric, or acetic acids—conc. or dil., cold or hot. L. Leprovost studied the corrodibility of the **iron-copper-silicon alloys** and found that the 78 : 8 : 16 alloy resists nitric and organic acids very well, but is rapidly attacked by hydrochloric acid. P. Lebeau observed that a silicide, or iron is soluble in silicide of copper, and crystallizes out on cooling.

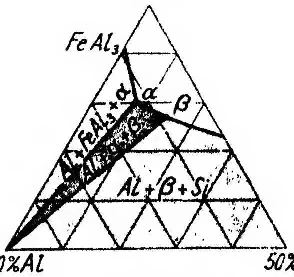

FIG. 432.—Phase Relations at 560° in the System: Fe–Al–Si.

A. G. C. Gwyer and H. W. L. Phillips studied the constituents of the **aluminium-silicon-iron alloys** cast at room temp., and they observed the existence of aluminium silicide, and iron trialuminide, as well as of various solid soln., 0 to 100 per cent. silicon, and 0 to 100 per cent. aluminium. H. Endo observed a 3 to 4 per cent. change in vol. during the melting or freezing of *silumin*, an alloy of iron, aluminium, and silicon (0·5 : 87·5 : 12). H. C. H. Carpenter and C. C. Smith, D. Hanson, E. H. Dix, P. D. Merica and co-workers, V. Fuss, W. L. Fink and K. R. van Horn, E. H. Dix and A. C. Heath, A. G. C. Gwyer and H. W. L. Phillips, and W. Rosenhain and co-workers also studied the iron-aluminium-silicon alloys. The phases include α and β solid soln. of iron and silicon. The X-radiograms indicate that the α-phase is a solid soln.

of silicon in $FeAl_3$, whilst the β-phase is a ternary soln. with an excess of aluminium. E. H. Dix and A. C. Heath's diagram of the phase relations at 560° is shown in Fig. 432. The nitridization of these alloys was studied by T. Oertenblad; and W. Hummitzsch and F. Sauerwald, and F. Sauerwald and co-workers studied the **iron-phosphorus-silicon alloys** and found Fe–Fe_2Si–FeSi is an independent ternary system; Fe_2P and FeSi is quasi-binary; and Fe_3P–FeSi is not quasi-binary. There is a ternary eutectic with 6·35 per cent. Si, 7·45 per cent. P, and 86·20 per cent. Fe, at 1018°.

The **iron-titanium alloys,** and the preparation of *ferrotitanium* were discussed in connection with titanium—**7.** 41, 3 and 6. C. J. B. Karsten[15] observed that traces of titanium occur in many varieties of cast iron; and E. Riley found that some titanium is also present in some cast irons. M. Faraday and J. Stodart did not succeed in alloying titanium with steel, by intensely heating a mixture of steel filings, rutile, and a little charcoal. J. Percy did not succeed any better. Some of M. Faraday and J. Stodart's alloys were examined by R. A. Hadfield. R. Mushet obtained a titaniferous steel or iron by heating titaniferous iron sands, like the New Zealand titaniferous sand, with iron or steel and some carbonaceous matters. R. Mushet obtained a number of patents for the application of titanium to the manufacture of iron or steel; and its manufacture was studied by A. J. Rossi, P. Girod, E. Bahisen, C. Grandjean, G. H. Stanley, J. B. Nau, W. Heym, P. Oberhoffer, J. Chállansonnet, G. T. Holloway, W. Venator, E. von Maltitz, E. H. Rothert, O. Simmersbach, L. O. Kellogg, R. W. Stimson and W. Borchers, F. C. Weber, J. Ohly, G. P. Scholl, W. and H. Mathesius, S. S. Steinberg and F. S. Kusakin, F. Peters, C. T. Starke, J. Escard, J. W. Richards, W. Guertler, F. M. Becket, S. Heuland, H. C. Sicard, B. Osann, A. Haenig, and J. W. Thomas. A. Stavenhagen and E. Schuchard, and W. R. Hulbert obtained the alloys by the thermite process. The use of titanium in steel for the removal of nitrogen was discussed by R. W. Raymond, J. B. Nau, H. Braune, and E. von Maltitz; it has also been employed as a deoxidizing agent—a subject discussed by P. H. Dudley, C. V. Slocum, G. B. Waterhouse, H. Schiemann, G. Vivanti, H. M. Boylston, B. Stoughton, M. H. Wickhorst, E. F. Lake, J. E. Hurst, E. Piwowarsky, J. Hörhager, G. F. Comstock, W. A. Janssen, W. Huppertz, O. J. Steinhart, A. Carnot and E. Goutal, L. Jordan, C. H. Gale, F. A. J. Fitzgerald, G. K. Burgess and G. W. Quick, etc. It has also been employed for preventing the segregation of steel. The alloys have also been recommended for making rails more durable, but, according to E. von Maltitz, H. Otto, and A. Pjaessezky, the evidence in favour of the use of titanium for this purpose is by no means satisfactory.

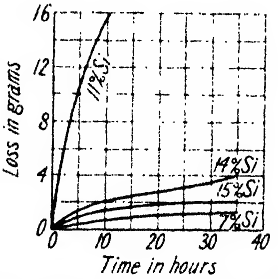

FIG. 433.—The Action of Hydrochloric Acid on Iron-Silicon Alloys.

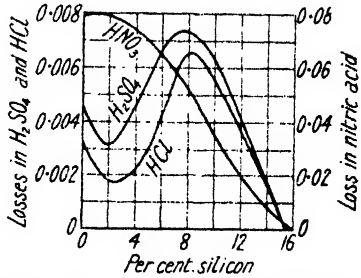

FIG. 434.—The Corrosion of Silicon Steels by Acids.

J. Laissus, and N. Agéeff and M. Zamotorin discussed the diffusion of titanium in iron. The equilibrium diagram of the iron–titanium system was partially explored by J. Lamort, and it was discussed in connection with the iron titanide, Fe_3Ti. A. Carnot and E. Goutal made observations on the subject. R. Vogel studied a portion of the system: Fe–Ti–C. Portions of the binary systems Fe–Ti, and Fe–C are known, and the system Fe_3Ti–C has been partially explored by K. Tamaru. If it forms a eutectic equivalent to Fe_3C+Fe_3Ti, the equilibrium diagram of the ternary system may approach Fig. 435. The three curves, E_1O, E_2O, and E_3O, are eutectic curves, in which the three surfaces, AE_2OE_1, E_1OE_3C, and E_2OE_3B, represent the beginning of the crystallization; and the point of intersection, O, is the ternary eutectic. The eutectic plane, CNB, passes through these points forming the fields with a binary solid soln., FN, and cementite, FNC; the binary solid soln., QN, and iron tritatitanide, QNB; and the ternary solid soln. $AQNF$. As crystallization proceeds, the three-phase triangular fields, f_1a_1C, f_2a_2C, and NOC, appear. K. Tamaru found that in the ternary alloys of iron and carbon with less than 4 per cent. of titanium, all the titanium is retained in solid soln. in the ferrite. Titanium decreases the amount of carbon in the iron-carbon eutectic, and also the solubility of carbon at high temp. E. L. Reed, and A. Michel and P. Bénazet studied the effect of titanium on the transformation points of steel.

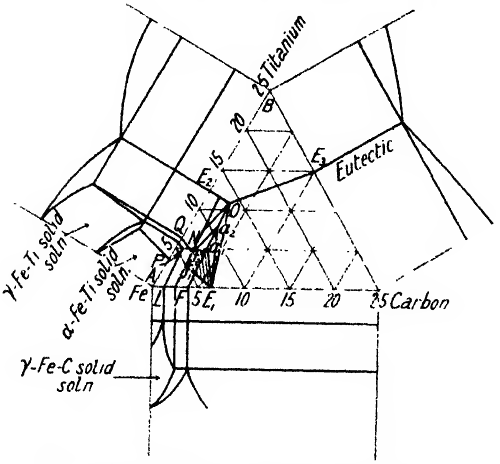

FIG. 435.—Portion of the Ternary System: Fe–C–Ti.

A. M. Portevin observed that titanium raised the temp. of the martensite and pearlite transformation of steel with 0·6 per cent. of carbon—1 per cent. of titanium raises it about 50°, while a higher proportion of titanium produces a less rapid change. Thus, with 0·6 per cent. carbon steels, the transformation points are:

Ti . .	0·32	0·64	0·72	2·57	4·63	8·71 per cent.
Ac_1 . .	755°	800°	810°	812°	825°	828°
Ar_2 . .	716°	765°	765°	765°	765°	768°

With steel having 0·1 per cent. carbon, the beginning of the transformation is lowered by titanium, while the austenite and pearlite transformation remains constant at 690°. Thus, with 0·1 per cent. carbon steels, the transformation points are:

Ti . . .	0·42	0·88	1·40	2·57 per cent.
Ar_3 . . .	860°	850°	830°	830°
Ar_2 . . .	780°	780°	780°	780°
Ar_1 . . .	690°	690°	690°	690°

J. Lamort found that the magnetic transformation falls linearly from 780° to 690° as the proportion of titanium rises to 21 per cent. The subject was studied by A. Michel and P. Bénazet, who found that titanium lowers the A_4-arrest, and raises the A_3-arrest, making the γ-field of the system bounded by a closed curve extending outwards to about 1·5 per cent. of titanium. R. Vogel said that increasing the titanium-content, with slow cooling, reduces the temp. of the transformation of carbon; the effect is most marked with 1 per cent. carbon and 6 per cent. titanium. It consists in the formation of an osmonditic structure characterized by a great susceptibility to attack by acids. The almost complete absence of the carbon transformation is due to the sluggishness of the pearlite transformation caused by the titanium. Part of the titanium appears to form titanoferrite, a part is probably associated with the iron carbides, and part appears as titanium carbide. W. A. Janssen, and J. Lamort also observed that some titanium nitride may be present. C. V. Slocum said that if 5 to 8 per cent. of carbon is present in ferrotitanium, most occurs as graphite, and about 0·12 to 0·18 per cent. is there as combined carbon. E. Piwowarsky found that in cast iron containing 1 per cent. of silicon, the addition of up to 0·5 per cent. of titanium lowered the proportion of combined carbon, but with higher silicon—1·7 and 2·6 per cent.—the influence of titanium was indefinite. For the cementation of these steels, *vide supra.*

J. Lamort found that Brinell's hardness increases from 96 to 500 on the addition of 21·5 per cent. titanium—*vide infra.* W. Giesen found that steel with up to 12 per cent. titanium behaves like ordinary steel with respect to the hardness, tensile strength, and brittleness. The tensile strength of the metal is considerably increased by the addition of titanium, especially in the case of cast irons. The titanium also hinders the formation of air-bubbles, and thus furnishes better and more compact castings. L. Guillet added that steels with up to 10 per cent. titanium are pearlitic. The mechanical properties are not much affected by titanium; though the tensile strength may be slightly increased and the elongation diminished. The elastic limit and resistance to shock are not changed. A. M. Portevin found that the tensile strength and elastic limit on shearing increase slowly as the proportion of titanium increases, as shown in Table LXII. The last five results in this table are due to G. B. Waterhouse. Observations were also made by L. Guillet, H. W. Gillett and E. L. Mack, J. Ohly, R. Moldenke, A. L. Colby, E. K. Smith and H. C. Aufderhaar, J. H. Küster and C. Pfannenschmidt, R. Wasmuth, I. Musatti and G. Calbiani, E. Kothny, W. Kroll, R. C. Good, W. E. Remmers, J. W. Donaldson, J. Arend and M. Loebe, A. E. M. Smith, C. H Gale, B. Stoughton, J. E. Johnson, M. H. Wickhorst, F. Bertrand, J. E. Hurst, B. Feise, E. von Maltitz, L. Treuheit, W. Venator, H. Mathesius, G. F. Comstock, H. Otto, A. Pjaessezky, P. Blum, J. V. McCrae and R. L. Dowdell, K. Taniguchi, and H. Fleck.

A. M. Portevin found the electrical resistance, *R* microhms per cm. cube, at 18° of steels with 0·1 and 0·6 per cent. carbon:

TABLE LXII.—MECHANICAL PROPERTIES OF TITANIUM STEELS.

Composition		Elastic limit (kgrms. per sq. mm.)	Tensile strength (kgrms. per sq. mm.)	Elongation (per cent.)	Reduction of area (per cent.)	Brinell's hardness
C (per cent.)	Ti (per cent.)

	R Hardened .	29·3	30·3	31·0	31·5	34·3	37·9

According to K. P. Applegate, the addition of less than 1 per cent. of titanium improves the magnetic permeability a little, and reduces the loss by hysteresis. J. Lamort found that the remanence of iron alloys increases slowly as the proportion of titanium rises to 14 per cent., and thereafter rapidly; the magnetization falls rapidly as the titanium rises above 14 per cent.; an alloy with 23 per cent. titanium is practically unmagnetizable. M. A. Hunter and J. W. Bacon, and A. Michel and P. Bénazet studied the magnetic properties of the titanium steels.

N. Tschieschewsky and N. Blinoff, and S. Satoh studied the nitridization of these steels by heating them in ammonia at 560° to 580°, and M. Wunder and B. Jeanneret, the action of phosphoric acid. H. Endo represented the losses in weight, in grams per sq. cm., of some titanium steels in different acids for 5 hrs. at ordinary temp. by Fig. 436, the proportion of carbon was 0·42 to 0·46, and the proportions of titanium were:

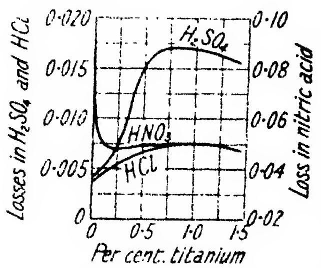

FIG. 436.—The Corrosion of Titanium Steels by Acids.

E. Wedekind,[16] and T. E. Allibone and C. Sykes prepared a **zirconium-iron alloy,** or ferrozirconium, by fusing a mixture of the two elements in vacuo. Alloys were also prepared by J. L. Brown and H. S. Cooper, J. B. Grenagle, H. L. Coles and J. R. Withrow, E. K. Smith and H. C. Aufderhaar, F. M. Becket, R. H. McKee, H. C. Sicard, J. W. Marden and M. N. Rich, H. W. Gillett and E. L. Mack, C. M. Johnson, H. E. Potts, H. Fleck, E. Kothny, R. C. Good, W. Stimson and W. Borchers, H. C. Meyer, J. Garçon, L. Bradford, W. Guertler, E. M. Becket, L. Persoz, P. Guy, A. L. Feild, R. Tull, F. B. Riggan and H. C. Aufderhaar, and G. K. Burgess and R. W. Woodward—see **7.** 42, 6. J. Laissus discussed the diffusion of zirconium in iron. R. Vogel and W. Tonn studied the equilibrium diagram, and their results are summarized in Fig. 437. There is formed **iron tritadizirconide,** Fe_3Zr_2, melting at 1640°. The effects on the transformation points are indicated in the diagram. About 0·7 per cent. of zirconium dissolves in γ-iron.

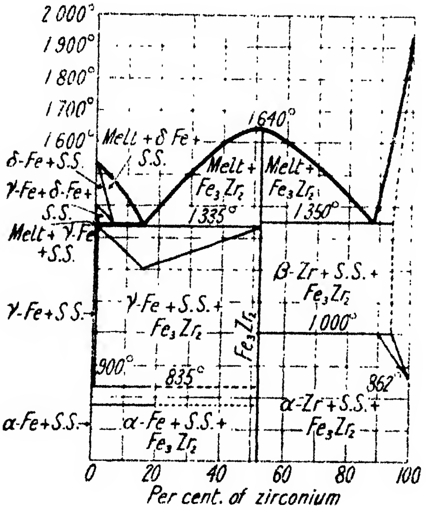

FIG. 437.—Equilibrium Diagram of the Fe–Zr System.

Zirconium, like titanium, is regarded as a possibly useful scavenger for iron and steels. F. M. Becket, and A. L. Feild found that it combines with and eliminates sulphur; and it may reduce the nitrogen-content of steel. Zirconium is also said to counteract the brittleness by the impact test due to the presence of phosphorus. The subject was also studied by J. V. McCrae and R. L. Dowdell, J. E. Hurst, and C. T. Evans, who attributed the good effects of zirconium rather to its scavenging action than to its work as an alloying element. Thus, F. M. Becket found:

	0·70 C; 0·15 Zr		0·70 C; no Zr	
Drawing temperature	375°	412°	375°	412°
Elongation (per cent.)	8·3	12·7	5·2	7·5
Reduction of area (per cent.)	23·3	45·8	6·6	22·9
Yield-point (lbs. per sq. in.)	185,962	172,620	128,125	180,180
Ultimate strength (lbs. per sq. in.)	227,203	198,828	197,800	207,144
Izod impact test	7·5	14·8	7·5	10·5
Brinell's hardness	414	407	433	418

T. E. Allibone and C. Sykes found that iron retains in soln. about 0·3 per cent. zirconium at ordinary temp. The eutectic alloy contains 15 per cent. zirconium. Beyond this, up to 30 per cent. zirconium, the second constituent appears in constantly increasing amount, but then it has not yet been identified. The m.p. of the eutectic is near that of iron. The hardness—*vide infra*—of the alloys constantly increases from 1 to 30 per cent., and there is a steeper rise from 0 to 1 per cent. This indicates the presence of a solid soln. at low percentages. The second constituent is not so brittle as the nickel alloy of the same composition. The Brinell hardness of the alloy is 290, or five times that of iron. Alloys with 0 to 6 per cent. of zirconium were forged hot, the optimum forging temp. increases with increasing proportions of zirconium; the forging of samples with over 8 per cent. of zirconium was not successful. The samples were normalized at 970° until the hardness was constant. The 5 per cent. alloy had a tensile strength 50 per cent. greater than that of iron, and a ductility 10 per cent. less. The observed tensile strengths, in tons per sq. in., were:

Zirconium		0	0·3	0·6	1·05	1·48	3·38	5·20
Brinell's hardness	forged	105	123	——	146	160	181	206
	cast	57	71	135	140	148	160	183
Tensile strength		19·20	21·9	20·3	25·3	25·2	31·1	30·5
Ductility		26·0	38·0	26·0	21·0	22·0	16·0	0·1 per cent.

The effect of zirconium is to lower the Ar_3 transition points of iron from 900°, but the Ar_2-arrest is not affected. Zirconium shows no analogy with silicon. H. W. Gillett and E. L. Mack thus summarize the effect of zirconium:

> Zirconium should be classed with its chemical sister, titanium, as a possibly useful scavenger rather than an alloying element. Much work on zirconium in steels of the high silicon-nickel type failed to show any trace of true alloying behaviour due to zirconium; or, at least, that it has any greater effect than so much silicon. F. M. Becket, and A. L. Feild have produced far more definite evidence as to the scavenging value of zirconium in plain carbon steels than exists in the case of titanium. They show clearly that zirconium combines with sulphur, and may also eliminate some sulphur. This action is quite analogous to that of manganese and of cerium. It is said that steels treated with zirconium are unusually free from dispersed slag particles. Rather good evidence is also adduced to show that zirconium combines with nitrogen and it may decrease the total nitrogen content of the steel. In some way not yet understood, zirconium appears to reduce the brittleness, on impact test, due to high phosphorus-content. The mechanical properties of heat-treated carbon steels with small amounts of zirconium are changed but slightly and the average effect is that to be expected from increased cleanliness of the steel, *i.e.* slight improvement in both strength and ductility, rather than an increased hardness and strength concomitant with lowered ductility, as would be expected from a true alloying element. C. T. Evans states that while, for the production of a certain chromium-tungsten cutlery steel, he prefers to add silico-zirconium, the zirconium of which is practically eliminated before the steel freezes, he can at times get just as good results without zirconium, and only uses it because he finds that the properties aimed for are more readily obtained by the use of zirconium as a scavenger. No data have yet been presented to show that zirconium has any alloying effect, either alone, or when present in combination with the common alloying elements.

W. Zieler studied the deoxidizing and desulphurizing action of zirconium in steel, and noted that inclusions of zirconium sulphide do not make steel brittle. F. R. Palmer found that 0·4 per cent. of zirconium sulphide added to a high chromium steel improves its machining and grinding properties; there was a slight loss of toughness and tensile qualities, but the product was suited for corrosion-resisting parts. The zirconium sulphide helped to prevent air-hardening in low-carbon grades of stainless steel, and raised the temp. necessary for hardening. A. M. Portevin and A. Sanfourche, and M. Wunder and B. Jeanneret studied the action of phosphoric acid. C. Sykes measured the electric resistance, and magnetic induction of some iron-zirconium alloys.

F. Roll[17] showed that with the **germanium-iron alloys,** the germanium partly preserves and partly decomposes cementite. C. A. Edwards and A. Preece found that the solubility of tin in solid iron increases with increasing temp. up to 760°, and then becomes less as the temp. is further raised to the m.p. of iron. Their equilibrium curves are summarized in Fig. 438, with the effect of tin on the γ-phase of iron observed by F. Wever and W. Reinecken. C. O. Bannister and W. D. Jones studied the diffusion of tin into iron.

G. Tammann and K. Schaarwächter found that the attack of iron by tin begins at about 215°, and increases with rise of temp. C. J. B. Karsten said that the alloying of 1 per cent. of tin with iron does not make the latter red-short, the metal can be worked while white-hot, but at that temp. it always gives off white vapours; he also added that 0·19 per cent. of tin lowers considerably the tensile strength of iron. T. Bergman prepared **iron-tin alloys** with iron ; tin as 1 : 22, and as 2 : 1. Alloys were made by W. Guertler. S. Stevanovic found that in a series of alloys the crystals near Fe_4Sn_5 in composition are hexagonal and those near $FeSn_2$ are tetragonal. J. L. Lassaigne observed that in the distillation of mercury, in cast-iron retorts, from mirrors silvered with tin-amalgam, an alloy of iron and tin is formed approximating **iron tritastannide,** Fe_3Sn; and it occurred in tetragonal needles. It can be freed from the excess of tin by boiling it with hydrochloric, or by treating it with nitric acid. The compound, thus purified, forms shining, square needles of sp. gr. 8·733. The compound is brittle, and when the powder is projected in the flame of a candle, it burns with the emission of sparks and a white smoke. It does not rust in air when it is moistened with water; it is not attacked by nitric acid—conc. or dil., hot or cold—it dissolves slowly in boiling hydrochloric acid, and rapidly and completely in aqua regia. This compound was prepared by W. P. Headden. L. J. Spencer described some probably tetragonal crystals of Fe_3Sn obtained at the bottom of some baths of molten tin. J. Percy also commented on the rust-resisting properties of an alloy with 9 per cent. of tin. C. A. Edwards and A. Preece found that **iron hemistannide,** Fe_2Sn, is stable between 760° and 900°, but can react with tin at 800° to produce the monostannide. H. St. C. Deville and H. Caron said that **iron stannide,** FeSn, crystallizes from a soln. of iron in an excess of tin; it was also prepared by W. P. Headden. C. A. Edwards and A. Preece found that the monostannide is stable at all temp. below 800°, and reacts with tin below 496° to form the distannide. C. Nöllner said that some tin from the East Indies, when digested with hydrochloric acid, left a residue consisting of small crystals of **iron distannide,** $FeSn_2$, of sp. gr. 7·446. C. A. Edwards and A. Preece observed that the distannide exists below 496°, and when heated above that temp. forms the monostannide and a liquid rich in tin. W. P. Headden also obtained this compound. P. Berthier, and W. P. Headden, reported *iron tetritastannide,* Fe_4Sn, and *iron tritatetrastannide,* Fe_3Sn_4; C. F. Rammelsberg, *iron pentastannide,* $FeSn_5$, and *iron hexastannide,* $FeSn_6$; and W. P. Headden, *iron hemitristannide,* Fe_2Sn_3; *iron pentitahexastannide,* Fe_5Sn_6; and *iron tetritapentastannide,* Fe_4Sn_5; and *iron ennitastannide,* Fe_9Sn. The proof of the chemical individuality of all these products is wanting. E. Isaac and G. Tammann found that tin and iron are only partially miscible in the fused state; at 1140°, with from 50 to 89 per cent. of tin, two layers are present. Tin is soluble to the extent of about 19 per cent. in crystallized γ-iron; at 1140°, the layer rich in iron decomposes into a solid soln. and a fused mass, and, at 893°, the solid soln. reacts with the fused mass to form what may be **iron tritastannide,** Fe_3Sn. These changes appear as breaks in the cooling curve. At 780° there is a third break which is thought to represent a polymorphous transition; there is a fourth break at 496°.

From 89 to 100 per cent. tin, the f.p. curve falls rapidly. F. Wever and W. Reinecken observed no gap in the miscibility of the molten metals, and they found that the sat. solid soln. contains 18 per cent. of tin; C. A. Edwards and A. Preece observed a miscibility-gap, but obtained no evidence of the formation of the tritastannide; R. Ruer and J. Kuschmann showed that the two metals have a limited miscibility which is not explained away by assuming that the separation into two layers is caused by segregation during solidification. This combines with the liquid phase at 1132° to form the compound Fe_3Sn if the alloy contains between 18 per cent. and 48 per cent. of tin. Below 890°, this compound decomposes into $FeSn_2$ and mixed crystals, or, if the alloy contains more than 41·3 per cent. of tin, combined with tin to form the same compound. The compound $FeSn_2$ undergoes polymorphic transformations at 780°, 755°, and 490°. Tin does not affect the temperature of the magnetic $(\alpha \rightarrow \beta)$ transformation of iron. The $\alpha \rightarrow \gamma$ transition point, however, is raised 40° by 1 per cent. of tin, and the $\gamma \rightarrow \delta$ transition point depressed 140°. With a conc. greater than about 1·9 per cent. of tin, iron does not pass through the γ-phase at all in cooling. C. A. Edwards and A. Preece studied the constitution of the iron-tin alloys, and they showed that the thermal transformations at about 760° and 800°, which F. Wever and W. Reinecken attributed to polymorphic changes occurring in the distannide, are more probably due to the decomposition and formation of the hemistannide and monostannide. G. Tammann and W. Salze studied the residue left after treatment of the alloy with an acidified soln. of ammonium persulphate. E. F. Kohman and N. H. Sanborn discussed the formation of a tin-iron alloy in the production of tin-plate. J. W. Donaldson, and F. Roll observed that tin with cementite produces grey cast iron.

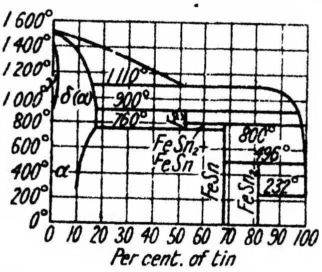

FIG. 438.—Equilibrium Diagram of the Fe-Sn Alloys.

TABLE LXIII.—MAGNETIZATION OF IRON-TIN ALLOYS.

W. F. Ehret and A. F. Westgren found that the FeSn lattice is hexagonal with $a=5{\cdot}292$ A., and $c=4{\cdot}440$ A., and unit cell has three FeSn mols. The Fe_2Sn-cell has two mols. per unit cell. The cell is hexagonal with $a=5{\cdot}449$ A., and $c=4{\cdot}353$ A. The unit cell of $FeSn_2$ is hexagonal; it contains 12 atoms, and has $a=5{\cdot}317$ A., and $c=9{\cdot}236$ A. J. E. Hurst, W. H. Spencer and M. M. Walding, C. F. Burgess and J. Aston, E. K. Smith and H. C. Aufderhaar, P. Blum, and W. Keller described some working qualities of the tin-iron alloys. A. L. Norbury studied the effect of tin on the hardness of iron. K. Taniguchi also studied the hardness of these alloys. A. Ledebur observed the tensile strength, T tons per sq. in., and the percentage elongation of ingot iron and crucible steel to be:

	Ingot iron					Crucible steel			
Tin	0	0·10	0·19	0·25	0·63	0·23	0·50	0·68	per cent.
T .	20·9	26·2	24·6	25·1	29·7	45·9	45·9	46·9	
Elon.	31·3	28·7	18·0	26·8	19·7	15·5	16·5	3·5	

Alloys with as little as 2·5 per cent. of iron are magnetic ; and the temp. at which iron loses its magnetic properties is practically unaffected by the presence of tin. C. F. Burgess and J. Aston measured the magnetization, or magnetic induction, *B*, of alloys of iron and tin—unannealed, annealed at 675° and 1000°, and quenched at 900°— for magnetic fields of intensity *H* gauss, and the results are summarized in Table LXIII ; while the results for the coercive force ($H_{\text{max.}}=200$), and retentivity ($H_{\text{max.}}=200$) are summarized in Table LXIV. " S " refers to Swedish iron, and " El " to electrolytic iron.

TABLE LXIV.—COERCIVE FORCE AND RETENTIVITY OF IRON-TIN ALLOYS.

Tin (per cent.)	Coercive force				Retentivity			
	Not annealed	Annealed at 675°	Annealed at 1000°	Quenched from 900°	Not annealed	Annealed at 675°	Annealed at 1000°	Quenched from 900°

1·57	6·0	4·0	4·0	3·3	10,000	13,100	11,900	10,800
2·06	3·0	4·3	3·5	2·5	8,100	11,300	9,300	8,600

F. Wever observed that with increasing proportions of tin, the $\alpha\rightarrow\gamma$ transition temp. is raised and the $\gamma\rightarrow\delta$ transition temp. is lowered. F. Wever and W. Reinecken found that iron takes up 18 per cent. of tin in solid soln. The γ-iron region is reduced by and disappears with 1·9 per cent. of tin. Iron tritastannide decomposes at 890°, producing iron distannide, $FeSn_2$, which separates along *h* to *q* ; the distannide undergoes allotropic transformations at 780°, 755°, and 490°. The liquidus is horizontal with between 48 and 75 per cent. of tin. The compound Fe_3Sn decomposes at 890°. A. S. Russell exposed a mixed tin and iron amalgam to the action of an oxidizing agent, and found no sign of the formation of a compound ; as soon as the tin is nearly all oxidized, the oxidation of the iron begins. F. Wever showed that with over 2 per cent. of tin, the γ-transformation of iron disappears, and the A_3 and A_4 points of iron meet, and with more than that proportion of tin, the α- and δ-iron areas are continuous—*cf.* chromium-iron alloys. P. Goerens and K. Elligen found that tin acts on pig-iron similarly to antimony (*q.v.*). M. Faraday and J. Stodart said that steel is not improved by alloying it with tin. L. Guillet observed that tin dissolves in molten iron, and when 5 to 7 per cent. has been added, a stannide is formed which is found in the shape of needles usually in well-defined clusters. The carbon remains in the pearlitic stage. Tin makes steel brittle and unworkable when the proportion exceeds 1·5 per cent. L. Guillet, and M. Hamasumi noticed the hardening effect of tin on iron. E. H. Saniter observed an alloy with 0·35 per cent. of tin gave off a white fume when rolled ; it rolled fairly well, but did not draw to wire satisfactorily. Alloys were also described by C. F. Burgess and J. Aston, B. Eyferth, H. J. French and T. G. Digges, P. G. J. Gueterbock and G. N. Nicklin, G. Jones, W. Longmaid, E. Mauer and W. Haufe, L. Mayer, P. Oberhoffer, J. Percy, S. Rinman, H. de Sénarmont, J. E. Stead, and M. Stirling. The use of imperfectly de-tinned sheet-iron in the manufacture of steel may introduce a small proportion of tin. A. Ledebur showed that 0·1 per cent. of tin in low-carbon steel raised the breaking-point 1·4 tons per sq. in., and reduced the elongation 0·8 per cent. J. E. Stead found that sensible quantities of tin raised the yield-point and maximum stress, and also increased the hardness of steel when hot. The presence of tin should be low because it tends to make the metal difficult to roll, and hard and stiff when in the heated state. J. H. Whiteley and A. Braithwaite also showed that the presence of small proportions of tin—even 0·06 per cent.—in medium carbon steel is liable to impair its ductility; the harmful effect increases with the carbon-content, but in mild steel, 0·06 per cent. had no detrimental effect. The degree of brittleness produced by tin is influenced by the heat-treatment. E. Griffiths and F. H. Schofield studied the thermal and electrical conductivities of some aluminium bronzes containing iron; and L. Néel, the Curie points. M. Faraday and J. Stodart, and R. Mallet noted that alloys with tin are less corrodible than iron. C. F. Burgess and J. Aston found that alloys of tin and electrolytic iron lost, in grams per sq. dm., when immersed in 20 per cent. sulphuric acid for an hour; and in kgrms. per sq. metre per year when exposed to the weather for 162 days from February to July:

Tin		0	0·288	0·342	0·686	1·568 per cent.
Loss	Acid	1·300	0·284	0·350	0·386	1·030
	Atm.	0·499	0·337	0·190	0·239	0·283

A. S. Russell and H. A. M. Lyons studied the system **mercury-tin-iron alloys**; and H. Brintzinger and F. Rodis, the action of chromous chloride on some **tin-iron-bismuth alloys**.

L. B. G. de Morveau[18] stated that the **lead-iron alloys** are formed with difficulty when the two are fused together, they form two alloys one above the other, the lower one containing very little iron, and the upper one very little lead. E. Biewend thought that he had obtained a hard, brittle, lustrous, steel-grey alloy with 3·24 per cent. of lead by reducing a slag containing iron and lead in a crucible lined with charcoal. S. Rinman, and F. L. Sonnenschein also obtained what they regarded as ferriferous lead. E. Isaac and G. Tammann, J. Percy, P. Oberhoffer, and C. J. B. Karsten were unable to prepare iron-lead alloys because the two elements are not miscible either in the solid or molten state, and no compounds are formed. E. K. Smith and H. C. Aufderhaar, J. E. Hurst, and W. H. Spencer and M. M. Walding discussed these alloys. A. S. Russell observed that when an amalgam of the two metals is oxidized, the lead is first removed, and then the iron; there is no sign of a compound. G. Tammann and W. Oelsen found that at 400° and 1600°, lead dissolves respectively 0·0003 and 0·0002 per cent. of iron. F. Roll showed that the presence of lead promotes the formation of graphite in cast iron. N. Agéef and M. Zamotorin studied the diffusion of lead in iron. L. Guillet, and W. Guertler and F. Menzel found that the immiscibility of the iron-lead and copper-lead in the binary systems persists to a large degree in the **copper-lead-iron alloys.** The cooled mixtures show two or three layers, the three consisting essentially of the three metals, each showing inclusions of the other two; where two layers are formed, one is iron containing inclusions of copper and lead, the other consists of copper crystals in a ground of lead, although in the liquid state the copper is completely miscible with the iron. C. E. Eggenschwiler studied the **copper-tin-lead-iron alloys.** C. F. Burgess and J. Aston found that the working properties of an alloy with lead were poor; they also observed that alloys with 0 and 0·061 per cent. of lead lost 1·300 grms. per sq. dm. in each case when immersed for an hour in 20 per cent. sulphuric acid; and respectively 0·499 and and 0·273 kgrm. per sq. metre per year when exposed to the weather for 162 days from July to February.

The preparation of the **iron-vanadium alloys,** or *ferro-vanadium*, was discussed in connection with vanadium—**9.** 54, 3. For the occurrence of vanadium in iron, ***vide*** **9.** 54, 2. In 1896, M. K. Hélouis[19] first made systematic tests on the use of **vanadium steels**; this was followed, in 1900, by F. Werner, and J. O. Arnold, who obtained the alloys by adding ferro-vanadium to the molten steel just before it was teemed from the clay crucible. The preparation of vanadium-iron alloys was also described by B. de Alzugaray, L. J. Barton, F. M. Becket, W. F. Bleecker and W. L. Morrison, R. Cazaud, A. P. Child, A. Cone, A. S. Cushman, J. Escard, H. Fleek, H. J. French, P. Froger, N. J. Gebert, G. Gin, P. Girod, W. Guertler, A. Haenig, A. Heinzel, W. Heym, G. T. Holloway, E. Houdremont and co-workers, R. M. Keeney, H. B. Knowlton, W. L. Morrison, P. Müller, K. Nishida, P. Oberhoffer, W. Oertel and co-workers, J. Ohly, F. Peters, N. Petinot, E. Pohl, F. Rapatz, J. W. Richards, B. D. Saklatwalla, R. Scherer, E. Schilling, G. P. Scholl, J. K. Smith, S. S. Steinberg and P. S. Kusakin, O. J. Steinhart, G. and E. Stig, G. Surr, and W. Venator. W. R. Hulbert obtained them by the thermite process. J. E. Stead observed that ordinary pig-iron may contain up to 0·262 per cent. of vanadium; L. Blum also observed it in blast-furnace slags. J. Laissus, and N. Agéeff and M. Zamotorin dicussed the diffusion of vanadium in iron. R. Vogel and G. Tammann prepared alloys by the aluminothermite process in a crucible lined with fused magnesia. When an ordinary crucible was employed, up to 7 per cent. of silicon was dissolved from the walls. The f.p. curve falls from 1750°, the m.p. of vanadium, to a minimum with 31·5 per cent. of vanadium and then rises to the m.p. of iron, 1525°. Except at the minimum, the crystallization intervals are considerable, and, as the alloys are homogeneous throughout, the metals form a complete series of mixed crystals. The behaviour of the alloys containing silicon is considerably more complicated; the minimum of the f.p. curve is lower, and at 1380° there is a break in miscibility from 55 to 90 per cent. of vanadium. In the alloys containing 20 to 52 per cent. of vanadium, there is a transition between 1100° and 1250°, the nature of which has not been elucidated. The vanadium steels, except those very rich in iron, are hard and fairly brittle, but can be filed and hammered. The presence of silicon greatly increases the hardness and brittleness. Pure vanadium-iron alloys are acted on by nitric acid, but those containing silicon, only by hot aqua regia. The results of M. Oya are summarized in Fig. 439; they agree with those of R. Vogel and G. Tammann. M. Oya also found that the alloys form a complete series of solid soln., that the A_4-point is rapidly lowered by vanadium, but that the A_2-point rises rapidly to form a loop at 2·5 per cent. vanadium. The A_2-point rises at first gradually, attains a maximum with 15 per cent. vanadium, falls slowly to 20 per cent., and is rapidly lowered to room temp. with 35 per cent. J. A. M. van Liempt discussed the solid soln. of the two elements. E. Maurer and co-workers observed that with 2·5 per cent. of vanadium, the γ-transformation of iron disappears, and the A_3- and A_4-points of iron meet, so that with over that proportion of vanadium, α- and δ-iron are identical—*cf.* chromium-iron alloys. F. Roll observed that vanadium stabilizes the cementite in cast iron. V. N. Svechnikoff studied the γ-phase.

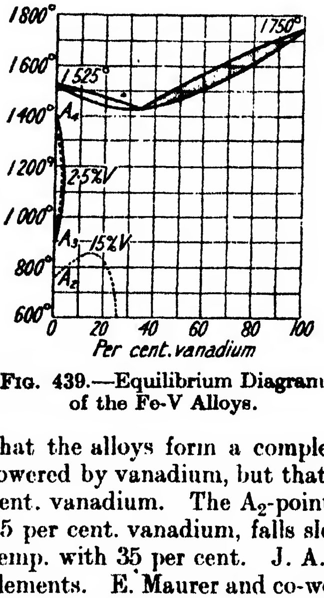

FIG. 439.—Equilibrium Diagram of the Fe-V Alloys.

G. L. Norris observed that the presence of vanadium in cast iron increased the transverse strength and tensile strength, and lengthened the life of locomotive cylinders. J. K. Smith said that the beneficial effects of vanadium on steel are (i) the result of its acting as a unique scavenger in removing both oxides and nitrides, forming fluid and readily separable products, so that the metal is directly toughened. W. H. Hatfield does not agree with this for cast iron. J. K. Smith also attributed the favourable effects of vanadium (ii) to the passage under normal conditions of a proportion of vanadium into solid soln. with the ferrite, so that the ferrite is then more resistant to wear and to the formation of slip-bands, and it opposes the ready passage of carbides through it, so that vanadium steel has a tendency to be sorbitic in character; and (iii) the direct strengthening of the steel owing to the formation of complex carbides. F. M. Becket, and C. F. Burgess and J. Aston discussed the working qualities of the iron-vanadium alloys; and Z. Nishiyama, the X-radiograms. F. L. Coonan, and R. Moldenke made some observations on the influence of vanadium on cast iron; and W. H. Hatfield concluded that additions of vanadium have a definite influence on the physical properties of cast iron, in that it helps the carbon to persist in the combined state, by making it more stable. The combined carbon does not differ physically from the normal carbide of cast iron. P. Pütz said that a small addition—0·2 per cent.—of vanadium suffices to raise the Ar_1-point nearly 10°, but further additions do not raise this point any higher; and the $Ar_{3\text{-}2}$ point is raised proportionally with the increase in the percentage of vanadium. A. M. Portevin observed that with steels having 0·2 per cent. of carbon, the breaks in the heating and cooling curves are as follow:

Vanadium.	0·60	0·75	1·04	1·54	2·98	5·37	7·39	10·27 per cent.
Heating .	810°	810°	795°	800°	840°	812°	860°	--
Cooling .	905°	985°	920°	945°	950°	960°	—	—
	810°	810°	805°	800°	830°	815°	840°	820°
	730°	730°	690°	—	--	—	590°	570°

whereas with a steel with 0·8 per cent. carbon the results were more definite, being:

Vanadium.	0·25	0·60	0·80	1·15	1·58	2·89	4·99	7·85 per cent.
Heating .	800°	800°	800°	798°	785°	790°	782°	780°
Cooling .	740°	738°	740°	740°	732°	730°	720°	700°

P. Nicolardot said that the V_3C_2 or the V_2C carbide is formed in steel, and this forms with the cementite a complex iron vanadium carbide. P. Pütz supposed that the vanadium carbide present in the vanadium steels is $V_{2n}C_{3n}$. J. O. Arnold and A. A. Read stated that with steels containing as little as 0·71 per cent. of vanadium, vanadium replaces iron in the carbide to form a mechanical mixture of $11Fe_3C+V_4C_3$; and as the proportion of vanadium increases, more is found with the carbide, until with 2·32 per cent. of vanadium, the carbide of the steel is $2Fe_3C+V_4C_3$; and with higher proportions of vanadium—say, 5·84 per cent.—practically all the iron of the carbide is replaced by vanadium. L. Guillet found that the higher the proportion of carbon, the more is the vanadium required to avoid the presence of pearlite. The pearlite steels are hardened by quenching a proportion as the vanadium-content rises. Steels containing carbide and pearlite are less affected. Steels with carbide are slightly softened; the carbide is never all dissolved, whatever be the temp. of quenching. As a rule, annealing softens the vanadium steels. In the pearlitic steels containing much carbide, the carbide is precipitated as graphite, and in that case the steels become extremely brittle. Case-hardening in a pearlitic steel may result in the production of much carbide.

M. Oya's observations on the ternary system involving low-vanadium steels showed that the solubility of carbon in the γ-phase, markedly decreases on the addition of vanadium, and hence the existing range of the γ-phase in this system is very narrow. In the region of the γ-phase there exist three proeutectoid surfaces in which the α-phase, Fe_3C and V_4C_3 begin to separate, respectively. The A_1-point, that is, the eutectoid temperature, in the Fe–Fe_3C system is raised 15° by the addition of 0·5 per cent. vanadium and remains constant on further increasing the vanadium. The binary eutectoid reaction ($\gamma \rightarrow \alpha + V_4C_3$) takes place in the temp. range from 745° to about 1330°. A non-variant reaction, $V_4C_3+\gamma \rightleftarrows Fe_3C+\alpha$, takes place in the neighbourhood of the composition of about 0·5 per cent. vanadium and 0·9 per cent. carbon. The subject was studied by E. L. Reed, R. Vogel and E. Martin, F. Wever and W. Jellinghaus, and H. Hougardy. C. H. Mathewson and co-workers investigated the Fe–V–O_2 system.

Observations on the subject were made by P. Blum, J. Challansonnet, E. T. Clarage, J. W. Donaldson, E. O. Fitch, W. Giesen, L. Guillet, A. Haenig, R. Maréchal, E. Martin, G. L. Norris, N. Petinot, A. M. Portevin, K. Ruf,

M. Sauvageot, and D. Zuege. J. O. Arnold said that vanadium forms a true steel, 100 per cent. pearlite, when 4·8 per cent. of vanadium is present, and 0·83 per cent. of carbon. Vanadium pearlite has $72Fe+V_4C_3$. H. Scott observed that vanadium had no marked effect on the transformation temp. of martensite to troostite. J. Challansonnet found that vanadium hindered the graphitization of steel—*vide* nickel-vanadium steels. E. Piwowarsky, A. Campion, J. W. Donaldson, H. Sawamura, and J. E. Hurst studied the effect of vanadium in cast iron.

A. Osawa and S. Oya represented the relation between the lattice parameter, a A., and the percentage of vanadium, [V], in iron-vanadium alloys by $a=2·852+0·000614[V]+0·0000131[V]^2$. Z. Nishiyama found the lattice parameter, a; the sp. gr.; and the elastic modulus, E kgrms. per sq. cm., at 15·1° to 15·3°, to be:

V . . .	0·1	2	3	4	6	7	8 per cent.
a . . .	2·857	2·860	—	2·866	2·868	—	2·871 A.
Sp. gr. . .	7·8548	7·8602	7·7999	7·7905	7·7617	7·7206	—
$E\times10^{-6}$ . .	2·162	2·127	2·151	2·142	2·130	2·093	—

Observations were also made by F. Wever and W. Jellinghaus, who found:

Vanadium.	0	13·4	28·6	38·4	47·8	63·6	79·8	100 per cent.
$a\times10^8$ cm.	2·860	2·865	2·875	2·88	2·89	2·925	2·955	3·04

K. Ruf measured the sp. gr. of iron-vanadium alloys. W. H. Hatfield gave for alloys with combined carbon 2·9 per cent., 0·66 Si, 0·28 Mn, 0·03 S, 0·08 P, and

Vanadium		0	0·138	0·22	0·45	0·65 per cent.
Hardness	Brinell's . . .	387	418	430	418	430
	Scleroscopic . .	48	48	48	47	48

G. W. Quick and L. Jordan recommend these steels for the balls in Brinell's test for hardness. G. Tammann and V. Caglioti studied the recovery of the hardness after cold-work. L. Guillet observed that the pearlitic steels have a tensile strength and an elastic limit which rise rapidly with the percentage of vanadium; the elongation and reduction of area slowly decrease, while still preserving relatively high values; the brittleness does not increase; but the hardness increases rapidly. The tensile strength and elastic limit of steels containing pearlite and carbide are lower as the proportion of vanadium is lower, and, in consequence, of the carbide, are higher. The elongation and reduction of area increase, but the resistance to shock decreases rapidly. The mechanical properties of steels containing carbide vary but little with their composition. The tensile strengths and elastic limits are low; the elongations and reduction of area are high, but the products are brittle. These results were discussed by G. Auchy, M. Ballay, J. Baxeres, P. Blum, H. M. Boylston, A. L. Colby, E. F. Cone, E. O. Fitch, H. Fleek, R. C. Good, R. Hohage and A. Grützner, W. A. Johnson, W. Kahlbaum and co-workers, O. von Keil and F. Ebert, M. Kinkead, A. B. Kinzel and C. O. Burgess, E. Kothny, R. W. Moffatt, I. Musatti and G. Calbiani, A. L. Norbury, W. Oertel and F. Pölzguter, P. Prömper and E. Pohl, A. Rys, E. B. Saklatwalla and co-workers, E. K. Smith and H. C. Aufderhaar, H. P. Smith, J. K. Smith, B. E. D. Stafford, J. Strauss and G. L. Norris, K. Taniguchi, J. L. Uhler, M. Vasvari, and F. Werner. Z. Nishiyama's results for the elastic modulus are indicated above. J. O. Arnold and A. A. Read obtained the results indicated in Table LXV. C. L. Clark and A. E. White measured the influence of temp. on the tensile strength. E. Piwowarsky said that vanadium increases the resistance of iron to shock. According to F. Robin, the resistance of the vanadium steels to crushing is very high so long as the formation of double carbide does not occur. The resistance to crushing of carbon-vanadium steels, like their hardness, is sharply accentuated by slight additions of vanadium. Near 1000°, the crushing strength of a steel with 0·8 per cent. of carbon and 0·2 to 1·5 per cent. of vanadium is rather low. E. Piwowarsky observed that the addition of silicon increases the amount of combined carbon, and this influence is greater when the silicon is low.

R. W. Moffatt found that vanadium steel castings have a greater resistance to impact than straight carbon steel castings; they are also tougher and more ductile.

TABLE LXV.—MECHANICAL TESTS ON VANADIUM STEELS.

Percentage Composition				Yield-point (tons per sq. in.)	Maximum stress in tons per sq. in.	Elongation (per cent.)	Reduction of area (per cent.)	Alternating stress (alternations endured)
C	Si	Mn	V					
0·60	0·05	0·06	0·71	12·0	35·9	22·0	41·4	119
0·63	0·09	0·07	2·32	14·0	35·0	24·5	52·0	191
0·93	0·21	0·11	5·84	17·0	33·4	25·0	53·2	135
1·07	0·32	0·12	10·30	15·0	33·7	23·0	31·5	119
1·10	0·47	0·12	13·45	18·0	37·0	10·0	9·7	15

K. Ruf measured the thermal expansion between 0° and 250° and found that alloys with over 6 per cent. of vanadium show no marked anomaly in the thermal expansion at higher temp. K. Ruf measured the sp. resistance for the thermoelectric force against platinum. Observations were also made by E. T. Clarage, E. F. Lake, P. Pütz, A. McWilliam and E. J. Barnes, J. K. Smith, H. R. Sankey and J. K. Smith, M. K. Hélouis, W. Giesen, A. M. Portevin, R. Hohage and A. Grützner, E. Maurer, A. Campion, and R. Moldenke. G. Tammann and V. Caglioti discussed the recovery of resistance after cold-work. A. M. Portevin found that the addition of 1 per cent. vanadium raised the electrical resistance of iron 6·7 microhms per cm. cube; and with steels containing 0·1 to about 0·2 per cent. of carbon—normal and hardened by quenching from 1000° to 20°—had the following values for the electrical resistance, R microhms per c.c.:

Vanadium	0·60	0·75	1·04	1·54	2·98	5·37	7·39 per cent.
R Normal	14·0	15·1	16·2	18·8	30·1	31·7	38·6
R Hardened	15·7	19·9	21·7	21·9	31·8	31·6	38·4

and with steels having about 0·8 per cent. carbon:

G. Mars stated that from the general behaviour of vanadium steels, the presence of vanadium confers no special advantages in the use for permanent magnets, and is not likely to have a stronger remanence than normal steel. J. Challansonnet found vanadium lowered the Curie point. F. Wever and W. Jellinghaus obtained the two magnetization curves for alloys with 29·5 per cent. V, and 33·5 per cent. V (Fig. 440, dotted). J. J. Lonsdale observed that the coercive force of vanadium steel is increased when it has been heated above its critical temp., and when it has been annealed and quenched. The permeability is lower than that of other steels containing the same amount of carbon, but the hysteresis and coercive force are greater.

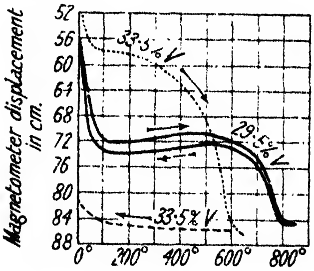

FIG. 440.—Magnetization Curves of Iron-Vanadium Alloys.

L. Kirschfeld measured the hydrogen absorbed by the ferrovanadium alloys. Alloy I had 9·1 per cent. of vanadium and 0·07 per cent. of carbon; II had 22·0 per cent. of vanadium and 0·56 per cent. of carbon; III had 70·9 per cent. of vanadium. Values for Fe, iron, and V, vanadium, are also indicated in the isothermal and isobaric (about 760 mm.) curves, Figs. 441 and 442. The absorption increases as the proportion of vanadium increases, but is always less than the value calculated by the mixture rule. The isobars for 9 and 22 per cent. of vanadium show minima at 700° to 800°, but with 71 per cent. of vanadium, the minimum disappears, and the isobar approximates to that for vanadium alone. The isotherms of the alloys assume the parabolic form at a higher temp. According to G. Tammann and G. Siebel, the thickness of the air-films, $y\mu\mu$, is represented by $t=a(e^{by}-1)$, where a and b are constants, t represents the time. There is a discontinuity in the curves connected with the transformation of α- into γ-iron. Some of L. Kirschfeld and A. Sieverts' results are shown in Fig. 443. L. B. Pfeil observed that when vanadium steel is heated at about 1000° for many hours in air, the three-layer scale which is formed—*vide supra*—has a concentration of vanadium in the innermost layer, and only small amounts occur in the middle and outer layers. G. Tammann and G. Siebel studied the oxidation or temper colours of vanadium steels. Vanadium steels ought to be more acid-resistant than ordinary steels because vanadium carbide is not readily attacked by acids. L. Aitchison found that the corrosion of vanadium steels represented by the loss in weight per 100 sq. cms. after exposure in the dark to 3 per cent. sodium chloride soln. and 1 per cent. sulphuric acid for 77 days, and 10 per cent. sulphuric acid for 45 days, was as follows:

A. B. Kinzel, and L. Guillet studied the action of nitrogen; and M. Wunder and B. Janneret, the action of phosphoric acid; and H. J. French, the action of hydrogen sulphide and other corrosive agents; and N. Tschieschewsky and N. Blinoff, the action of nitrogen. The general uses of vanadium steels were discussed by E. F. Lake, P. Girod, P. Breuil, J. A. Mathews, O. M. Becker, H. R. Sankey and J. K. Smith, M. Dierfeld, H. Fleek, G. G. Blackwell, E. Lievenie, and J. Ohly; and ferrovanadium as a catalyst, by I. E. Adaduroff and G. K. Boreskoff. E. Piwowarsky, and J. Challansonnet studied the **titanium-vanadium-iron alloys.**

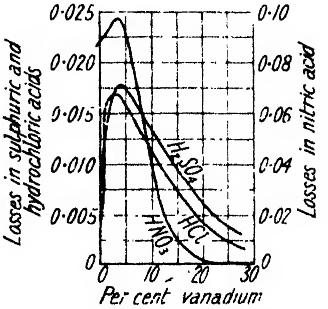

FIG. 444.—The Corrosion of Vanadium Steels by Acids.

J. G. Gahn and J. J. Berzelius[20] obtained a **tantalum-iron alloy** by heating a mixture of tantalic oxide and iron filings in a charcoal crucible. The product is hard, and scratches glass. Hydrochloric acid slowly extracts the iron, leaving the tantalum behind. Alloys were described by W. Heym, G. T. Holloway, W. Guertler, H. J. French and T. G. Digges, and F. C. Kelley. J. Laissus discussed the diffusion of tantalum in iron. A. M. Portevin found that the tantalum steels are pearlitic; and that the effect of tantalum on the shearing tests is small. The values for resistance to shear, tensile strength, etc., in Table LXVI are expressed in kilograms per sq. mm. L. Guillet obtained the results indicated in Table LXVII. The alloys were described by O. J. Steinhart, and P. Breuil. A. M. Portevin observed that the

electrical resistance of steel is very little affected by the addition of up to 1·05 per cent. of tantalum. M. Faraday and J. Stodart,[21] G. T. Holloway, and R. Mallet noted that **columbium-iron alloys** are less corrodible than iron.

M. Faraday and J. Stodart,[22] in their experiments on the alloys formed by different metals with iron, prepared some **chromium-iron alloys.** They found that an alloy with about 2·9 per cent. of chromium was as malleable as iron, and exhibited a damasked surface. Some of these alloys were examined by R. A. Hadfield. W. Sowerby said that in the southern part of India, the celebrated hog-spears and knives made by Anachelan of Salem, Madras, were manufactured from the chrome iron-stone found in the district. J. E. Stead observed that ordinary steel, and iron may contain up to 0·120 per cent. of chromium. The work, *Sur les alliages du chrôme avec le fer et avec l'acier*, was taken up by P. Berthier, who stated that the two metals could be alloyed in all proportions; that the alloys were very hard, brittle, and crystalline; and that they were a greyer and brighter white, less fusible, less magnetic, and less easily attacked by acids than iron alone. E. Frémy also prepared an alloy by heating a mixture of chromic oxide and iron in a blast-furnace, and said that the alloy frequently crystallizes in long needles, and that it resembles cast iron but scratches the hardest bodies, even hardened steel. R. Mushet used a similar mode of preparation. J. Percy also reported the alloys to be formed by heating a mixture of hæmatite and chromic oxide, in a charcoal-lined crucible, filled up with charcoal powder, and heated to whiteness for a couple of hours. Patents were obtained by J. Bauer in 1865–1869, A. Parkes in 1870; and H. Biermann wrote on the subject in 1873; and, according to A. Brustlein, chrome steel was manufactured at Unieux, Loire, in 1877. The *ferrochromium* of J. Bauer was obtained by heating a mixture of powdered chromite, and charcoal or anthracite along with a flux containing calcium or sodium fluoride, lime, and borax, in a plumbago crucible at a high temp. S. Kern also prepared it by melting chromite and charcoal in a plumbago crucible; and E. Héroult, by heating chrome ore with fluxes in an electric furnace. W. Borchers recommended the following process:

> In preparing ferrochromium, the ore is first mixed with the following substances: charcoal, 12 to 15 per cent.; resin or pulverized pitch, 6 to 7 per cent.; glass scrap, 5 per cent.; and quartz sand, 10 to 12 per cent. An intimate mixture is desirable, and can be best secured by piling the ingredients in a heap, each forming a separate layer, and then removing in vertical sections to form a new heap. After repeating this process several times the mass will have a uniform appearance. The ore is then fused in a graphite, or strong clay crucible, the bottom of which is covered with a thin layer of fine glass and coarse charcoal. The cover of the crucible is sealed with clay; only a small opening should be left for the escape of gases. The ore can be reduced by a crucible furnace with good draught, but to melt the metal a gas regenerative furnace will be required. Where a Siemens furnace for crucible steel is at hand this may be employed to advantage for smelting ferrochromium.

W. R. Hulbert obtained the alloys by the thermite process. The preparation of ferrochromium was described by W. B. Ballantine, F. M. Becket, H. Behrens and A. R. van Linge, C. Benedicks, W. Borchers and R. W. Stimson, H. Brearley, A. Brustlein, T. H. Burnham, R. Calberla, H. C. H. Carpenter, F. Cirkel, A. W. Clement, J. Escard, G. Gin, P. Girod, M. A. Grossmann, W. B. Hamilton and T. A. Evans, J. Hébert, W. Heym, E. Houdremont, F. Hütte, R. M. Keeney, R. S. Kerns, Firma Krupp, S. Meunier, H. H. Meyer, P. Monnartz, P. Oberhoffer, F. R. Palmer, D. St. Pierre du Bose, H. D. Phillips, V. S. Polansky, J. W. Richards, W. R. Saltrick, G. P. Scholl, E. J. Shackleford and W. B. D. Penniman, H. C. Sicard, F. T. Sisco, J. K. Smith, S. S. Steinberg and P. S. Kusakin, O. J. Steinhart, G. Surr, C. Tama, W. Venator, R. Waddell, H. Wedding, and R. S. Wile; G. Fuseya and K. Sasaki studied the electro-deposition of chromium-iron alloys. F. P. Zimmerli compiled a bibliography on chromium steels.

N. Agéeff and M. Zamotorin, J. Laissus, W. van Drunen, and F. C. Kelley studied the diffusion of chromium in iron. G. Grube and W. von Fleischbein showed that when a rod of iron is surrounded with powdered chromium and heated in hydrogen, the chromium-content of the surface layer of the iron and the depth of penetration of the chromium increase with rising temp. and increasing duration of heating. Thus,

	24 hrs.	72 hrs.	96 hrs.		
Surface layer .	5·3	28·4	43·3	47·4	52·9 per cent.
Penetration .	0·3	1·7	—	—	—

the composition is then constant for a depth of about 0·3 mm., and probably represents the solubility of chromium in iron at the several temps. The chromium-content of a rod does not diminish uniformly with increasing depth, and the diffusion coeff. is therefore different at different depths. The diffusion layer consists of mixed crystals of iron and chromium arranged radially. J. Laissus studied the cementation of iron by chromium.

According to R. A. Hadfield, unlike aluminium or silicon, chromium does not confer soundness on steel. When the proportion of carbon is high, as in pig-irons, sound ingots free from honeycombs may be obtained, but an alloy with 1·35 per cent. of chromium and 0·28 per cent. of carbon "rose" badly in the moulds. Aluminium does not act so powerfully with low-carbon chromium steels as it does with carbon steels. Alloys with more than 11·13 per cent. of chromium,. and 1·27 per cent. of carbon were not forgeable, but with less chromium the steels could be forged. If less carbon was present, probably steels with higher proportions of chromium would be forgeable. Chromium is not favourable to welding, for, as A. Brustlein also showed, a comparatively small proportion of chromium interferes with the welding. It may be possible to fuse chromium and attach it to steel or to wrought iron, but the ordinary process of welding two bars together is not possible. F. Reiser said that an alloy with 0·2 per cent. of chromium is unsuited for puddling. C. F. Burgess and J. Aston discussed the working qualities of the alloys.

In the study of the thermal diagram, W. Treitschke and G. Tammann observed that the f.p. curve consists of a number of irregular bends, and they suggested that the results can be explained by assuming that a compound is formed which is completely miscible in the solid state with its components. P. Monnartz supposed that the compound formed is **iron dichromide,** $FeCr_2$, and that it shows as a maximum on the f.p. curve with 66 per cent. of chromium. K. Bornemann discussed the subject; and E. Jänecke stated that the conclusions of W. Treitschke and G. Tammann are wrong because of the presence of aluminium in their alloys. He said that there is a single eutectic which can form mixed crystals with either component. The eutectic is at 1320°, and 75 per cent. of chromium; and the limit over which the mixed crystals can form, is 55 to 85 per cent. of chromium. K. Fischbeck represented the iron–chromium system as having two eutectics—Fig. 445—and a maximum corresponding with **iron hemichromide,** Fe_2Cr. These different conclusions all show that there is something yet to learn about this system.

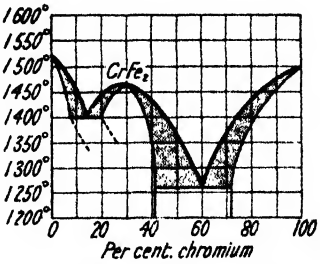

FIG. 445.—Equilibrium Curves of the Iron-Chromium Alloys.

E. Pakulla, A. von Vegesack, and T. Murakami inclined to the hypothesis that the two metals form solid soln. in all proportions; and that the apparent eutectics are due to the lack of diffusion during solidification which results in solid soln. differing in concentration. Thus, a dark etching portion showed a marked diminution in quantity on annealing at 1100° for 2 hrs., and it was inferred that a prolonged annealing would render the structure homogeneous. A. von Vegesack said that chromium and iron form a continuous series of solid soln. The m.p. of iron is depressed to a minimum of 1490° by the addition of up to 28 per cent. of chromium, and it then rises to over 1700°, the m.p. of chromium. The lower values for the m.p. of chromium are due to the presence of carbon. A. Westgren and co-workers also found that the lattice dimensions vary continuously with composition in agreement with the observation that *a*-iron and chromium have the same type of lattice. P. Oberhoffer and H. Esser represent the equilibrium curves by Fig. 446. T. Murakami showed that the A_2- and A_3-transformation points are lowered by chromium, and E. Pakulla and P. Oberhoffer obtained similar results. A. B. Kinzel found that the chromium-iron austenite loop runs from 0 to 12·2 per cent. of chromium; its upper boundary runs from 1400° to 900°, and its lower boundary from 900° and 0 per cent. of chromium to 900° with 12 per cent. of chromium.

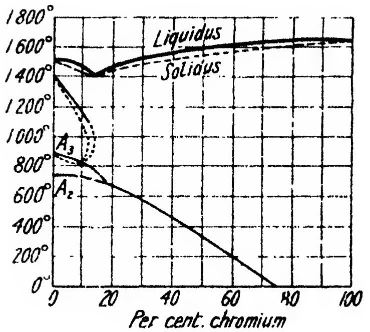

Fig. 446.—Equilibrium Diagram of the Iron-Chromium Alloys.

The equilibrium diagrams for the chromium and iron carbides have been previously indicated—**5**. 39, 19, Fig. 29, and **5**. 39, 20, Fig. 31. The diagram for the ternary system: Fe–Cr–C, has not been completed; only a few limited areas have been partially explored. P. Goerens and A. Stadeler found that the solidification temp. of iron remains practically constant at about 1130° when chromium is present to the extent of 10·4 per cent., but with higher proportions of chromium, the solidification temp. rises rapidly, attaining 1535° with 62 per cent. of chromium. With up to 21 per cent. of chromium, the carbide inversion remained at about 700° to 715°, and with higher proportions it could not be observed. The following is a selection from the results:

C . .	4·0	4·2	4·4	4·7	5·7	5·9	7·0	7·4	9·2 per cent.
Cr . .	0·0	1·2	2·7	5·0	13·7	20·5	33·4	43·2	62·0 ,,
F.p. . .	1130°	1126°	1128°	1128°	1145°	1161°	1270°	1370°	1535°
A_1-arrest .	711°	709°	710°	713°	715°	710°	*nil*	*nil*	*nil*

E. D. Campbell and J. F. Ross, H. Nienhaus, F. Adcock, F. Wever and W. Jellinghaus, E. Friemann and F. Sauerwald, T. Murakami, T. F. Russell, N. H. Aall, J. H. Andrew and H. A. Dickie, T. Kase, F. Wever and W. Jellinghaus, and P. Oberhoffer and K. Daeves made observations on the effect of chromium on the eutectic and eutectoid points of the carbon–iron system. A. B. Kinzel said that the austenite loop in the iron–chromium system ends with 12·37 per cent. of chromium. J. H. G. Monypenny measured the solubility curves of cementite; with the higher proportions of chromium, the cementite network does not dissolve until the pearlite carbide is dissolved; and the carbide dissolves rapidly above 1050° to 1100°. The cementite and carbide appear to dissolve simultaneously with the 1·36 and 2·8 per cent. chromium steels, indicating a possible difference in the two carbides. C. R. Austin found that for alloys having a chromium-iron ratio from 1 : 20 to 1 : 5, the addition of chromium up to 15 per cent. has relatively little effect on the amount of carbon in the eutectic, while with 20 per cent. of chromium, the eutectic has a little less than 4 per cent. carbon. There is no definite break on the curves other than the eutectic until the amount of chromium reaches 20 per cent., when there is a break with about 1·3 per cent. carbon. There is evidence of a maximum on the carbon side of the eutectic. With alloys having 30 to 50 per cent. chromium, the addition of carbon up to about 2·5 per cent. lowers the f.p. of the alloys linearly with increasing carbon; and the amount of carbon in the eutectics is nearly the same in all these cases. K. Fischbeck represented the data as a quaternary system involving the four phases Fe, Cr, Fe_3C, and Cr_5C_2. With steel, F. Osmond observed that chromium lowers the beginning of the A_3-transformation, and raises the end of the A_1-transformation, while the action of chromium on the A_2-transformation is not noticeable. S. Curie found that the transformations occur at a higher temp. with chromium steels than with ordinary steels. H. C. H. Carpenter obtained the following results for the change-points of the carbide with chromium steels:

Carbon	Chromium	Cooled from	Change-point
0·54	1·12	918°	729°
		1127°	728°
		1250°	709°
0·27	3·24	910°	738°
		1127°	736°
		1250°	721°
1·09	9·55	900°	776°
		1230°	750°

Hence, it was concluded that chromium tended to raise the carbide change-point, so that if 700° be taken as the change-point for carbon steels, the change-points rose respectively to 729°, 738°, and 776° on cooling from about 900° as the proportion of chromium was increased. Again, although when cooling from progressively higher temp., the change-point was lowered only a little, indicating that chromium tended to raise the carbide change-point, the temp. from which the steel was cooled had no great influence on that point. C. A. Edwards and co-workers found for the carbide transformation on heating, Ac_1, and cooling Ar_1:

Cr		1·96	4·20	6·18	8·08	10·39	12·08 per cent.
C 0·35 per cent.	Ac_1 .	797°	817°	833°	835°	835°	830°
	Ar_1 .	743°	764°	768°	774°	764°	762°
Cr		2·09	3·92	5·07	6·16	8·12	10·41 per cent.
C 1·0 per cent.	Ac_1 .	790°	795°	805°	825°	829°	836°
	Ar_1 .	748°	757°	767°	785°	794°	800°

H. Moore observed that the position of the Ac_1-transformation is progressively raised by additions of chromium from 746° with a steel containing 0·25 per cent. of chromium, to 821° when 6·417 per cent. of chromium is present. With steels having about 3 per cent. of chromium another critical point occurs below the Ac_1-point, and magnetic observations show that it is the Ac_2-point. The occurrence of the Ac_2 point below Ac_1 is taken to support the hypothesis that the carbide formed is insoluble in β-iron. A. McWilliam and E. J. Barnes observed the critical temp. shown in Table LXVIII with steels containing 2 per cent. of chromium.

TABLE LXVIII.—THE CRITICAL TEMPERATURES OF 2 PER CENT. CHROMIUM STEELS.

Carbon (per cent.)	Heating			Cooling		
	Ac_1	Ac_2	Ac_3	Ar_3	Ar_2	Ar_1
0·20	765°	791°	822°	785°	765°	732°
0·25	759°	789°	810°		758°	731°
0·32	753°		785°		748°	733°
0·50	759°		778°		721°	
0·65		783°			718°	
0·85		777°			714°	

A. B. Kinzel stated that the A_4-arrest is gradually lowered from 1400° to 1250° with the addition of 10 per cent. chromium, and with 12·25 per cent. chromium, the A_4- and A_3-arrests coincide; the A_3-arrest is not changed. With 12·37 per cent. of chromium, the transformation could not be observed, and the austenitic loop ends at this point. A. B. Kinzel also found that the addition of up to 4 per cent. of chromium gradually lowers the A_4-transformation from 1400° to 1250°; and with higher proportions of chromium, the lowering is more abrupt, so that with 12·25 per cent., the A_4- and A_3-arrests coincide. The A_3-arrest is not affected.

Fig. 447 represents a portion of the standard iron-carbon diagram—*vide* Fig. 31, **5**. 39, 20—which changes very little with a small proportion of chromium. The area A_4BM represents a region of mixed austenite and δ-iron; and the area A_3SP, a region of mixed austenite and α-iron—the term δ-iron is used to indicate material that has been heated above the A_4-arrest, in contrast to α-iron, *i.e.* a material which has been transformed from austenite by cooling through the transformation temp. at the proper rate. Both δ-iron and α-iron crystallize in a body-centred cubic lattice, and the $\gamma\rightarrow\delta$-transformation is a reversion of the $\alpha\rightarrow\gamma$-transformation, and P. Oberhoffer found that in the re-crystallization of the iron-silicon alloys, the A_2- and A_3-arrests approach one another with increasing percentages of silicon, and coincide with 2·5 per cent. silicon. This was confirmed by P. Oberhoffer and C. Kreutzer. A. Westgren and G. Phragmen's X-radiograms confirm this. E. C. Bain inferred that a similar phenomenon occurs with the iron-chromium alloys, and this was confirmed by A. Westgren and co-workers. In the complete absence of carbon, the γ-change disappears completely when enough alloying element is present. Since A. Westgren and G. Phragmen have shown that chromium crystallizes only in one single type of lattice, it follows that the γ-range should be limited to alloys rich in iron, and E. C. Bain showed that this occurs when about 14 per cent. of chromium is present; P. Oberhoffer and C. Kreutzer gave 12·62 per cent. of chromium with 0·01 per cent. of carbon; and F. Stäblein, 18 per cent. of chromium with 0·03 per cent. of carbon. As chromium is added to the iron, there is a slight rise in the A_3-point, and a sharp drop in the A_4-point until, with about 14 per cent. of chromium the two points meet, and beyond that there is no transformation to γ-iron. Hence, when carbonless iron-chromium alloys containing over 14 per cent. of chromium are heated to a high temp., the α-iron remains as such. When carbon is present, M. A. Grossmann showed that the conditions are very different. The results can be represented on a ternary diagram, Fig. 447. A. von Vegesack also observed that the transformation point of γ- to α-iron is lowered by the addition of chromium, and cannot be observed when over 15 per cent. of chromium is present. P. Oberhoffer and H. Esser gave 14·77 per cent. as the limit at which γ-Fe can be no longer observed. This agrees with C. Kreutzer's observations of the X-radiograms. The effect of chromium on the $\alpha\rightarrow\gamma$- and the $\gamma\rightarrow\delta$-transformations could not be observed because of the volatilization of the chromium; but the α-phase passes directly into the δ-phase when over 15 per cent. of chromium is present. J. A. Jones, J. P. Gill, A. Michel and P. Benazet, L. R. Austin, L. J. Barton, E. Jänecke, T. Murakami and Y. Fujii, E. L. Reed, W. Haufe, J. E. Johnson, A. Merz, E. Maurer and co-workers, V. N. Krivobok and M. A. Grossmann, H. F. Moore, and P. Oberhoffer and C. Kreutzer, discussed the range of the Ac_1-arrest; H. Moore, the A_2-arrest; and V. N. Svechnikoff, the γ-phase.

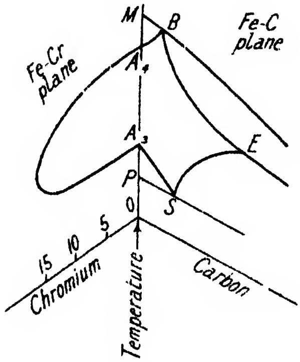

FIG. 447.—Portion of Equilibrium Diagram for Iron-Carbon-Chromium Alloys.

F. Osmond concluded that chromium exists in steel in at least three states—separately or simultaneously: (i) as dissolved chromium; (ii) as a complex compound of chromium, iron, and carbon in the form of isolated globules; and (iii) as a solid soln. with the ternary complex. The triple complex is very hard, and when incorporated with a more malleable matrix, it naturally communicates to it a certain degree of hardness. The chromium and iron carbides have been previously discussed. H. Behrens and A. R. van Linge reported that a non-magnetic crystalline complex **iron chromium carbide,** $Cr_2Fe_7C_3$, is obtained as a residue by treating ferrochromium with 13·3 per cent. chromium and 5·5 per cent. carbon with acid; while a 50 per cent. carbon chromium alloy with acid yields Cr_3FeC_2. A. Carnot and E. Goutal obtained residues corresponding with $Fe_3C.3Cr_3C_2$, and $3Fe_3C.Cr_3C_2$ from two chromium steels; P. Williams obtained $3Fe_3C.2Cr_3C_2$ by heating a mixture of chromic oxide, iron and petroleum coke in an electric furnace; while J. O. Arnold and A. A. Read concluded that the carbides in chromium steel—with carbon 0·64 to 0·85 per cent., and chromium 0·65 to 23·7 per cent.—varied with the composition. Thus, the residues, remaining after the acid treatment of alloys with nearly 0·85 per cent. carbon, corresponded with the mol. ratios $Fe_3C : Cr_3C_2 : Cr_4C$:

C .	0·64	0·84	0·835	0·85	0·88	0·85	0·85	per cent.
Cr .	0·65	0·99	4·97	10·15	15·02	19·46	23·70	,,
Ratios	20 : 1 : 0	12 : 1 : 0	4 : 1 : 1	1 : 1 : 1	2 : 0 : 1	2 : 0 : 1	2 : 0 : 1	

and T. Murakami inferred that the α-carbide is $(Fe_3C)_{18}Cr_4C$; the β-carbide is $(Fe_3C)_9Cr_4C$; and the γ-carbide is $(Fe_3C)Cr_4C$. He supposes that the lowering or suppression of the carbide change in low-chromium steels is caused by dissolved chromium. Above the Ac_1-point, the carbide Cr_4C dissolves in austenite, and by heating it to a suitable temp., it dissociates: $2Cr_4C \rightleftharpoons Cr_3C_2 + 5Cr$. High temp. favour the constituents on the right. During cooling, re-combination to form Cr_4C proceeds only slowly, and therefore, in alloys containing Cr_4C, the carbide change is lowered by the normal cooling from a high temp., by the retarding action of the dissolved chromium. The hardness of chromium steel is attributed to the solid soln. of the carbide Cr_3C_2 in a soln. of chromium in iron. The subject was discussed by P. Oberhoffer, and F. Rapatz. H. C. Boynton found that the pearlite in a 1 per cent. chromium steel is seven times harder than that of ordinary steel, but the ferrite was about the same in both cases, and it was hence assumed that at least 1 per cent. of the chromium is in the form of carbide. C. A. Edwards and co-workers assumed that in the ternary system, there is a region I, containing $Fe_3C + (Fe_3C)Cr_3C_2 + Fe$, and that as the proportion of chromium increases, the mols. of Fe_3C will be all used up in forming the double carbide, $Fe_3C.Cr_3C_2$, that is, FeCrC; and there appears region II, containing the double carbide, some unknown chromium carbide, say, Cr_5C_2, along with a solid soln. of iron and chromium with steels containing still less carbon; and there remains a region III, with chromium carbide along with a solid soln. of chromium and iron. T. F. Russell's experiments also indicate that FeCrC is the only double carbide formed; and he concludes tentatively, from measurements of the electrical resistance, that when chromium is added to a plain carbon steel, the chromium first associates itself with the iron carbide until the mol. ratio of chromium to carbon is 4·3, corresponding with FeCrC, and probably only a small proportion of chromium goes with the ferrite to form a solid soln.—*chromoferrite*. With further additions of chromium, the bulk goes into solid soln. with the iron, and raises the electrical resistance. This agrees with the observations of C. A. Edwards and A. L. Norbury. Even when the ratio Cr : C exceeds 4·3 : 1, some of the chromium is associated with the carbide, as indicated by observations of J. O. Arnold and A. A. Read, etc., to form another carbide with a higher proportion of chromium, but T. F. Russell considers that this chromium is either carried down mechanically, or else is in solid soln. with the carbide. M. A. Grossmann found that the carbon in a high chromium iron is not distributed uniformly after heat-treatment. The subject was studied by A. Carnot and E. Goutal, T. Meierling and W. Denecke, W. E. Remmers, F. Sauerwald and co-workers, E. L. Henderson, O. Smalley, E. Valenta, and H. Wentrup and W. Stenger. F. Roll showed that chromium stabilizes the cementite in cast iron, and the subject was investigated by J. W. Donaldson, T. F. Jennings, H. Sawamura, and T. Isihara.

K. Daeves found that the solubility falls off rapidly at first as the chromium-content increases, then more slowly, the general form of the curve being hyperbolic. Points on the curve were determined by observing what chromium-content was necessary, with a given carbon-content, to cause the appearance of a eutectic in the structure of the metal. To make the hard alloys workable, for the preparation of polished surfaces, it was necessary to heat for several hours at 800°, just below the Ac_1-point, by which treatment the solid soln. was broken up and the metal softened. Etching was accomplished by electrolysis in ammonium persulphate soln. In eutectoid alloys, the cementite is practically unattacked by hot sodium picrate soln. Cold alkaline potassium ferricyanide turns the hard constituent of the eutectic brown to yellow, leaving the mixed crystals untouched. The solubility curve explains many of the known properties of chromium steels. The melting-point of steel and the arrest points are little affected by chromium up to 10 per cent. About a dozen complex carbides have been reported, and in no particular case has its existence as a chemical individual been established, although the existence of FeCrC is highly probable. H. Brearley added that after numerous and fruitless attempts he had learned to distrust evidence based on the chemical analysis of residues employed to establish the existence of compounds which can be distinguished microscopically in steel. By means of X-radiograms, A. Westgren and co-workers found that the Cr_3C_2 carbide crystallizes in the rhombic system, and the elementary parallelopiped has 20 atoms, and the dimensions $a_1=2{\cdot}8121$ A., $a_2=5{\cdot}52$ A., and $a_3=11{\cdot}46$ A. The carbide usually given as Cr_5C_2 is considered to be Cr_7C_3. It is trigonal, and the elementary prism contains 80 atoms, and it has the dimensions—edge of base, 13·98 A., and height, 4·523. Another carbide, Cr_4C, *chromium tetritacarbide*, has a face-centred cubic lattice with 120 atoms, and side, $a=10{\cdot}638$ A.

L. Guillet found that quenching acts upon chromium steels in the same manner as it does on carbon steels, but with a far greater intensity, for the increase in tensile strength and elastic limit are much greater than with ordinary steels containing the same proportion of carbon. The martensitic steels are but little altered by quenching; while those richest in chromium are slightly softened. The troostite steels are hardened by quenching. Steels containing carbides are slightly softened by quenching from 850° without undergoing any alteration in their structure; quenching from 1200° has the effect of partially dissolving the double carbide and of producing γ-iron, while the hardness and brittleness are reduced. Annealing slightly softens all chromium steels. With steels containing carbide, annealing produces an increase in the grain-size, while in steels containing much chromium, an eutectoid carbide appears to be formed. The subject was studied by T. Murakami and co-workers, E. C. Bain, E. Houdremont, A. M. Portevin, K. Daeves, and D. Uno. J. H. G. Monypenny emphasized that the change with increasing amounts of chromium are all continuous, and there are no abrupt changes which can be represented sharply by boundary curves. L. Guillet found certain steels are austenitic when quenched from high temp., and J. H. G. Monypenny found that high carbon chromium steels, when quenched from a sufficiently high temp., are almost wholly austenitic. The proportion of carbon required varies with the proportion of chromium, being lower as the latter is higher. The region between the lines, Fig. 447, represents a mixture of the two. If the austenitic steel be tempered at 450°, the apparent drop in hardness is due to the presence of some martensite in the untempered sample; at 450°, there is an incipient decomposition of the austenite; at 600°, the hardness is a maximum, and the structure is martensite with a network of troostite; at 700°, the martensite is broken down, and the hardness drops considerably; while at 750°–800°, the carbide balls up. The austenite can be transformed into martensite by press. By slow cooling, it can be shown that the martensite is a transition product between austenite and pearlite, and it is obtained by a slower rate of cooling than is needed for austenite. The sequence of changes from austenite is martensite→troostite→carbide. W. Giesen said that steels low in chromium are pearlitic; and with medium chromium, martensitic; and that high-chromium steels, etched with picric acid, contain white globules of a carbide—*vide supra*. Observations on the microstructure were also made by C. A. Edwards and co-workers, W. Aichholzer, and E. Maurer and H. Nienhaus. T. F. Russell found that with alloys with up to nearly 12 per cent. of chromium and 1 per cent. of carbon, the steels were all pearlitic when cooled about 40 minutes, and all the steels recalesced between 700° and 770°. L. Guillet's pearlitic steels can be made martensitic by the air-cooling of small pieces. P. Oberhoffer also considers that the martensite area should be taken away from the diagram; and A. M. Portevin demonstrated what he considered to be the instability of the martensite zone. H. Scott found that chromium in certain proportions raised the temp. of the transformation of martensite to troostite. E. C. Bain showed that alloys containing more than about 25 per cent. of chromium are without transformation, the α-iron and δ-iron solid soln. being continuous and identical; and any carbon in excess of 0·40 per cent. is required to produce an appreciable amount of austenite at any temp. Alloys with over 10 per cent. of chromium furnish δ-iron in a form sufficiently stable to be quenched unchanged at room temp.; it is formed at a decreasing temp. with increasing chromium-content, and at room temp., it is then ordinary ferrite and is permanently stable. In the absence of appreciable quantities of carbon, chromium, in excess of about 14 per cent., does not dissolve in γ-iron, so that γ-iron is not produced in alloys containing more than this amount of chromium. Carbon increases the solubility of chromium in γ-iron, and renders it a stable constituent in alloys with over about 14 per cent. chromium. Alloys of iron with less than 10 per cent. of chromium behave like low-carbon steels, producing a material on quenching which is structurally martensitic, with rather lower carbon-content than would be found in a steel with the same structure. Both chromium and carbon render austenite more sluggish and reluctant to change into α-iron or martensite on cooling; and about 12 per cent. of chromium is required to preserve any appreciable austenite at room temp. after quenching in water, even when the carbon is as high as 0·3 per cent. W. Giesen reported that pearlitic chromium steels with 0 to 8 per cent. chromium and 0·5 per cent. carbon, or 0 to 5 per cent. chromium and 0·95 per cent. carbon, differ very slightly from ordinary carbon steels with a corresponding amount of carbon. The elastic limit, breaking strength, and elongation are similar; the hardness increases with the proportion of chromium, and is independent of the carbon-content, whilst the brittleness is less than in carbon steels with the same carbon-content. Chromium steels with 8 to 18 per cent. of chromium and 0·3 per cent. of carbon, or steels with 5 to 12 per cent. of chromium and 0·95 per cent. of carbon of martensitic or troostitic structure have a high tensile strength, elastic limit, and breaking strength in comparison with pearlitic chromium steels, whilst their ductility is low, the hardness is very high, and the brittleness medium. If the proportion of chromium exceeds 25 per cent. when 0·3 per cent. of carbon is present, and over 22 per cent. with 0·95 per cent. of carbon, the elastic limit sinks considerably, whereas the brittleness increases in the same proportion and attains a high value. The ductility and breaking strength are then medium. The tensile strength with a troostitic structure is much less than when the structure is martensitic. Chromium steels with martensitic or troostitic structure are very hard, and have a high elastic limit and tensile strength, with low elongation and contraction. Annealing makes pearlitic chromium steels milder, as is also the case when the martensitic steel is hardened—small quantities of γ-iron being formed in each case. A double carbide, chromium steel has a white appearance after heating to 1250°, and when quenched from this temp. the carbide structure disappears provided the proportion of chromium is high enough. Chromium steels with the double carbide structure are very liable to fracture; those of pearlitic structure are said to be best adapted for commercial use. J. O. Arnold said that chromium does not form a true steel with 100 per cent. pearlite. X-radiograms show that for each of the chromium carbides substitution of iron for chromium may to some extent take place. In the cubic form the chromium may be replaced by iron up to about 25 per cent.: in the trigonal carbide the iron-content may rise to 55 per cent., but in the rhombic carbide only a few per cent. of chromium can be replaced by iron. No definite double carbide, the presence of which would necessitate the presence of both iron and chromium atoms, is found. The solubility of the carbide in austenite is reduced as the chromium is increased, and the cementite line consists of two distinct portions corresponding to the solubility of different types of carbide. With 3 per cent. chromium, for example, the lower portion of the curve represents the solubility of the trigonal carbide, and the higher temp. region the solubility of cementite. With 15 per cent. of chromium the lower temp. portion gives the solubility in the γ-phase of the cubic carbide, and at higher temp. of the trigonal one.

According to A. Westgren and co-workers, A. von Vegesack's observations show that it is probable that along the trigonal carbide and γ-metal eutectic, and along the trigonal carbide and α-metal eutectic, the temp. rises continuously with an increasing percentage of chromium. This means that the points representing the liquid in equilibrium with the cubic and trigonal carbides and α-metal, or with trigonal carbide and α- and γ-metals, are both situated outside the respective triangles of the ternary system. The liquidus surface of cementite falls with an increasing percentage of chromium. The point of intersection of the liquidus surfaces of cementite, trigonal carbide, and γ-metal form a minimum point in the homogeneity range of the liquid phase. The evidence indicates that with a fairly low content of chromium, cementite is stable towards graphite so that the liquidus surface of cementite should intersect that of graphite. If the liquidus surface of cementite sinks with an increasing proportion of chromium, then that of graphite must necessarily decline still more rapidly. This indicates that chromium carbide mols. are present in the liquid phase. All three chromium carbides may separate from austenite on annealing. The homogeneity range of austenite is limited by four surfaces, three of which correspond with carbides, and one with the α-phase. E. C. Bain, and B. Kalling and G. Pagels have shown that the stability of austenite towards the α-phase rises with the carbon-content. It is remarkable that the cubic carbide can be in equilibrium with austenite at these low temp. The chromium-content of the metal phase, being in equilibrium with both trigonal and cubic carbides, is reduced to less than half its value at the moment of solidification. The maximum iron-content of the cubic carbide, however, seems to increase. As the chromium-content is raised the area of the γ-iron phase is gradually reduced and finally disappears: the eutectic occurs at a lower carbon-content than in iron-carbon alloys, for example, at about 3·7 per cent. with 15 per cent. of chromium.

In annealed chromium steels containing only 1 or 2 per cent. of chromium, the only carbide found is cementite, the iron of which is partially replaced by chromium. The difference of distribution of the carbide in such steels appears to be due not to any definite difference of composition, but to something of the nature of segregation. The carbide in stainless steel is the cubic carbide sat. with iron. In a steel, used for dies, containing about 1 per cent. of nickel, 11 per cent. of chromium, and 2 per cent. of carbon, the trigonal carbide occurs, rather more than half of the chromium of which is replaced by iron. K. Hilgenstock discussed the desulphurizing action of chromium on steel; R. J. Anderson, O. Bauer and K. Sipp, F. B. Coyle, A. B. Everest, C. D. Foulke, D. Hanson, J. R. Houston, A. Labo, E. Piwowarsky and co-workers, H. J. Schuth, E. K. Smith and H. C. Aufderhaar, L. Thiery, and M. Waehlert, the action of chromium on cast iron, etc.; and H. Styri, the heat-treatment of chromium steels.

P. Schoenmaker, and K. Honda and T. Murakami discussed the structure of chromium steels; W. Riede, and A. Phillips and R. W. Baker, the effect of chromium on the grain-growth; and G. D. Preston, A. E. van Arkel and W. G. Burgers, A. Westgren, and Z. Nishiyama, the X-radiograms. The lattice parameter, a; the sp. gr.; and the elastic modulus, E kgrms. per sq. cm., at 15·1° to 20·5°, are:

Cr . .	1·85	3·49	5·34	7·22	8·04	11·67	13·23 per cent.
a . .	2·865	2·869	2·869	2·871	2·872	2·871	2·873 A.
Sp. gr. .	7·8346	7·7980	7·7722	7·7474	7·7614	7·7419	7·7261
$E \times 10^{-6}$.	2·137	2·163	2·187	2·216	2·162	2·212	2·253

A. Westgren showed that the lattice dimensions of iron-chromium alloys vary continuously with the composition:

Chromium .	0	8·3	19·3	32·1	51·6	72·6	80·3	100·0 per cent.
a . . .	2·861	2·863	2·866	2·868	2·871	2·874	2·876	2·878 A.

Analogous observations were made with the cubic and trigonal carbides in which part of the chromium was replaced by iron. E. C. Bain discussed the X-radiograms; and R. Blix, the X-radiograms of ferro-chromium associated with nitrogen. According to R. A. Hadfield, the sp. gr. of chromium steels is as follows:

C .	0·07	0·14	0·77	0·77	1·27	2·12	4·00	5·00	6·00	6·47 per cent.
Cr .	0·22	0·57	3·51	5·19	11·13	16·74	8·30	28·00	44·00	66·00 ,,
Sp. gr.	7·777	7·759	7·740	7·712	7·675	7·595	7·597	6·954	6·814	7·000

F. Stäblein said that the sp. gr. of iron-chromium alloys decreases by 0·0033 for every 1 per cent. of chromium. J. H. G. Monypenny gave for a steel—0·3 C; 12·6 Cr—annealed at 950°, 7·731, which became 7·738 on tempering at 700°; for samples fully hardened and tempered: mild steel, 7·869; 0·3 C, 10·6 Cr, 7·751; 0·3 C, 12·6 Cr, 7·738; 0·08 C, 12·3 Cr, 7·779; 0·08 C, 15·4 Cr, 7·722; and 0·1 C and 20·4 Cr, 7·683. C. Benedicks and co-workers also measured the sp. vol. of stainless steels. The subject was discussed by J. O. Arnold, B. Simmersbach, H. A. Dickie, and J. H. Andrew and co-workers.

K. Ruf measured the sp. gr. of alloys of iron and chromium. W. Brown found the sp. gr. and sp. vol. of steels with 0·90 per cent. of carbon and 2·00 per cent. chromium are respectively 7·7611 and 0·12885; with 0·43 per cent. of carbon and 3·25 per cent. of chromium, respectively 7·7653 and 0·12878; and with 1·09 per cent. carbon and 9·50 per cent. chromium, respectively 7·7032 and 0·12982; so that with up to 3·3 per cent. of chromium, the sp. vol. can be represented by 0·1269 +0·00034 Cr, where Cr denotes the percentage of chromium, and higher proportions – up to 9·5 per cent.—have no further effect on the sp. vol. H. Rowsing and J. Sissener noted the changes in vol. which occur during the heat-treatment of chromium steels.

According to R. A. Hadfield, annealed steels or unannealed steels with 0·39 per cent. of carbon and up to 3 per cent. of chromium, are easily filed; with increasing proportions of chromium, the samples become harder and annealing makes very little difference to this property. With over 9·18 per cent. of chromium and 0·71 per cent. of carbon, the steel is very hard and can scarcely be touched with a file. The relative hardness of steels by the sclerometer test was found to be:

C . . .	0·16	0·12	0·27	0·39	0·77	0·86	0·71 per cent.
Si . . .	0·07	0·08	0·12	0·14	0·50	0·31	0·36 ,,
Mn . . .	0·18	0·18	0·21	0·25	0·61	0·29	0·25 ,,
Cr . . .	0·29	0·84	1·18	2·54	5·19	6·89	9·18 ,,
Hardness . .	22	21	24	24	55	38	43

when that of lead is 1; copper, 8; the softest iron, 15; and very hard white iron, 72. M. Brustlein, and J. B. J. D. Boussingault also stated that chromium steel with a very low proportion of carbon does not harden when water-quenched; and G. Rolland observed that chromium does not take the place of carbon in hardening steel. G. Tammann and V. Caglioti studied the recovery of hardness after cold-work. R. A. Hadfield's results are taken to show that chromium in its effect on iron, in the absence of carbon cannot be regarded as a hardening agent; but if not less than 0·35 per cent. of carbon be present, quick cooling is followed by a considerable hardening; and this under conditions where in the absence of carbon the alloy would not have been hardened. He also showed that if sufficient carbon be present, chromium makes the steel self-hardening. W. Giesen found that the hardness of steels with 0·5 per cent. of carbon and 0 to 8 per cent. of chromium, or 0·95 per cent. carbon and 0 to 5 per cent. chromium, increases with the chromium-content, and is entirely independent of the carbon-content; steels with 8 to 18 per cent. of chromium, and 0·3 per cent. of carbon, or 5 to 12 per cent. of chromium, and 0·95 per cent. of carbon, are extremely hard. Chromium steels with the martensitic or troostitic structure are exceedingly hard. The hardness of chromium steels was discussed by E. C. Bain, A. Campion, H. A. Dickie, J. W. Donaldson, C. A. Edwards and co-workers, V. Fedoroff and N. Trofimoff, L. Grenet, L. Guillet, M. Hamasumi, D. Hanson, H. Jüngbluth, T. Kase, A. Kussmann and B. Scharnoff, J. H. G. Monypenny, T. Murakami and Y. Fujii, H. O'Neill, E. Piwowarsky, A. M. Portevin, H. Redenz, M. Rudolph, L. R. Seidell and G. J. Horvitz, K. Taniguchi, and O. Smalley. W. H. Hatfield's results are indicated in Table LXIX. C. R. Austin measured the effect of annealing at different temp. with steels containing approximately 0·35 per cent. of carbon, and found Brinell's hardness to be:

Cr	. . .	1·95	4·02	6·18	8·08	10·39	12·08 per cent.
Temp.	805° . .	205	180	200	175	185	185
	850° . .	195	137	160	174	190	190
	960° . .	146	163	170	177	200	192
	Oil . .	645	512	286	255	248	270

where the samples in the last line were quenched in oil from 960°. Similarly, with samples of steel containing nearly 1·0 per cent. of carbon:

Cr	. . .	2·09	3·92	5·07	6·16	8·12	10·42 per cent.
Temp.	805° . .	207	255	210	223	223	153
	850° . .	202	225	202	210	207	143
	960° . .	269	321	228	202	196	140
	Oil . .	418	350	340	350	241	2455

where the last two samples in the last line were quenched in oil from 1200°–1300°, the others, from 960°. Steels with the martensitic structure are hard, the hardness is scarcely affected by tempering at 500°, and the martensitic structure persists, tempering at 500° to 600° softens the steel corresponding with the breaking up of the martensitic structure and the appearance of carbide. This is more pronounced by tempering at 700°–750° when the carbide granules are larger. Annealing at higher temp. results in an increase in the hardness corresponding with the re-solution of the carbides. C. A. Edwards and co-workers studied the relation between Brinell's hardness and the velocity of cooling from the initial temp. indicated in the diagram; and the hardness of the steels cooled from different initial temp. in air—*vide* Table LXIX for some data on the hardness of these steels.

F. Robin studied the acoustic properties of chromium steels; and D. S. Muzzey, the longitudinal vibrations of magnetized cylinders. The mechanical properties of chromium steels were measured by W. Aichholzer, J. H. Andrew, C. O. Burgess, A. L. Colby, J. H. Critchett, H. J. French, H. J. French and H. K. Herschmann, J. P. Gill, E. Greulich, L. Guillet and co-workers, R. A. Hadfield, R. Hall, G. A. Hankins and co-workers, E. L. Henderson, V. O. Homerberg and I. N. Zavarine, E. Houdremont and co-workers, A. Hultgren, J. A. Jones, E. Kothny, F. C. McGrail, P. G. McVetty and N. L. Mochel, A. McWilliam and E. J. Barnes, P. Marsich, N. N. Menshih, F. W. Meyer, K. H. Müller and E. Piwowarsky, I. Obinata, W. Oertel and K. Würth, C. W. Pfannenschmidt, F. Rapatz, H. Redenz, M. Schmidt and O. Jungwirth, B. Stoughton and W. E. Harvey, and E. C. Wright and P. F. Mumma. F. L. Coonan, and L. Guillet said that with pearlitic steels, the tensile strength and elastic limit are higher, the higher the proportion of chromium, without, however, differing greatly from those of ordinary steels with the same proportion of carbon. The brittleness is increased a little. The martensitic steels are said to have the same qualities as nickel and manganese steels, but have less brittleness. The mixed martensitic and carbide steels also resemble the manganese steels; while the double carbide steels have a somewhat low tensile strength and elastic limit, and they have high contractions and medium elongations. Z. Nishiyama's measurements of the elastic modulus are indicated above. The observations of C. R. Austin are summarized in Table LXIX. The tensile strength of steel with 1·96 per cent. of chromium, not tempered, was 44·0, and after tempering an hour at 610°, it was 74·4, and the elongation 11·0 per cent. The tensile strength of the 4·02 per cent. chromium steel, not tempered, was 78·0, and after tempering an hour at 610°, 56·3, and the elongation was 18·7 per cent. The tensile strengths and percentage elongations of the steel, tempered at 500° and 650°, with 6·18 per cent. of chromium, were respectively 60·4 and 17·2; with 8·08 per cent. Cr, 59·2 and 18·0; with 10·39 per cent. Cr, 56·4 and 17·2; and with 12·08 per cent. Cr, 60·1 and 18·7. Again, the tensile strength of the steel with 2·09 per cent. Cr, tempered at 500° and 650°, was 85·7; the tensile strength and elongation of the steel with 3·92 per cent. of chromium, tempered an hour at 500° and 650°, were respectively 81·0 and 11·0; and likewise for the steel with 5·07 per cent. of chromium, respectively 75·8 and 12·5. The tensile strength of the steel with 6·16 per cent. of chromium, tempered an hour at 500° and 650°, was 49·0, and when tempered an hour at 650°, 59·0. The test-pieces broke in the shoulder in the cases where the elongations are not stated. The mechanical properties were discussed by H. H. Abram, L. Aitchison, P. A. E. Armstrong, C. R. Austin, H. W. Baker and A. H. Gibson, P. Blum, C. B. Callomon, F. B. Coyle, H. C. Cross, H. A. Dickie, J. W. Donaldson, P. Eyermann, H. J. French, G. Gabriel, F. L. Garrison, N. J. Gebert, J. P. Gill, R. C. Good, W. Guertler, A. Hultgren, W. H. Hatfield, W. Haufe, J. E. Hurst, T. F. Jennings, J. A. Jones, W. Kahlbaum and co-workers, B. Kjerrman, J. H. Küster and C. Pfannenschmidt, C. B. Lord, T. D. Lynch and co-workers, R. S. MacPherran, P. G. McVetty and N. L. Mochel, Y. Matsunaga, T. Matushita, J. H. G. Monypenny, H. Moore, R. R. Moore, I. Musatti and G. Calbiani, J. B. Nealey, A. L. Norbury, O. K. Parmiter, A. R. Page and J. H. Partridge, A. Phillips and R. W. Baker, F. Rapatz and H. Pollack, W. Riede, A. Rys, K. Sasakawa, A. Schulze, F. W. Shipley, E. K. Smith and H. C. Aufderhaar, T. Swinden and P. H. Johnson, and W. Zieler. J. H. G. Monypenny obtained the results indicated in Table LXX for the effects of tempering and annealing on steel-1 with 0·07 per

TABLE LXIX.—THE MECHANICAL PROPERTIES OF CHROMIUM STEELS.

Percentage composition				Annealed 805°			Annealed 850°			Annealed 960°

cent. C, 0·08 Si, 0·12 Mn, 0·57 Ni, and 11·7 Cr. The results correspond with the effects on the hardness indicated above.

TABLE LXX.—THE EFFECT OF ANNEALING TEMPERATURES ON THE MECHANICAL PROPERTIES OF CHROMIUM STEELS.

	Treatment	Yield-point (tons per sq. in.)	Maximum stress (tons per sq. in)	Elongation (per cent.)	Reduction area (per cent.)	Brinell's hardness	Izod impact (ft.-lbs.)
I	O.H. 930°	—	73·2	13·5	41·9	340	28
	W.H. 200°	—	73·0	12·0	38·0	340	34
	W.H. 300°	—	72·4	12·5	36·4	332	38
	W.H. 400°	-	72·3	15·5	51·0	332	38
	W.H. 500°	58·8	72·4	18·0	52·2	340	36
	W.H. 600°	38·0	49·1	22·0	62·4	241	65
	W.H. 700°	30·6	40·4	26·5	65·8	196	79
	W.H. 750°	27·9	36·4	31·0	68·8	179	87
	W.H. 800°	33·6	53·6	13·5	44·6	255	40
II	W.H. 650°	38·0	61·9	7·0	13·4	302	7
	W.H. 700°	40·8	59·7	10·0	18·3	385	8
	W.H. 750°	33·6	58·9	10·0	18·3	281	8
III	A.H. 950°; W.H. 700°	26·0	36·8	34·0	62·6	—	69
	A.H. 1000°; W.H. 700°	32·0	44·2	23·0	53·4	—	55
	O.H. 1000°; W.H. 700°	34·0	45·4	24·0	60·4	—	75

The symbols O.H. and W.H. refer respectively to oil- and water-hardening. The results show that up to 500°, the tensile strength is not affected by tempering, but the ductility (elongation and reduction in area) and toughness (impact test) are improved; between 500° and 600°, the tensile strength falls rapidly, while the ductility and toughness increase in value; at 600° to 750°, these results are more accentuated; between 750° and 800°, corresponding with the dissolution of the carbides, the steel shows evidence of hardening. By increasing the proportion of carbon, the tensile strength gradually rises, while the ductility and toughness become less; when the proportion rises to 0·3 per cent., the steel becomes hypereutectoidal, and gives high values for Brinell's hardness. These steels cannot be softened by tempering below a tensile strength of 50 to 55 tons per sq. in. With still higher proportions of carbon, the materials contain large proportions of free carbide. The series for steel-II refer to a high-carbon chromium steel: 1·42 C, 0·12 Si, 0·35 Mn, 0·44 Ni, and 13·1 Cr. The results for a high-chromium steel-III refer to a steel with 0·17 C, 0·26 Si, 0·18 Mn, and 15·9 Cr. As the proportion of chromium increases, a higher quenching temp. is needed to harden the steel, and eventually the possible increase in hardness obtainable by quenching from at least 1200° is very small. The tensile strength obtainable after hardening and tempering is rather lower than with lower-chromium steels, at the same time the ratio of yield-point to maximum stress is also lower.

J. H. G. Monypenny found the modulus of elasticity—*i.e.* Young's modulus—in tension, expressed in lbs. per sq. in., for a steel with 0·09 C, and 12·0 Cr, was $0{\cdot}0_4296$; and for a steel with C 0·23 and Cr 12·8, $0{\cdot}0_4306$. H. H. Abram obtained values ranging from $0{\cdot}0_4296$ to $0{\cdot}0_4323$ for a series of stainless steels with 0·10 to 0·43 C, and 12·37 to 14·7 Cr. The former also gave $0{\cdot}0_4125$ for the modulus of elasticity in shear for a steel with 0·25 C, and 12·5 Cr. C. L. Clark and A. E. White studied the effect of temp. on the tensile properties of chromium steel. For the effect of hydrogen, see that element.

The fatigue, that is, the failure of the steel under alternations of tension and compression over a long period of time, has been examined by F. H. Moore and J. B. Kommers, D. J. McAdam, H. J. Gough and co-workers, etc. The fatigue range for a chromium steel with a tensile strength of 43·5 tons per sq. in., was ±21 tons per sq. in. for a hundred million cycles of stress; and it behaves with respect to fatigue like other ferrous metals. D. J. McAdam made corrosion-fatigue and fatigue tests of stainless steel, as well as some static, mechanical tests. The endurance tests were made with cycles running 1450 revs. per min.—*vide* the corrosion of iron. The corrosion was effected by fresh carbonate water, and by salt-water, river-water with about one-third the saline contents of sea-water. The results were:

Chromium	11·54	12·20	13·35	15·09	per cent.
Nickel	0·08	0·18	0·08	0·15	,,
Silicon	0·09	0·23	0·22	0·10	,,
Carbon	0·33	0·08	0·13	0·09	,,
Copper.	0·84	0·13	0·45	0·01	,,
Tensile strength . . .	97,600	61,500	91,200	102,700	lbs. per sq. in.
Elongation	27·7	41·0	25·3	27·7	per cent. in 2 ins.
Reduction of area . . .	59·5	67·5	63·5	59·0	,,
Fatigue	52,000	39,000	59,000	—	lbs. per sq. in.
Corrosion-fatigue Fresh . .	35,000	30,000	40,000	33,000	,, ,,
Corrosion-fatigue Salt . .	—	—	13,000	—	,, ,,

J. H. S. Dickenson showed that at temp. exceeding 500°, ordinary steels and alloy steels of various types stretch by plastic flow, and finally break with much smaller loads than the values for the tensile strength obtained at the same temp. Hence, a steel with, say, a tensile strength of 20 tons per sq. in. at 650°, would stretch continuously and finally break at a far less load if given sufficient time. For a 0·30 per cent. carbon steel, and a 0·26 C, 14·68 Cr steel, he found that the maximum stress in tons per sq. in., and the percentage reduction of area, at different temp., are as follow:

		14°	100°	400°	500°	600°	700°	800°	1000°
Tenacity	0·3 C .	43·2	40·4	40·8	27·6	20·8	12·6	7·2	4·0
	14·68 Cr .	54·0	49·9	44·4	38·0	27·6	17·4	8·8	6·1
Reduction	0·3 C .	64·8	59·2	67·8	79·4	86·1	92·8	99·0	99·8
	14·68 Cr .	57·0	54·6	52·2	64·4	70·7	84·1	91·4	91·4

The periods required for the same materials to break down at different temp. while under a load of 8·5 tons per sq. in:, were:

	500°–550°	550°–600°	600°–650°	700°	775°
0·3 C . . .	3400 hrs.	956 hrs.	28 hrs.	3 mins.	6 secs.
14·68 Cr . . .	10,000 hrs.	1728 hrs.	79 hrs.	3 mins.	6 secs.

W. H. Hatfield also made some observations on this subject. With ordinary carbon steels, there is a range of brittleness, called *blue brittleness*—*vide supra*, tensile strength—roughly between 300° and 500°. It is indicated by means of the notched-bar impact test. F. Robin observed that variations in the resistance of pearlitic chromium steels to crushing are similar to those of martensitic steels generally (*q.v.*). The resistance increases rapidly in liquid air, and it diminishes thereafter at rising temp., but not uniformly. Above 500°, the resistance diminishes more rapidly, and attains a high value at 1100°. The high-speed tool steels—*vide infra*—are the only steels at these temp. which show an even higher resistance. According to J. H. G. Monypenny, various nickel alloy steels show a maximum brittleness about 600°, and a minimum about 700°; beyond that temp., the bars bend but do not break. The chromium steels have fairly uniform impact values with rise of temp., and show no range of blue brittleness. The effect of the initial temp. on the physical properties of the alloy was discussed by J. H. Andrew and co-workers, and C. L. Clark and A. E. White; and the effect of annealing, by C. B. Callomon—*vide* the physical properties of iron.

According to J. H. G. Monypenny, stainless steel is rather more difficult to cold-work than is the case with ordinary steel; but it can be drawn into wire, rolled into sheets or strips, made into weldless drawn tubes, and pressed or stamped into various shapes. All this, however, provided the steel be more frequently softened between the successive stages of the mechanical working. Thus, the maximum stress in tons per sq. in., M.S.; and the reverse binding test, R.B., were found, for the hard-drawing of steel with 0·07 C, and 11·7 Cr, to be:

Diameter.		0·111	0·0804	0·0706	0·0568	0·0465
As drawn	M.S.	68	78	89	114	103
	R.B.	5	5	5	4	13
Tempered 500°	M.S.	59·5	64·5	61	67	61
	R.B.	6	7·5	9	11·5	22
Tempered 600°	M.S.	46	50	49	50·5	46
	R.B.	8	16·5	18	20	30
Tempered 700°	M.S.	36	39·5	38	40·5	39
	R.B.	9	15	18	27	11

S. H. Rees obtained the results given in Table LXXI, with stainless iron with 0·12 C and 12·0 Cr, and stainless steel with 0·40 C and 13·0 Cr. The indicated temp. refer to the temp. of annealing for one hour. The annealing of the iron at 300°–375°, and of the steel at 375°–450°, results in a marked improvement in the elastic properties of the cold-drawn rods. R. A. Hadfield observed that at −182°, the results are normal.

TABLE LXXI.—EFFECT OF ANNEALING ON THE PROPERTIES OF COLD-DRAWN RODS OF CHROMIUM IRON, AND CHROMIUM STEEL.

Treatment		Tensile				Compression		
		Elastic limit (tons per sq. in.)	Yield-point (tons per sq. in.)	Max. load (tons per sq. in.)	Elongation (per cent.)	Reduction of area (per cent.)	Elastic limit (tons per sq. in.)	Yield-point (tons per sq. in.)
Iron	Cold-drawn	7	32·0	37·2	28·5	70	9	28·0
	100°	8	32·0	37·2	28·0	70	9	28·0

	100°	10	39·0	50·8	21·0	52	10	34·0
	200°	17	40·0	51·2	19·0	50	17	36·0
	300°	24	43·0	50·8	20·0	52	22	37·0
	375°	29	40·0	50·4	21·0	52	26	35·5
	450°	28	39·0	50·4	22·0	53	25	35·0
	550°	26	35·0	49·2	22·0	55	26	33·5
	650°	24	32·0	38·4	25·0	57	23	32·5
	780°	24	31·0	47·6	26·0	57	25	31·5

The mechanical properties of stainless steel were discussed by E. Piwowarsky, P. Oberhoffer and E. Piwowarsky, R. S. Poister, T. L. Robinson, T. Matushita, J. Galibourg, A. Abraham, C. E. MacQuigg, and H. J. French; the effect of silicon on the mechanical properties of stainless steel were discussed by E. Kothny, H. H. Abram, and J. H. G. Monypenny; of nickel, by J. H. G. Monypenny, and B. Strauss and E. Maurer; of manganese, by L. Guillet, and J. H. G. Monypenny; of copper, by J. H. G. Monypenny, and L. Grenet; and of vanadium, by F. Rogers.

K. Ruf measured the thermal expansion of iron-chromium alloys between 0° and 250°. An anomalous expansion with iron occurs between 950° and 870°; with a 6 per cent. chromium alloy, between 830° and 770°; and with a 12 per cent. chromium alloy, between 845° and 810°; whilst no anomaly occurs with alloys having over 13 per cent. chromium. F. Stäblein found that the mean coeff. of thermal expansion decreases with an increase of chromium. J. A. N. Friend and R. H. Vallance found three samples of stainless steel had coeff. of thermal expansion between $0{\cdot}0_4110$ and $0{\cdot}0_4117$ at temp. between 10° and 100°. Observations were made by A. M. Portevin and P. Chévenard, H. Jüngbluth, P. Hidnert, P. Hidnert and W. T. Sweeney, J. B. Austin and R. H. H. Pierce, and H. J. French. W. H. Souder and P. Hidnert found the coeff. of thermal expansion of chromium steel—with C, 0·30 per cent.; Si, 0·11; Mn, 0·18; and Cr, 13·1—on hardened samples, and samples tempered at 760°. The average values respectively for hardened and tempered steels are $0{\cdot}0_599$ and $0{\cdot}0_4103$ between 20° and 100°; $0{\cdot}0_598$ and $0{\cdot}0_4107$ between 20° and 200°; $0{\cdot}0_599$ and $0{\cdot}0_4122$ between 200° and 400°; $0{\cdot}0_4138$ and $0{\cdot}0_4133$ between 400° and 600°; $0{\cdot}0_4134$ and $0{\cdot}0_4136$ between 600° and 800°; and $0{\cdot}0_4122$ and $0{\cdot}0_4121$ between 20° and 600°. B. Kjerrman, T. Matushita, and P. G. McVetty and N. L. Mochel made some observations on this subject. F. Stäblein found that the presence of chromium rapidly reduces the heat conductivity of iron, and alloys with 5 to 13 per cent. of chromium have only half the heat conductivity of iron. T. Matushita found the heat conductivity, k_1, of samples slowly cooled from 900°, and, k_2, of samples rapidly cooled from 1100°, to be:

Cr	0	0·5	2·0	5·0	10·0	13	20 per cent.
k_1	0·100	0·099	0·095	0·073	0·052	—	0·043
k_2	0·098	0·089	0·087	0·044	—	0·033	0·043

W. H. Hatfield found the thermal conductivity of stainless steel to be less than that of ordinary mild steel; the value for stainless or chromium steel is k=0·0363 to 0·0466 cal. per cm. per sec. per degree, when the value for iron is 0·1450, and for mild steel 0·1436 at 18°, and 0·1420 at 100°. The rate of heating of chromium or stainless steel is nearly the same as that of ordinary steel, so that if the rate of heating depends on the diffusivity, where the diffusivity=k/sD where s denotes the sp. ht., and D the sp. gr.—the conductivity k must increase with temp., or the product sD must decrease with temp. sufficient to satisfy observations. W. Brown found that the presence of chromium has little influence on the sp. ht., for with the percentage proportions of C and Cr—0·90 : 2·00, the sp. ht. was 0·1202; with 0·43 : 3·25, 0·1169; and with 1·09 : 9·50, 0·1206. F. Wüst and co-workers represented the mean sp. ht. by 0·10233+0·00003347θ, and the true sp. ht. at θ° by 0·10233 +0·00006694θ for temp. between 0° and 1500°. W. H. Hatfield gave 0·115 to 0·121 for the sp. ht. of chromium or stainless steel at ordinary temp. F. Osmond found that 44 per cent. ferrochromium ran a little at the point of contact with an iron area at 1355°, but the fusion was quite local, the sample melted at about 1430°; 66 per cent. ferrochromium liquated at 1440° into a fusible and a refractory part which did not melt at 1475°; while 90 per cent. ferrochromium did not melt at 1485°. The f.p. curve is indicated in Figs. 445 and 446. A. Ludgren noticed that there is a particularly strong evolution of heat during the annealing of hardened chromium steel, when the steel had previously been converted into austenite by quenching from a high temp.; if the structure is martensitic, no development of heat is perceptible because the breaking up of the martensitic structure proceeds so slowly. W. W. Coblentz and R. Stair measured the reflecting power of stainless steel; and H. Pincass, the spectrum of the Fe-Cr catalyst.

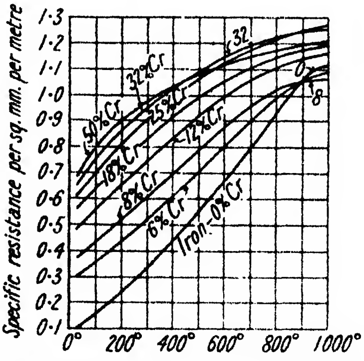

FIG. 448.—The Specific Resistance of Fe-Cr Alloys.

K. Ruf's values for the sp. resistance in ohms per sq. mm. per metre are shown in Fig. 448. J. Hopkinson found that the electrical resistance is lowered by annealing. The following values were obtained for the sp. resistance:

C	Cr	Hard-drawn	Annealed	Hardened in water
0·16 per cent.	0·29 per cent.	$0{\cdot}0_4 2234$	$0{\cdot}0_4 1917$	$0{\cdot}0_4 1903$
0·27 ,,	1·18 ,,	$0{\cdot}0_4 3351$	$0{\cdot}0_4 3305$	$0{\cdot}0_4 5706$
0·77 ,,	5·19 ,,	$0{\cdot}0_4 2012$	$0{\cdot}0_4 2234$	$0{\cdot}0_4 4062$
0·71 ,,	9·18 ,,	$0{\cdot}0_4 2315$	$0{\cdot}0_4 2401$	$0{\cdot}0_4 2843$

F. Stäblein found the sp. resistance of the iron-chromium alloys increases linearly up to 2 per cent. chromium, and then increases less rapidly. A. M. Portevin gave 5·4 microhms per cm. cube for the increase in the resistance of iron produced by 1 per cent. of chromium ; and he found that, at 15° to 20°, for samples with about 0·2 per cent. of carbon, the electrical resistance *R* microhms per cm. cube for chromium steel before and after hardening by quenching from 980° in water :

Cr . .	1·20	4·50	10·14	14·52	22·06	31·75
R Before .	16·3	33·2	49·7	62·9	56·0	63·7
R After .	18·0	35·0	50·8	69·7	57·7	66·3

Similarly with steels containing about 0·8 per cent. of carbon :

Cr . .	0·62	2·14	7·28	13·94	26·54	40·03
R Before .	23·1	27·8	39·6	65·4	67·1	71·5
R After .	43·5	54·0	62·2	72·5	68·4	73·5

C. Benedicks' formula was found to be applicable for steels with up to 2·67 per cent. of chromium. T. Spooner, F. K. Fischer, O. Boudouard, M. A. Hunter and A. Jones, T. Murakami, H. A. Dickie, W. F. Barrett and co-workers, and T. F. Russell made observations on this subject. C. A. Edwards and A. L. Norbury observed that there is a gradual increase in resistance by quenching from gradually increasing temp. above the Ac_1-point, and this increase takes place in the range over which the carbide of the pearlite gradually dissolves. The fully tempered stainless steel has a resistance of about 0·000050 to 0·000055 ohm per cm. cube, and this increases to about 0·00007 ohm when the steel is quenched from temp. high enough to dissolve all the carbide. C. Benedicks and R. Sundberg found unquenched specimens of stainless steel having practically the same resistance as hardened specimens when the carbon is low, this is taken to show that the chromium is in solid soln. ; on raising the proportion of carbon, the resistance is much lowered. If δR, microhms per cm. cube, denotes the differences observed between the quenched and unquenched samples, and $\delta R'$ the increase which would occur with the carbon going into soln., the higher values for δR indicate that much of the chromium is precipitated with the carbon in the slowly cooled samples :

Carbon . . .	0·07	0·20	0·28	0·34	0·45	0·47 per cent.
δR	3·0	11·8	16·0	12·6	17·4	16·2
$\delta R'$	1·9	5·4	7·5	9·1	12·1	12·6

F. K. Fischer found that the electrical resistance ranges from 43 to 53 microhms per cm. cube, and the value varies at the rate of 0·60 microhm for each per cent. of chromium added. G. Tammann and V. Caglioti discussed the recovery of the resistance after cold-work. A. Kussmann and B. Scharnoff observed no relation between coercive force and hardness.

G. Tammann said that assuming a chromium atom on the surface can render an adjacent iron atom passive to dil. acids, the (101)-face should become passive with 0·25th of a mol. of chromium, and the (100)- and (111)-faces, passive with ⅜th mol. Actually passivation occurs with 0·16 to 0·28 mol. of chromium : this is less than the predicted amount. Hence, other factors— *e.g.* the nature of the solvent— are involved. C. Benedicks and R. Sundberg found that the electrode potential, *E*, of unquenched steel—with 0·04 to 0·08 per cent. of carbon— in neutral $0{\cdot}82N\text{-}FeSO_4$, free from oxygen, rises from $E=-0{\cdot}711$ to $-0{\cdot}744$ volt when 8 per cent. of chromium is added, and the potential is sensibly baser than that of iron or carbon steel ; the addition of more chromium lowers the value of *E*, to a minimum with 13 to 14 per cent. of chromium, and with more chromium, *E* rises again. With chromium constant at 13 per cent., E is much lowered when the proportion of carbon is raised. With quenched specimens, E rises with increasing chromium, but with chromium constant at 13 per cent., E is reduced to $-0{\cdot}55$ volt on increasing the proportion of carbon. If the neutral soln. of $0{\cdot}82N$-$FeSO_4$ be partially oxidized by the addition of hydrogen dioxide, the electrode potential, E, is remarkably constant at 0·31 volt, and this is not affected by carbon or chromium over 8 per cent.; in quenched specimens with 0·04 to 0·08 per cent. of carbon, E' is reduced to $-0{\cdot}64$ volt with 8·05 per cent. of chromium, and to 0·31 for higher proportions of chromium. Quenched specimens with 13 per cent. of chromium have E' between 0·275 and 0·308 volt. The electrical resistance, sp. vol., and the electrode potentials, all indicate an abrupt change near 13 per cent. of chromium. This is thought to be due to the gradual fading out of the γ-region with the higher proportions of chromium, as indicated by E. C. Bain. According to C. Benedicks and R. Sundberg, a stainless steel with 0·10 per cent. of carbon and 13 per cent. of chromium, when immersed in N-KCl, assumes temporarily a higher or active potential, and a visible rusting occurs. A photoelectric cell was constructed by using two strips of stainless steel immersed in a soln. of ferrous sulphate. This cell is sensitive to light. The light causes an increase in the electrode potential rendering the steel slightly baser. G. Tammann and E. Sotter found that the electrode potential of iron-chromium alloys in $0{\cdot}1N$-H_2SO_4 is strongly positive to chromium with cathodic polarization, and only slightly so with anodic polarization. The end anodic potential is attained in accord with the exponential law, but with cathodic polarization the case is more complex, there being apparently three distinct periods. Polishing with emery, and heating at 400° decrease the electropositiveness of the alloys. The presence or absence of air bubbling through the soln. affects the potential but little, but the presence of a reducing agent, such as pyrogallol, phosphorus, or quinol, reduces the electropositiveness of cathodically polarized iron-chromium alloys to a remarkable extent. E. Newbery, and O. Meyer and K. Roesch also studied the potential of chromium steels, and their tendency to rust. According to B. Strauss, the potential of iron-chromium alloys in N-$FeSO_4$ soln. against a $0{\cdot}1N$-calomel electrode, ranges from $-0{\cdot}6$ volt to $+0{\cdot}2$ volt. The former value is the same as that of mild steel, and with low-carbon steels, the negative potential was found with less than 12 per cent. of chromium; both values with between 13 and 15 per cent. of chromium; and the positive potential with over 16 per cent. of chromium. With 0·8 per cent. of carbon, both values were given with steels having 13 to 15 per cent. of chromium, and a negative potential when more carbon was present. Steels with 20 per cent. of chromium gave a positive potential with up to 2 per cent. of carbon, and a negative potential with more carbon. E. Newbery, H. Stäger and H. Zschokke, R. Borchers, M. de K. Thompson and R. B. Morrissey, T. P. Hoar and U. R. Evans, and L. C. Bannister and U. R. Evans studied the electrode potentials of these alloys.

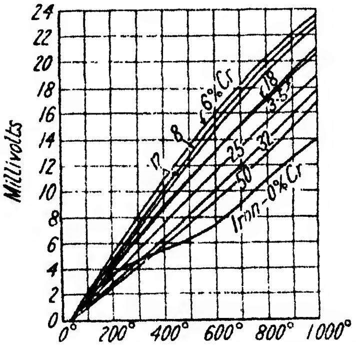

FIG. 449.—The Thermoelectric Force of Fe-Cr Alloys.

K. Ruf's values for the thermoelectric force of the alloys against platinum are indicated in Fig. 449. Observations were also made by M. A. Hunter and A. Jones, and P. Nicolau. T. S. Fuller found the thermoelectric force, E millivolts, against copper between 0° and 100° for alloys of iron and

Chromium .	10	18	20	23·5	29·5 per cent.
E . . .	1·20	1·04	0·43	8·32	0·31

E. L. Dupuy and A. M. Portevin measured the thermoelectric force of chromium steels against copper over a range of temp. from −80° to 100°. The results, expressed in millivolts, are indicated in Table LXXII. The blanks mean that the samples cracked.

TABLE LXXII.—THERMOELECTRIC FORCE OF CHROMIUM STEEL AGAINST COPPER.

Per cent.		Untreated		Annealed at 100°		Hardened by quenching from 1000°	
C	Cr	−80°	100°	−80°	100	−80°	100°
0·06	1·20	17·1	16·6	17·53	16·93	6·70	16·4
0·08	1·89	15·2	16·6	15·43	16·65	14·50	15·20
0·28	2·66	14·70	17·10	16·94	18·11	14·60	21·50
0·07	7·84	8·50	12·70	9·75	14·92	9·80	13·50

0·52	9·85	2·78	3·63	11·48	14·48	4·98	3·58
0·96	11·52	9·41	11·90	10·40	13·60	6·90	9·70
0·90	18·65	0·81	1·55	4·99	7·95	3·25	4·64
0·82	26·54	2·90	5·37	3·30	5·91	2·00	4·64
0·92	32·46	4·87	6·28	6·84	6·30	4·32	5·55

W. Treitschke and G. Tammann observed that all the iron alloys with up to 80 per cent. chromium are magnetic. J. Hopkinson found that ferrochromium with 8 to 28 per cent. chromium is strongly magnetic; with 44 per cent. chromium, it is feebly magnetic but is strongly magnetic when in the form of powder; and 66 per cent. ferrochromium is feebly magnetic. In general, the magnetism of ferrochromium alloys decreases with increasing chromium and carbon. J. Hopkinson obtained the results for the magnetic induction, *B*, per sq. cm., with different values for the magnetizing force, *H*, from which the following is a selection, for steel with 0·71 per cent. of carbon and 9·18 per cent. chromium:

Before heating	*H*	0·018	0·075	0·30	1·02	4·04	11·86	22·78	33·24
	B	0·75	1·53	6·2	23·4	93·1	286	603	978
After heating to 850°	*H*	0·17	0·07	0·38	1·16	4·05	11·72	22·7	31·67
	B	1·5	5·0	20·2	86·0	323	1070	7580	11,553

The induction, *B*, per sq. cm., for the same steel after heating to the temp. indicated:

H, 1·02		395°	558°	640°	701°	773°	839°	860°
	B	31	41	98	161	201	331	0
H, 4·04		416°	645°	717°	789°	823°	841°	860°
	B	113	416	603	1022	1462	1863	0
H, 11·9		438°	584°	661°	735°	807°	829°	860°
	B	340	661	2226	5489	6424	4943	0
H, 27·06		456°	616°	677°	746°	813°	834°	860°
	B	832	2891	7796	8728	7112	5375	0

R. Abt, H. A. Dickie, R. L. Dowdell, F. K. Fischer, E. Gumlich, W. S. Messkin and E. S. Tovpenjez, P. Oberhoffer and O. Emicke, J. H. Partridge, J. Safranek, S. Saito, E. H. Schulz and W. Jenge, H. Scott, T. Spooner, J. Würschmidt, E. A. Watson, C. E. Webb, and L. W. Wild measured the magnetic properties; and A. Kussmann and B. Scharnoff, E. Gerold, H. Scott, and S. Curie measured the coercive force, magnetic moments, and remanence of chromium steels. F. Stäblein found the coercive force of chromium-iron alloys rises to an ill-defined maximum with 10 per cent. of chromium, and then falls to a minimum with 17 per cent. of chromium. W. Brown found for the magnetic moment M per gram, and the percentage loss by percussion :

Cr . .	1·75	1·96	2·11	3·50	5·79	9·22 per cent.
M . .	38·2	50·4	52·5	41·7	38·7	42·2
Loss . .	1·9	0·5	2·2	7·9	7·0	1·3 per cent.

F. K. Fischer found that the magnetic properties of the alloys with 10 to 20 per cent. of chromium vary with the proportion of chromium and with the heat-treatment. Annealing produces the best magnetic results. The best magnetic results were obtained with alloys ranging from 17·5 to 18·7 per cent. of chromium—in the region of zero magnetostriction. The effect of quenching on the magnetic properties is to reduce the flux density by a large amount and to make practically permanent magnetic material out of the ring samples except those in the neighbourhood of zero magnetostriction. Baking the alloys at 500° after annealing was harmful to the properties as it reduced the permeability. The magnetic critical point varies from about 675° to 750°, the average being about 700°. The best alloy obtained was one of 18·7 per cent. chromium. When annealed, this alloy has a maximum permeability of about 2000 at approximately 6000 gausses. Its hysteresis loss for B_m=5000 is 1770 ergs per c.c. per cycle, or it has about the permeability and 4 times the hysteresis loss of Armco iron.

A. W. Smith and co-workers found the minimum reluctance—*i.e.* the reciprocal of the maximum permeability—occurs when the proportion of carbon approaches 0·8 per cent., and a maximum with about 0·5 per cent. R. L. Sanford and W. L. Cheney found that the maximum induction of oil-quenched chromium steel is 11,200, and the coercive force 53·5. G. Mars investigated the use of chromium steel in permanent magnets. His results are indicated in Table LXXIV.

TABLE LXXIII.—THE HARDNESS AND MAGNETIZATION OF CHROMIUM STEELS.

Composition				Hardening temp.	Brinell's hardness	Magnetization		
C	Si	Mn	Cr			Just after magnetization	After 8 days	Percentage loss
1·01	0·20	0·25	1·21	720	713	86	83·5	2·9
0·82	0·19	0·18	1·40	750	652	94	90	4·3

TABLE LXXIV.—MAGNETIC PROPERTIES OF CHROMIUM STEELS.

Cr (per cent.)	Residual magnetism	Intrinsic residual magnetism	Coercive force	Residual magnetism after percussion	Residual magnetism after heating and cooling	Percentage loss magnetism by percussion	Percentage loss magnetism by heating and cooling
1·0	660	295	28	275	245	6·8	9·5
4·05	600	374	39	354	334	5·3	5·3
8·0	580	385	46	371	364	3·6	1·9
12·0	435	332	54	328	322	1·2	1·8
16·0	340	286	56	284	278	0·7	2·1
20·0	320	252	44	239	235	5·2	1·5

The magnetic properties resemble those of high-carbon steels, and stainless steel when suitably hardened makes a good permanent magnet, which is not so good as the 6 per cent. tungsten steel commonly employed. M. B. Moir obtained hysteresis curves of annealed and quenched chromium steels, at 15° and at —190°, and found the value with the annealed alloy to be too small to be worth investigating for permanent magnetism, but the quenched specimens, while not ideal, make useful magnets, with the properties indicated in Table LXXIII.

L. Jordan and F. E. Swindells discussed the decarburization of ferrochromium by heating it in **hydrogen**; and E. Martin, the absorption of hydrogen and nitrogen by chromium steels. The commercial importance of the chromium steels as *rustless steels*, *non-corrosive steels*, or *stainless steels* was developed by H. Brearley, although the resistance of these steels to corrosion had been previously noted by B. Strauss and E. Maurer, and E. Haynes, and a mixture for a resistant chromium steel patented by the Firma Krupp for use as cutlery, propeller blades, etc. Indeed, over a century ago P. Berthier drew attention to the fact that chromium-iron alloys are less corrodible than iron itself, and analogous observations have been made by M. Faraday and J. Stodart. The subject was discussed by P. R. Kuehnrich. E. A. and L. T. Richardson also noted that chromium enhances the effect of copper in resisting corrosive influences.

The corrosion-resisting alloys were discussed by H. H. Abram, W. Ackermann, L. Aitchison, R. J. Anderson and G. M. Enos, P. A. E. Armstrong, J. A. Aupperle, E. C. Bain, M. Ballay, C. B. Bellis, C. Benedicks and R. Sundberg, J. S. de Benneville, H. N. Booker, P. Bres, A. Brunner, W. S. Calcott, C. W. Carnell, H. C. H. Carpenter, F. F. Chapman, P. Chevenard, T. H. Chilton and W. R. Huey, D. G. Clark, A. Christiansen, J. Clavier, J. Cournot, J. L. Cox, W. H. Creutzfeldt, K. Daeves, G. Dillner, T. W. Downes, G. A. Drysdale, R. L. Duff, V. Duffek, C. Duisberg, T. G. Elliot and co-workers, G. M. Enos, H. Esselbach, H. O. Forrest and co-workers, H. J. French, H. A. de Fries, J. Fritz and F. Bornefeld, T. S. Fuller, C. Griff, M. A. Grossmann, L. E. Gruner, W. Guertler, W. Guertler and W. Ackermann, W. Guertler and T. Liepus, L. Guillet, R. A. Hadfield and co-workers, J. F. Hardecker, W. H. Hatfield, W. H. Hatfield and H. Green, E. Haynes, J. G. Hopcraft, E. Houdremont, F. Hütte, A. C. Iebens, R. Irmann, K. K. Järvinen, C. M. Johnson, W. E. Jominy and R. S. Archer, B. Kalling, J. F. Kayser, B. Kjerman, P. Koetzschke, A. Krüger, P. R. Kuehnrich, C. Küttner, L. Losana and G. Reggiani, D. J. McAdam, J. W. McMyn and V. Edge, C. E. MacQuigg, P. G. McVetty and N. L. Mochel, A. Mangin, W. H. Marble, J. A. Mathews, C. Matignon, W. H. Melaney, P. S. Menough, C. G. Merritt, O. Meyer and K. Roesch, J. L. Miller, W. M. Mitchell, P. Monnartz, J. H. G. Monypenny, T. H. Nelson, F. Ormo, A. R. Page and J. H. Partridge, A. E. Perkins, A. Phillips and R. W. Baker, H. D. Phillips, J. Pomey and P. Voulet, V. and G. Prever, W. J. Priestley, H. S. Primrose, M. J. Prucha, H. S. Rawdon and A. I. Krynitsky, E. A. and L. T. Richardson, W. D. Richardson, H. Rieger, F. Rittershausen, K. Roesch and A. Clauberg, W. Rohn, A. Rys, B. D. Saklatwalla, M. Sauvageot and L. Lauprète, R. Schäfer, C. A. Scharschu, F. Schmitz, E. H. Schulz and W. Jengo, H. Stäger and H. Zschokke, B. Strauss, J. Strauss and J. W. Talley, R. Stumper, G. Tammann and co-workers, J. G. Thompson, N. S. Torsueff, S. Tungay, T. H. Turner, E. Valenta, J. S. Vanick and F. L. la Que, R. Waddell, B. Waeser, E. Wellman, H. Whitaker, H. Williams, T. R. Wilton, J. K. Wood, C. F. Würth, A. C. Yorke, and V. Zsak. E. C. Rollason discussed the intergranular corrosion of stainless steels.

J. F. Kayser said that most of the useful heat- and acid-resisting alloys of nickel, chromium, and iron fall within the area *abc*, Fig. 450, and the best of these within the shaded zone *def*. Alloys in the dotted region to the left are brittle; those to the right are difficult to work in the foundry, and when cast are unmachinable. The stainless irons fall in the region *gh*, and alloys falling in the region about *k* have been exploited. P. A. E. Armstrong found that the Cr-Fe-C alloys with a composition within the shaded area, Fig. 451, can be rendered immune to food acids by heating them about 300° above their upper transformation point, and cooling them rapidly. V. Duffek found the rate of corrosion to be faster, the higher the proportion of contained carbon. E. C. Bain and co-workers studied the intergranular corrosion of austenitic stainless steels; and J. Cournot and L. Halm, the effect of polish.

According to J. K. Wood, when chromium is added to steel, it forms a solid soln. with the iron, so lessening the tendency of the iron to go into soln. Sufficient chromium in an iron alloy will reduce its corrodibility to zero. All the chromium added does not, however, go to the making of the iron-chromium solid soln., but some is locked up in any carbides present, so that the higher the carbide-content the greater the amount of chromium necessary to confer immunity from corrosion. On the other hand, suitable heat-treatment will reduce the carbide-content by inducing a fine martensitic structure, and that will leave more chromium available to protect the iron. The action of chromium is to cause the eutectoid point to occur at a lower percentage of carbon; thus, with no chromium, the eutectoid carries 0·85 per cent. carbon; but with 4 per cent. chromium, the eutectoid carries only 0·56 per cent. carbon; and with 12 per cent. chromium, it carries only 0·31 per cent. carbon. Consequently, much less carbon is needed to produce the various structural changes in steel when chromium is present.

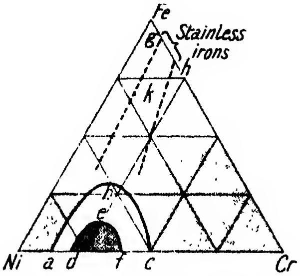

FIG. 450.—The Acid and Heat Resistance of the Ternary Alloys: Fe-Cr-Ni.

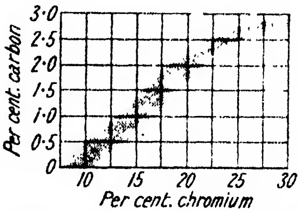

FIG. 451.—The Acid Resistance of the Fe-Cr-C Alloys.

The passivity of the iron-chromium alloys was studied by L. C. Bannister and U. R. Evans, C. Benedicks and R. Sundberg, R. Borchers, W. Guertler, J. Heibling, J. Hinnüber, E. Liebreich, E. Liebreich and W. Wiederholt, O. Meyer and K. Roesch, P. Monnartz, J. H. G. Monypenny, W. J. Müller, W. J. Müller and E. Noack, W. Oertel, H. Stäger and H. Zschokke, B. Strauss, B. Strauss and J. Hinnüber, B. Strauss and E. Maurer, J. Strauss, G. Tammann, and G. Tammann and E. Sotter.

According to J. H. G. Monypenny, a polished sample of stainless or about 12 per cent. chromium steel, when heated in **air**, assumes a series of temper colours similar to those of ordinary steel, but at a considerably higher temp.; a grey film appears on a polished surface at 750°–825°, but this interferes very little with the polish; above 825°, the steel begins to scale appreciably, but it is more resistant than nickel or vanadium steel. Increasing the chromium to 20 per cent. makes the alloy still more resistant to surface oxidation at high temp., and this is still more the case with 30 per cent. chromium. L. B. Pfeil observed that a three-layer scale—*vide supra*—is formed on stainless steel when it is heated for some hours in air; and that the inner layer contains 3·5 times as much chromium, as oxide, as the original steel, whilst the two outer layers contain only a fraction of that amount of chromium. P. Oberhoffer and K. Daeves observed that polished surfaces of steels with 0·3 to 0·5 per cent. carbon, and 15 to 20 per cent. chromium, preserved their polish when kept 18 hrs. at 800° in an oxidizing atmosphere. B. Strauss and E. Maurer also made observations on the resistance of high chromium steels to rusting. For the observations of H. O. Forrest and co-workers, *vide* corrosion. Y. Utida and M. Saito found that the gain in weight in grams per sq. cm. when samples are heated for an hour at 1100°; and the loss in weight in grams per sq. cm. when samples are immersed in 10 per cent. soln. of the acids for 24 hrs., were, for steels with 0·06 to 0·11 per cent. carbon, and

Chromium .	0	0·97	4·86	8·33	13·55	27·85	35·88 per cent.
At 1100° .	0·0212	0·0455	0·0510	0·0498	0·0407	0·0017	0·0004
HNO_3 .	0·9380	0·6240	0·5400	0·0181	0·0002	0·0000	0·0000
HCl . .	0·0712	0·2465	—	0·2801	0·3055	0·6158	0·7160
H_2SO_4 .	0·0990	0·1002	0·1110	0·2166	0·1248	0·0710	0·0132

H. Endo's results for 5 hrs.' action at ordinary temp. on steels with 0·28 to 0·35 per cent. of carbon, and the indicated proportions of chromium, are summarized in Fig. 452. J. A. N. Friend and co-workers noted that the resistance of chromium steels to corrosion by **sea-water** is better the higher the proportion of chromium—up to 5·3 per cent. Cr. The subject was discussed by J. Strauss and J. W. Talley, D. J. McAdam, H. H. Abram, W. Guertler and T. Liepus, P. S. Menough, L. Aitchison, W. Rohn, T. McKnight, W. B. Arness and J. N. Ostrofsky, and W. M. Mitchell. T. S. Fuller studied the action of steam on the endurance tests. F. M. Becket patented the use of high chromium alloys for resisting high temp., and the subject was discussed by C. E. MacQuigg. J. H. G. Monypenny found that the 12–13 per cent. chromium steel is corroded in towns, and particularly in the neighbourhood of factories, where the air contains distinct amounts of acid, and large amounts of dust, so that the metal becomes coated with dust which may adhere tenaciously. When the dust is removed, the polished surface may be marred by minute pitting, though the actual corrosion is exceedingly small, and out of all proportion with the rusting of ordinary steel. In the cleaner atm. of the country, or indoors, the metal retains its polish for long periods. W. G. Whitman and R. P. Russell studied the effect of oxygen dissolved in water on chromium steel. L. Gruner stated that the presence of chromium favours the corrosion of iron by humid air, sea-water, and acidulated water; but there is something amiss with this observation. P. Monnartz observed that steels with a high proportion of chromium—say, over 40 per cent.—resisted two years' exposure to a laboratory atmosphere without losing their bright lustre; and they also resisted **river-water** and sea-water—but alloys with less chromium are not so resistant. J. A. N. Friend and co-workers observed that if the corrosion factor for steel with 0·29 per cent. carbon and 0·39 per cent. manganese is 100, the values for alloys with 1·12, 3·58, and 5·30 per cent. of chromium are respectively 85, 58, and 43 for tap-water; 60, 26, and 23 for sea-water; and 93, 30, and 21 for steels subjected to alternate wet and dry conditions. J. H. G. Monypenny found that ordinary **tap-water** has no perceptible action during the exposure of either hardened or tempered steel; river-water, and well-water have usually no action; and sea-water is without action if the metal is wholly immersed, or alternately wet and dry; but under the prolonged action of spray, some pitting may be produced. J. A. N. Friend observed that 11·73 to 13·40 per cent. chromium steels resisted atm. corrosion almost perfectly; and they also resisted sea-water very well, although there were some severe localized pits developed by exposure to sea-water. J. H. G. Monypenny found that stainless steel resists the action of superheated steam remarkably well, even when the steel steam fittings are in contact with ordinary nickel or copper alloys used for the fittings. According to O. Meyer and K. Reesch, the rusting of 13 per cent. chromium steels commences whenever the potential falls below $E_H = -0{\cdot}015$ to $-0{\cdot}010$ volt. In acidic soln., the potential of chromium steels becomes more positive and the rate of corrosion decreases with an increase in the quenching temp. The higher the carbon-content of the steel the higher is the temp. from which the steel must be quenched in order to prevent rusting, as the more nearly the structure approaches a single solid soln. the greater is the chemical resistance; in this sense, therefore, carbon must be considered as an objectionable impurity in rust-resisting steels.

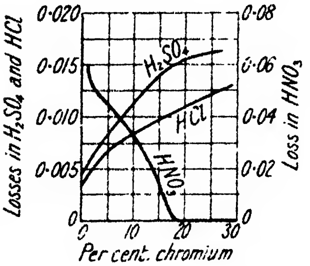

FIG. 452.—The Corrosion of Chromium Steels by Acids.

Soln. of **ammonia, alkali hydroxides,** or **alkali carbonates** have no perceptible action; and no attack occurs in damp atmosphere charged with gaseous ammonia. A. Krüger said that although chrome steels are attacked by hot, dil. acid soln., they resist boiling alkalies. The material also resists hydrogen dioxide, and soln. of sodium sulphide. According to J. H. G. Monypenny, 5 per cent. soln. of the following **salts,** during 4–5 weeks' action, produced no visible corrosion on immersed samples: alkali carbonates or hydrocarbonates; alkali nitrates, or sulphites; sodium chloride*, potassium chloride*, cyanide, chlorate, or dichromate; ammonium oxalate, persulphate or phosphate; copper acetate, nitrate, or sulphate; ferric nitrate or sulphate; ferrous sulphate; lead acetate, magnesium chloride* or sulphate*; and manganese sulphate. With the salts marked with an asterisk, corrosion may occur at the points of support of the metal below the surface of the soln. L. Aitchison observed that the losses in weight per 100 sq. cm. with chromium steels exposed 77 days in darkness to a 3 per cent. soln. of sodium chloride, were:

Cr	0·99	4·97	10·15	15·01	19·46	23·70 per cent.
Loss	1·31	1·38	0·79	0·91	0·00	0·24

J. H. G. Monypenny found that 12–13 per cent. chromium steel is slightly pitted by a dil. soln.—5 grms. per litre—of **ammonium chloride** in 10 days at 80° to 90°; while a piece of mild steel was badly corroded, and lost seven times as much weight. There was also a slight attack during two months' exposure to a conc. soln.—25 grms. per litre—at ordinary temp. Soln. of **ammonium sulphate** have no perceptible action when dil., but the chromium steel is slowly attacked by conc. soln. With 5 per cent. and a sat. soln. of **potash-alum,** stainless steel lost respectively 0·012 and 0·008 mgrm. per sq. cm. per hour, under conditions where mild steel lost respectively 0·065 and 0·035 mgrm. per sq. cm. per hour; similarly also with soln. of **ammonia-alum.** Soln. of **ferric chlorine,** even when fairly dil., attack the stainless steel; similarly also with soln. of **copper chloride**; the attack with soln. of **mercuric chloride** is fairly rapid. Dil. soln. of potassium or sodium sulphate have no action, but conc. soln. attack the metal—conc. soln. of these salts have an acidic reaction.

J. H. G. Monypenny observed that **hydrochloric acid** attacks stainless steel quite readily, and in 24 hrs. the loss in mgrms. per sq. cm. per hour with *N*-HCl and 5*N*-HCl was 0·82 and 5·00 respectively under conditions where the losses with mild steel were respectively 1·84 and 6·80. P. Koetzschke found that chromium decreases the corrodibility of cast-iron in hydrochloric acid. Y. Utida and M. Saito showed that chromium increases the corrosion of iron by hydrochloric acid—*vide supra*. W. H. Hatfield obtained the results indicated in Table LXXV for the losses in weight in grams per sq. cm. after 24 hrs.' immersion at 15°.

TABLE LXXV.—ACTION OF ACID ON CHROMIUM STEELS.

Composition					Condition	Brinell's hardness	HCl	HNO_3	H_2SO_4 10 per cent.

60°	0·0812	0·4027	0·8066	0·4133	0·8787	0·0187	0·0076	,,
80°	0·1043	0·4326	0·8061	0·4592	0·7199	0·2246	0·0103	0·0005

W. Rohn observed the relative losses in weight in grams per sq. dm., with N=not annealed, and A=annealed steels, in 10 per cent. acids :

Fe : Cr		84 : 16		75 : 25		68 : 32		50 : 50	
		N	A	N	A	N	A	N	A
HNO_3	24 hrs. cold	0	0	0	0	0·006	0	0·002	0·002
	1 hr. hot	0	0·04	0·003	0·003	0	0	0·004	0·004
H_2SO_4	24 hrs. cold	9·5	7·5	11·9	9·6	13	18	45·6	—
	1 hr. hot	47	32	22	19	64·8	57·6	52·8	—
HCl	24 hrs. cold	35	6·5	12·3	6·2	18·5	17	11·5	15·8
	1 hr. hot	70	27	26	14	62·6	57·6	30·5	43·2
CH_3COOH	24 hrs. cold	0	0·03	0	0	0	0	0	0
	1 hr. hot	0·10	0·240	0	0·003	0	0	0	0
H_3PO_4	24 hrs. cold	0	0·04	0	0	0	0	0	0
	1 hr. hot	0	2·44	0	0·003	0·003	0	0·003	0·003

The presence of 0·25 per cent. carbon, or of 1 per cent. of manganese, or 1 per cent. of silicon increased the corrosion—*vide infra*, sulphuric acid. H. Gruber observed that plates 60×13×12 mm. of 25 per cent. chromium alloy gained in weight on on an hour's exposure to hydrogen sulphide :

	700°	800°	900°	1000°
Gain in weight	0·58	3·2	8·0	13·2

L. Vernitz and A. Kudinova found that the alloy resists the action of dry **sulphur chlorides**—S_2Cl_2, and SCl_2. J. H. G. Monypenny found that stainless steel is attacked by **sulphurous acid** owing partly to the sulphuric acid always present in commercial sulphurous acid. M. Faraday and J. Stodart, L. Gruner, and P. Berthier noticed that, in general, iron-chromium alloys are less readily attacked by acids than iron, and the attack is less the higher the proportion of contained chromium ; and similar observations were made by G. W. Heise and A. Clemente, E. Frémy, J. Fritz, and J. B. J. D. Boussingault. P. S. Menough, and Y. Utida and M. Saito observed that chromium lessens the attack by sulphuric acid. R. A. Hadfield exposed samples of chromium steel to 50 per cent. **sulphuric acid** for 21 days, and found the following percentage losses :

					Mild steel	Wrought iron
C	0·27	0·77	0·71 per cent.			
Cr	1·18	5·19	9·18 ,,			
Loss	3·32	4·78	5·64	Loss	7·48	44·7 per cent.

For the observations of Y. Utida and M. Saito, and of W. H. Hatfield, *vide supra.* J. A. N. Friend and co-workers found that when the corrosion factor with steel containing 0·29 per cent. of carbon and 0·39 per cent. of manganese is 100, the values for steels alloyed with 0·12, 3·58, and 5·30 per cent. of chromium are respectively 71, 68, and 68 for 0·15 per cent. sulphuric acid, and 223, 61, and 78 for 0·5 per cent. acid. W. Guertler and W. Ackermann represented the loss in mgrms. per sq. cm. per hr. in sulphuric acid of sp. gr. 1·005 by the curve Fig. 453. P. Koetzschke and E. Piwowarsky found that the addition of up to 1 per cent. of chromium in grey cast iron had a marked effect on the corrosion by acids, but not by salt soln. A. Carnot and E. Goutal found that steels with a small proportion of chromium are readily attacked by cold, dil. acids, but if the chromium steels are highly carburized they are attacked more slowly than when only a small proportion of carbon is present. W. Borchers and P. Monnartz patented an acid-resisting steel with 10 per cent. of chromium and 2 to 5 per cent. molybdenum. Observations were also made by J. A. N. Friend and co-workers, who noted that up to 5·3 per cent. chromium steels resisted attack better the higher the proportion of chromium. E. Jänecke noted that hot 1 : 1 sulphuric acid attacks the iron-

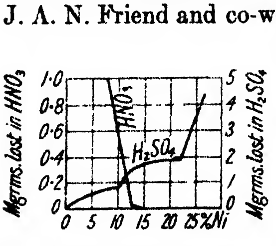

FIG. 453.—The Action of Sulphuric and Nitric Acids on Iron-Chromium Alloys.

chromium alloys. L. Aitchison found that chromium steels with about 0·85 per cent. carbon lost per 100 sq. cm. in 1 per cent. sulphuric acid for 77 days, and in 10 per cent. sulphuric acid for 45 days, in darkness:

Cr	. . . . .	0·99	4·97	10·15	15·02	19·46	23·70 per cent.
H_2SO_4	1 per cent. .	12·6	5·4	10·3	5·85	0·52	1·76
	10 per cent. .	15·9	11·0	18·3	33·6	29·0	23·7

J. H. G. Monypenny found that the loss in mgrms. per sq. cm. per hour at atm. temp. during 6 hrs.' attack with 5, 35, and 50 per cent. sulphuric acid were respectively 1·98, 15·8, and 0·50; with the 0·25 per cent. carbon and 12·1 per cent. chromium steel, and with mild steel, respectively 3·16, 11·55, and 0·23. In 24 hrs.' attack, with 50 per cent. sulphuric acid, on chromium steel and mild steel, the numbers were respectively 0·26 and 0·10. M. Sauvageot and L. Lauprète found that steels with about 13 per cent. of chromium were all practically unattacked by nitric acid of any conc. at any temp., but the nickel steel rapidly dissolved in hot, 1 to 25 per cent. nitric acid and slowly in cold acid of the same conc., although acid of a higher conc. than 30 per cent. was without action at any temp. The nickel steel was by far the most resistant to the action of hydrochloric acid, but all the samples were badly corroded by hot, 20 per cent. acid. Sulphuric acid had practically no action on the nickel steel whatever the temp. (up to 100°) or conc.: the other steels showed a maximum rate of dissolution in 40 to 45 per cent. acid. The subject was studied by J. Fritz.

Both copper and ferric sulphates occur in **mine-waters** along with sulphuric acid; with a soln. of 100 grms. of copper sulphate per litre, and a steel with 0·30 per cent. carbon and 12·6 per cent. chromium, no action occurs on the addition of sulphuric acid until 75–100 grms. of H_2SO_4 per litre is present, after that the rate of attack is determined by the conc. of the copper sulphate in soln.; if copper sulphate is gradually added to a dil. soln. of sulphuric acid, say, 100 grms. H_2SO_4 per litre, the attack on the steel increases rapidly. Flocculent copper is deposited on the steel and appears to set up electrochemical action. When nearly 20 grms. per litre have been added the attack falls off rapidly and soon ceases altogether. The amount of copper sulphate required to stop the reaction is relatively less, the smaller the concentration of the acid. The steel thus acquires a kind of passivity. W. H. Hatfield found that the amount of ferric sulphate required to prevent the attack of sulphuric acid is proportional to the conc. of the sulphuric acid. With hardened and tempered steel, no attack occurred if the conc. of the ferric sulphate is twice that of the free acid, while with hardened steel the same effect was produced when the conc. of the ferric sulphate is one-fifth that of the free acid. J. H. G. Monypenny made observations on this subject; and he also found mine-waters with copper 14·7 to 16 parts per 100,000; ferric iron, 71·2 to 188; ferrous iron, 160; free sulphuric acid, 14 to 30, did not act on stainless steel, though it rapidly attacked ordinary mild steel.

F. Adcock found that solid or molten alloys of iron and chromium take up **nitrogen,** and in quantities which increase with the proportion of chromium. Alloys with near 12 per cent. of chromium, in contact with nitrogen, acquire the martensitic structure closely resembling that with the iron-carbon alloys. The Brinell's hardness can be considerably modified by heat-treatment, and ranges from about 115 in the annealed state to 315 when quenched above the critical range. Most of the alloys containing nitrogen in the range 20 to 60 per cent. chromium, present a two-phase structure except in some cases where the material has been quenched at a temp. immediately below the m.p. Although one of these constituents invariably develops a structure of the sorbitic or pearlitic type on suitable heat-treatment, these changes are not accompanied by any great variation in hardness. This pearlitic or lamellar type of structure, which characterizes the alloys with 20 to 30 per cent. chromium containing nitrogen, is known to be absent from the corresponding pure iron-chromium alloys. Further, the deliberate addition of 0·05 per cent. of carbon to an alloy with approximately 28 per cent. chromium, free from nitrogen, fails to produce any signs of a lamellar structure in the furnace-cooled material, although a considerable amount of a second constituent is visible. Consequently, the presence of nitrogen in iron-chromium alloys can give rise to structures closely resembling those generally attributed to carbon in ordinary steel, and, further, that at high temp., the pure alloys of iron and chromium, whether solid or liquid, readily absorb nitrogen from the atmosphere. S. Satoh studied the nitridization of these steels by heating them in **ammonia** at 560° to 580°. E. Müller and H. Barck studied the action of **nitric oxide.**

P. Monnartz, and J. G. Thompson observed that the presence of chromium greatly increased the resistance of iron to **nitric acid ;** and with alloys containing up to 20 per cent. chromium, he concluded that the resistance of alloys with up to 4 per cent. chromium to dil. nitric acid decreases as the proportion of chromium increases, but the resistance to attack by the conc. acid is greater. The resistance of alloys with 4 to 14 per cent. chromium to dil. nitric acid increases rapidly as the amount of chromium increases; and as the proportion of chromium rises from 14 to 20 per cent., the resistance to attack by dil. acid increases slowly. W. M. Mitchell, E. S. P. Bellinger, G. Grube and W. von Fleischbein, W. R. Huey, W. H. Hatfield—*vide supra*—and Y. Utida and M. Saito observed that the introduction of chromium lessens the attack by nitric acid—*vide supra*. W. Guertler and W. Ackermann represented the loss in mgrms. per sq. cm. per hour in nitric acid of sp. gr. 1·005 by the curve Fig. 454. G. Grube and W. von Fleischbein observed that the rate of dissolution of the alloys in dil. nitric acid diminishes with increasing chromium-content; when this reaches 12·5 mol. per cent., the rate of dissolution of chromium diminishes suddenly; and when it reaches 25 mol. per cent., falls suddenly to zero; and the rate of dissolution of iron also shows a sudden drop to a low value. The iron dissolves more rapidly than the chromium relatively to its proportion in the surface layer. The protective effect of small proportions of chromium on the iron may be due to the dissolved chromic acid rendering the iron passive. The resistance of a bar is not diminished by rolling to half its initial diameter. E. Jänecke found that boiling conc. nitric acid is without action on the higher chromium alloys. J. H. G. Monypenny observed that at ordinary temp., the loss in mgrms. per sq. cm. per hour, during 5 hrs., varies with the proportion of chromium in the steel as follows:

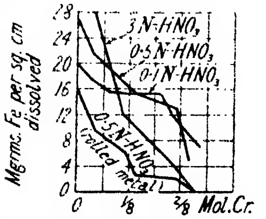

FIG. 454.—The Action of Nitric Acid on Iron-Chromium Alloys.

Carbon		0·16	0·14	0·16	0·09	0·09	0·13 per cent.
Chromium		0·00	4·72	10·0	12·0	14·0	17·5 „
Loss	N-HNO$_3$	16·2	15·65	2·1	0·35	0·03	*nil*
	HNO$_3$, sp. gr. 1·2	1·25	1·64	trace	*nil*	*nil*	*nil*

Thus, the attack by the conc. acid is greatly retarded when over 4·72 per cent. of chromium is present, and with dil. acid, when over 10 per cent. is present. At 80° to 85°, the results were:

Cr		10·6	11·1	12·2	13·3	14·4 per cent.
Loss	N-HNO$_3$	11·5	16·5	1·09	0·41	0·27
	$5N$-HNO$_3$	0·03	—	0·025	0·01	0·005

and with a steel with 12·2 per cent. chromium at 80° to 85°:

HNO$_3$	0·1N	0·2N-	0·5N-	N-	2N-	5N-
Loss	4·90	8·82	15·13	1·09	0·20	0·025

and at ordinary temp. in a 5 hrs.' and a 24 hrs'. attack the losses in mgrms. per sq. cm. per hour, were:

HNO$_3$		0·01N-	0·2N-	0·5N-	N-	2N-	2N-
Loss	5 hrs.	0·40	0·65	1·11	1·53	0·61	0·01
	24 hrs.	0·355	0·50	0·72	0·395	0·115	0·00

In general, the stainless steel with 12 to 13 per cent. chromium and 0·3 per cent. carbon is attacked by nitric acid at ordinary temp. only when the acid is very dilute—say, less than 5N-HNO_3 or 1·20 sp. gr.—and then the action is slow. By selecting a suitable steel, even this attack may be prevented. Hence, stainless steel may ultimately be useful in the manufacture and transport of nitric acid. The attack is augmented by raising the temp.; and it is decreased by raising the percentage of chromium in the alloy. As a result, a 15 per cent. alloy resists attack at ordinary temp. or at 85°. Thus the presence of chromium greatly increases the tendency of iron to become passive in nitric acid. The action of copper nitrate or ferric nitrate along with nitric acid resembles the effect of the corresponding sulphates on the attack by sulphuric acid. The presence of 8 grms. of copper as nitrate, or 5 grms. of iron as nitrate per litre, sufficed to prevent the attack of N-HNO_3 on steel with 0·3 per cent. carbon, and 12·6 per cent. chromium. W. M. Mitchell, and E. S. P. Bellinger discussed the use of stainless iron, or high chromium alloys of iron, in the construction of equipment for the manufacture and handling of nitric acid. G. Tammann tried the hypothesis that a chromium atom in the surface of iron can render an adjacent iron atom passive in dil. acids, so that the (101)-face of a crystal should become passive when 0·25 mol. proportion of chromium, and the (100)- and (111)-faces, passive with 0·375 mol. Passivation actually occurs with less, namely, 0·16 to 0·28 molecule of chromium. Hence, passivity is affected by other conditions—the nature of the solvent, previous treatment of the alloy, and the nature of the second component.

According to J. H. G. Monypenny, chromium steel is also slowly attacked by **phosphoric acid.** The losses in mgrms. per sq. cm. per hour with 5, 25, and 66·3 per cent. phosphoric acid were respectively 0·050, 0·20, and 0·47 with the chromium steel, and respectively 1·11, 2·60, and 4·62 with mild steel. The subject was studied by P. R. Kosting and C. Heins, and A. M. Portevin and A. Sanfourche. According to J. H. G. Monypenny, a soln. of 20·7 grms. of **boric acid** per litre had no action on this steel. H. R. S. Clotworthy recommended stainless steel for resisting the action of **carbon disulphide.** The action of dil. **acetic acid** or **vinegar** varies in that some vinegars contain appreciable amounts of sulphuric acid, while others are free from that acid. P. Kötzschke found that chromium decreases the corrodibility of cast iron in acetic acid. According to J. H. G. Monypenny, ordinary malt vinegar has 4 to 5 per cent. of acetic acid. The losses with 5, 15, 33 per cent. and glacial acetic acid, during 14 days, were respectively 0·014, 0·012, 0·012, and *nil* mgrm. per sq. cm. per hour, and with mild steel, respectively 0·067, 0·105, 0·115, and 0·124 mgrm. per sq. cm. per hour. Expressing the losses in mgrms. per sq. cm. per hour respectively with chromium steel and ordinary mild steel, 5 per cent. **carbolic acid,** with 14 days' exposure, had losses *nil*, and 0·005; 6 per cent. **citric acid,** in 7 days' action, had losses 0·011 and 0·260; 10 per cent. **formic acid** in 12 days' action, had losses 0·26 and 0·33; oleic acid had no action on the chromium steel during 14 days' exposure; normal **oxalic acid,** in 10 days' action, gave losses 0·021 and 0·036; 10 per cent. **tannic acid,** in 14 days' action, had losses *nil* and 0·0042; and in 14 days' action, normal **tartaric acid** had losses 0·0085 and 0·062, and 25 per cent. tartaric acid, 0·022 and 0·14. J. G. Thompson studied the action of aq. soln. of **urea** and of **ammonium carbonate.** J. H. G. Monypenny found that, in general, **fruit juices** have a similar action to that of vinegar, though their corrosive power varies. The pure acid, the same strength as the acid in fruit juice, has sometimes the greater action—*e.g.* vinegar and acetic acid, or lemon juice and citric acid. Possibly the natural fruit juice contains some colloid which acts as a retarding agent—*vide supra*, the corrosion of iron and steel. No action was observed with **lubricating oils, greases, paraffin, benzol,** or **petrol.** R. Tull discussed the resistance of the alloy to **smoke.**

General discussions on the use of chromium steels have been contributed by C. B. Bellis, E. Lievenie, T. Blair, J. Ohly, T. H. Nelson, T. H. Burnham, J. D. Corfield, W. M. Mitchell. The so-called **stainless steels** are essentially chromium steels containing from 12 to 15 per cent. of chromium, but their general properties are greatly affected by the carbon-content, which may vary from 0·1 to 0·5 per cent. The discovery of the non-corrosive properties of these steels was made by H. Brearley, in 1913, but, owing to counter-attractions, a British patent was not obtained, although they were obtained in Canada in 1915, and in the United States in 1916. He claimed an alloy steel with from 9 to 16 per cent. of chromium and less than 0·7 per cent. of carbon, and gave as an example an alloy with 0·30 per cent. of carbon, 0·30 manganese, and 13·0 chromium. A great variety of steels can be obtained by modifications of the central idea. Thus, by varying the proportion of carbon or manganese, and heat-treatment, steels of widely different hardness can be obtained, but all have the distinguishing property of great resistance to corrosion. According to J. H. G. Monypenny, with a fixed proportion of chromium, and the same heat-treatment, the resistance to corrosion will be greater the lower the proportion of carbon; and with a fixed proportion of carbon, and the other conditions equal, increasing the proportion of chromium augments the resistance. The mechanical properties of the steel, conditioned by the heat-treatment, are often as important as the degree of resistance to corrosion, and this restricts the permissible variations in composition. The cost of the chromium is also a factor to be considered. Hence, taking all things into consideration, H. Brearley considered that the proportions just indicated are best for commercial alloys. Silicon raises the temp. of the Ac_1-change, and also the temp. required for the complete dissolution of the carbide, and hence, higher hardening temp. are needed to obtain similar resistances to corrosion when silicon is present. H. H. Abram reported that high-silicon steels resist some chemical agents better, but their superiority over low-silicon steels for resisting the weather, and sea-water, is not evident, and it exists only in tempered, high-carbon steels. The effect of nickel favours the mechanical properties of steel; and up to 2 per cent. of nickel slightly favours resistance to attack by acids. Hence, additions of nickel can be made to suit the physical requirements. B. D. Saklatwalla showed that 0·5 to 1·5 per cent. of copper considerably improves stainless steel, and this was confirmed by J. H. G. Monypenny.

According to J. H. G. Monypenny, in general, a heterogeneous steel is more susceptible to attack than a homogeneous steel, so that when a steel is hardened by quenching, it consists almost wholly of martensite and is then in its most resistant form; while if the steel be annealed so as to produce a complete separation of carbide and ferrite, it is in its least resistant form. In the separation, the chromium has a tendency to accumulate in the carbide at the expense of the ferrite, and the ferrite is then more liable to attack; the separation also means that galvanic effects may be produced which hasten the corrosive actions. The greatest resistance to corrosion was obtained by quenching the steel from a temp. sufficiently high to dissolve all the carbide it contains. The hardness of these hardened steels persists on tempering up to 500°, and this does not markedly alter the martensitic structure of the steel, nor does it have any notable effect on the resistance to corrosion. As the tempering temp. is raised to between 500° and 600°, there is a marked fall in the hardness, and a slightly lessened resistance to corrosion. The martensitic structure changes, and small carbide particles coalesce to form larger ones; by tempering at 750° the effects at 600° are more marked. Similar remarks apply to material annealed at a high enough temp. to give a pearlitic structure. As indicated in connection with the corrosion of iron and steel—*vide supra*—most metals, including the chromium steels, have a greater tendency to corrode when they are distorted by cold-work. V. S. Polansky compiled a bibliography of the stainless steels; and observations on their corrodibility were made by L. Aitchison, H. Hubert, H. C. H. Carpenter, etc. A. Matsubara and J. Takubo found that copper pyrites in dil. sulphuric acid is decomposed cathodically into hydrogen sulphide, cuprous sulphide, and ferrous sulphate, and, ultimately, into metallic copper; preliminary anodic polarization produces the reverse effect of that observed with iron pyrites. Copper pyrites which yields but little hydrogen gives abnormal quantities of decomposition products. It is supposed that the fraction of the mineral which is dissolved directly by the acid exists in the solid in an ionized condition, the degree of ionization in various specimens of copper pyrites being 0·035 to 0·305.

O. K. Parmiter gave the following comparison of the effect of various reagents, at room temp., on carbon steel, stainless steel with 13 per cent. Cr, and stainless steel with 13 per cent. Cr and 8 per cent. Ni, respectively : 100 per cent. *acetic acid*, attacked, not attacked, not attacked ; 33 per cent. acetic acid, attacked, attacked, —— ; 5 and 15 per cent. acetic acid, attacked, attacked, not attacked ; 100 per cent. boiling acetic acid vapour, attacked, attacked, attacked ; 33 per cent. acetic acid vapour, attacked, attacked, slightly attacked ; 100 per cent. *acetic anhydride*, attacked, attacked, not attacked ; 100 per cent. *acetone*, attacked, slight corrosion, not attacked ; 10 per cent. *alum*, attacked, attacked, not attacked ; 1, 5, and 10 per cent. *aluminium sulphate*, attacked, attacked, not attacked ; *ammonia* (sp. gr. 0·880), not attacked, not attacked, not attacked ; 1, 5, 10, 20 per cent. *ammonium chloride* soln., attacked, slightly attacked, not attacked ; 5, 23, 47 per cent. ammonium chloride (boiling soln.), attacked, attacked, very slightly attacked ; 10 per cent. soln. of *ammonium nitrate*, attacked, not attacked, not attacked ; 10 per cent. soln. of *ammonium sulphate*, attacked, attacked, not attacked ; ammonium sulphate (sat. soln.) +5 per cent. sulphuric acid (at 50°), attacked, attacked, attacked ; *apples*, attacked, not attacked, not attacked ; *beer*, attacked, not attacked, not attacked ; *benzene*, not attacked, not attacked, not attacked ; aq. suspension of *bleaching powder*, attacked, attacked, slightly attacked ; 5 per cent. soln. of *boric acid*, attacked, not attacked, not attacked ; *bromine*, attacked, attacked, attacked ; 0·83, 1·65, 3·3 per cent. bromine water, attacked, attacked, attacked ; 0·165, 0·33 per cent. bromine water, attacked, attacked, very slightly attacked ; 10 per cent. soln. of *calcium chloride*, attacked, slightly attacked, not attacked ; *carbolic acid*, attacked, attacked, not attacked ; *carbon tetrachloride*, —— , not attacked, not attacked ; wet and dry *chlorine* gas, attacked, attacked, attacked ; conc. *chlorosulphonic acid*, attacked, attacked, not attacked ; 10 per cent. chlorosulphonic acid, attacked, attacked, attacked ; 0·5 per cent. chlorosulphonic acid, attacked, attacked, not attacked ; *cider*, attacked, not attacked, not attacked ; all concentrations of *citric acid*, attacked, attacked, not attacked ; conc. aq. extract of *coffee*, attacked, not attacked, not attacked ; Congo *copal* (370°), —— , attacked, not attacked ; *copal varnish*, not attacked, not attacked, not attacked ; sat. soln. of *copper carbonate* in ammonia, attacked, not attacked, not attacked ; 5 and 10 per cent. soln. of *copper chloride*, attacked, attacked, attacked ; 10 per cent. soln. of *copper sulphate*, attacked, not attacked, not attacked ; copper sulphate (10 per cent.) +2 per cent. sulphuric acid, attacked, not attacked, not attacked ; developers : (a) *hydroquinone*, attacked, not attacked, not attacked ; (b) *metolhydroquinone*, attacked, not attacked, not attacked ; (c) *pyrogallol*, attacked, very slightly attacked, not attacked ; 100 per cent. *ether* (ethyl), not attacked, not attacked, not attacked ; 100 per cent. *ethyl chloride*, attacked, not attacked, not attacked ; 5, 10, and 15 per cent. *ferric chloride*, attacked, attacked, attacked ; *food-pastes*, attacked, not attacked, not attacked ; 40 per cent. *formaldehyde*, attacked, not attacked, not attacked ; 5, 25, 50, and 100 per cent. *formic acid*, attacked, attacked, not attacked ; 50 per cent. formic acid (boiling), attacked, attacked, not attacked ; (40 hypo. 2·5 pot. met.) *fixing soln.* (acid), —— , attacked, not attacked ; *horse-radish cream*, attacked, slightly attacked, not attacked ; all concentrations of *hydrochloric acid*, attacked, attacked, attacked ; *hydrofluoric acid*, attacked, attacked, attacked ; *inks*, attacked, not attacked, not attacked ; *iodine* in 2 parts of potassium iodide, attacked, attacked, not attacked ; sat. *lactic acid*, attacked, attacked, not attacked ; *lemon*, attacked, not attacked, not attacked ; *lime-juice*, attacked, very slightly attacked, practically not attacked ; *lime* and *limestone*, attacked, not attacked, not attacked ; *lubricating oils*, not attacked, not attacked, not attacked ; 2 per cent. and conc. soln. of *lysol*, attacked, not attacked, not attacked ; 10 per cent. soln. of *magnesium chloride*, attacked, attacked, not attacked ; 10 per cent. soln. of *magnesium sulphate*, attacked, attacked, not attacked ; fresh and sour *milk*, attacked, attacked, not attacked ; ($65HNO_3$, $25H_2SO_4$, 10 water) mixed, or *nitric-sulphuric acid* (at 50°), attacked, not attacked, not attacked ; *nitric acid* (sp. gr. 1·42), not attacked, not attacked, not attacked ; nitric acid (sp. gr. 1·20), attacked, not attacked, not attacked ; up to 11 per cent. nitric acid, attacked, slightly attacked, not attacked ; *nitrous acid* (sp. gr. 1·41), attacked, slight staining, not attacked ; 5 per cent. nitrous acid, attacked, slightly attacked, not attacked ; 100 per cent. *oleic acid*, attacked, not attacked, not attacked ; *oranges*, attacked, attacked, not attacked ; 5 per cent. soln. of *oxalic acid*, attacked, attacked, not attacked ; *paraffin*, not attacked, attacked, not attacked ; *paregoric compound*, attacked, badly stained, not attacked ; *petrol*, not attacked, not attacked, not attacked ; 100 per cent. *phosphoric acid*, attacked, slightly attacked, not attacked ; 75 per cent. phosphoric acid, attacked, attacked, not attacked ; 5, 25, 50 per cent. phosphoric acid, attacked, slightly attacked, not attacked ; *pickles*, attacked, not attacked, not attacked ; *picric acid* (alcoholic), attacked, not attacked, not attacked ; 10 per cent. *potassium nitrate*, attacked, not attacked, not attacked ;

pyrogallol, attacked, not attacked, not attacked; *moist salt* (cerebos), attacked, attacked, not attacked; moist salt (ordinary), attacked, attacked, not attacked; *sauces*, attacked, not attacked, not attacked; *sea-water*, attacked, attacked, slightly attacked; sea-water (80°), attacked, attacked, not attacked; sea-water (agitated), attacked, attacked, not attacked; sea-water (intermittent spray), attacked, attacked, very slightly attacked; 100 per cent. *sebacic acid* (at 140°), attacked, attacked, attacked; 3, 5, 10 per cent. soln. of *sodium chloride*, attacked, slightly attacked, not attacked; 3·5 per cent. *sodium citrate*, ——, not attacked, not attacked; 33·66 per cent. soln. of *sodium hydroxide*, not attacked, not attacked, not attacked; sat. soln. of sodium sulphate, attacked, not attacked, not attacked; 10 per cent. *sodium sulphide*, attacked, not attacked, not attacked; 30 per cent. *sodium thiosulphate*, attacked, ——, ——; all conc. of *sulphuric acid*, attacked, attacked, not attacked; 5 per cent. *tannic acid*, attacked, practically not attacked, not attacked; 5, 10, 25, and 50 per cent. soln. of *tartaric acid* (all temp. up to boiling), attacked, attacked, not attacked; *vinegar*, attacked, not attacked, not attacked; *running water* (tap-water), attacked, not attacked, not attacked; 15° water (tap-water), attacked, not attacked, not attacked; liquid *zinc* (450°), attacked, attacked, attacked; *zinc chloride* (boiling), sp. gr. from 1·030 to 1·725, attacked, very slightly attacked, not attacked.

The use of alloys for resisting acidic and alkaline soln. in chemical plants has been discussed by A. E. Anderson and G. M. Enos,[23] P. A. E. Armstrong, F. M. Becket, T. H. Burnham, W. S. Calcott, W. S. Calcott and co-workers, C. M. Carmichael and co-workers, F. J. R. Carulla, F. F. Chapman, J. Cournot, G. A. Drysdale, U. R. Evans, H. J. French, E. D. Gleason, A. Grounds, W. Guertler, H. G. Haase, R. A. Hadfield, M. L. Hamlin and F. M. Turner, W. H. Hatfield, F. W. Horst, E. Houdremont and R. Wasmuth, W. E. Jominy and R. S. Archer, G. B. Jones, R. Lund, R. J. McKay, C. E. MacQuigg, W. R. Mott, T. H. Nelson, A. Portevin, H. Reiger, F. Ritterhausen, C. S. Robinson, K. Roesch and A. Clauberg, W. Rohn, F. W. Rowe, B. D. Saklatwalla, L. Sanderson, W. Schmidt, E. H. Schulz and W. Jenge, C. E. Sholes, R. Thews, G. Thompson, S. J. Tungay, A. Vacin, R. P. de Vries, H. F. Whittaker, E. C. Wright and K. E. Luger, and A. Zemanek. The subject is also discussed in more detail in connection with specific alloys.

B. D. Saklatwalla and A. W. Demmler,[24] E. H. Schulz, K. Sasakawa, and J. A. Jones studied the **chromium-copper steels.** The mechanical tests far exceed those of the plain, low-carbon, copper steels; the alloys can be rolled, forged, pressed, and stamped very well; and they also resist corrosion very well. V. and G. Prever also found that the alloys resist corrosion. E. Scheil and E. H. Schulz, C. Taillandier, and F. B. Lounsberry and W. R. Breeler studied the **chromium-aluminium steels.** L. Guillet recommended nitridized chromium-aluminium steels for the cylinders of internal combustion engines, and for propeller shafts. S. Sato studied the electrode potentials of the nitridized alloys. H. Gruber found that the aluminium-chromium-iron alloys are attacked by hydrogen at elevated temp. C. Casper, H. Moissan, J. B. Johnson and S. A. Christiansen, E. Valenta, W. Oertel and K. Würth, V. O. Homerberg and I. N. Zavarine, A. R. Page and J. H. Partridge studied the mechanical properties of **chromium-silicon steels,** and P. Bres, their resistance to corrosion; W. Denecke gave a ternary diagram of the system with up to about 30 per cent. each of chromium and silicon. The iron and chromium furnish a continuous series of solid soln. with minimum in the f.p. curves. No evidence was observed of the formation of the compound Fe_2Cr, or of a eutectic with 15 per cent. of chromium. The reaction between the solid soln. of iron and silicon, and the formation of FeSi, is accelerated by the presence of chromium. E. D. Campbell and H. W. Mohr studied the electrical resistance and the thermoelectric potentials; G. D. Newton, the shearing strength; H. H. Abram, J. N. Alcacer and G. Gayoso, T. G. Digges, H. J. French and W. A. Tucker, F. J. Griffiths, G. A. Hawkins and co-workers, W. Kahlbaum and co-workers, R. R. Moore and E. V. Schaal, T. Murakami and K. Yokoyama, T. L. Robinson, K. Roesch, S. C. Spalding, J. S. Vanick and co-workers, and C. F. Würth, the mechanical properties; and J. Cournot and K. Sasagawa, the viscosity. S. Sato studied the electrode potentials of nitrified **chromium-titanium steels,** and of **chromium-zirconium steels.** B. Stoughton and W. E. Harvey,

W. Kahlbaum and L. Jordan, T. Heczko, and H. M. Boylston investigated the physical properties, and J. G. Thompson and co-workers, and G. H. Keulegan and M. R. Houseman, the action of aq. soln. of urea and of ammonium carbamate on the **chromium-vanadium steels.**

Samples of iron alloyed with up to 28·49 per cent. of molybdenum were reported by C. J. Heine,[25] F. Stromeyer, A. Wehrle, H. A. L. Wiggers, and C. Steinberg. P. Berthier prepared **iron-molybdenum alloy, or ferromolybdenum,** with 2 per cent. of molybdenum which was as fusible as iron, but whiter, extremely hard, brittle and tenacious, and uneven and granular in fracture. J. J. Berzelius also described bluish-grey alloys with iron and molybdenum in the proportion 1 : 1 and 1 : 2. To prepare the iron-molybdenum alloys, J. Ohly recommended adding molten iron to a bath of fused molybdenum. H. Lautsch and G. Tammann prepared alloys by reducing a mixture of the oxides with aluminium. The strong affinity of molybdenum for oxygen, and the volatility of the molybdenum oxides may give large losses of the expensive metal molybdenum in the manufacture of alloys with iron or steel. Ferromolybdenum can be prepared in electric furnaces with 10 to 50 per cent. molybdenum, and at most 0·5 per cent. of carbon; and, by using ferromolybdenum, the losses in the preparation of molybdenum steels are smaller. S. S. Steinberg and P. S. Kusakin, O. J. Steinhart, R. Cazaud, F. M. Becket, R. M. Keeney, F. Peters, W. Guertler, G. P. Scholl, P. Girod, J. Pokorny, G. and E. Stig, and W. Borchers and R. W. Stimson prepared alloys of iron and molybdenum. W. R. Hulbert employed the thermite process. W. P. Sykes prepared alloys by heating together intimate mixtures of the constituent elements in a powdered form such as is produced by reduction in hydrogen. The mixture is compressed into bars which are sintered in hydrogen above 1440° until diffusion is complete. The bars are quenched and aged for several days above 600°—*vide* **11.** 61, 5. A. Stavenhagen and E. Schuchard obtained the alloys by the thermite process. C. F. Burgess and J. Aston discussed the working properties of these alloys. A. Kissock added calcium molybdate to steel. Some uses of molybdenum steels were discussed by M. H. Schmid, P. Oberhoffer, W. Borchers and R. W. Stimson, W. Heym, G. W. Sargent, G. T. Holloway, J. K. Smith, J. Escard, J. A. Mathews, J. W. Richards, F. W. Rowe, J. W. Evans, C. McKnight, V. L. Eardley-Wilmot, A. H. Hunter, A. Haenig, E. Lievenie, E. Schaaf-Regelman, G. Gin, P. Girod, W. Venator, and G. Surr.

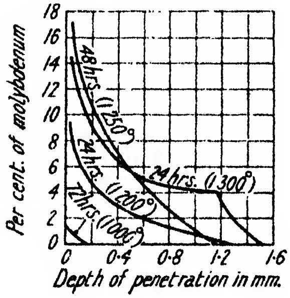

FIG. 455.—The Diffusion of Molybdenum in Iron.

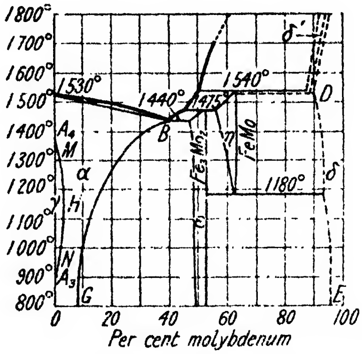

FIG. 456.—Equilibrium Diagram of the Iron-Molybdenum Alloys.

G. Grube and F. Lieberwirth, N. Agéeff and M. Zamotorin, and J. Laissus discussed the diffusion of molybdenum in iron. Fig. 455 has a selection from the results of F. Lieberwirth. The alloys were described by J. L. Gregg and H. W. Gillett. H. Lautsch and G. Tammann made a partial study of the binary system and found a eutectic with 43 per cent. molybdenum at 1360°. The breaks in the cooling curve indicated that a compound is formed which decomposes slowly at higher temp. The compound does not form mixed crystals with iron, and probably not with molybdenum, but the metals themselves form two series of mixed crystals. W. P. Sykes' diagram modified by T. Takei and T. Murakami is shown in Fig. 456. When alloys with up to 24 per cent. Mo are quenched from the solidus temp., large polyhedral grains of the solid soln. are formed; if cooled at a moderate rate, a second phase—**iron tritadimolybdide,** Fe_3Mo_2—appears, either as small globular grains, or as needle-like crystals. E. Vigouroux, and A. Carnot and E. Goutal observed the existence of this compound in alloys of iron and molybdenum free from carbon. T. Takei and T. Murakami also found a solubility of the ϵ-phase in the α-phase, *BG*, corresponding with 6 per cent. of molybdenum at room temp., and 38 per cent. at the eutectic 1440°. They observed solid phases named respectively α-, γ-, ϵ-, δ-, and δ'-; and in addition to iron tritadimolybdide, they found **iron molybdide,** FeMo, exists as the η-phase, and it is formed by the peritectic reaction: $\text{melt}+\delta'\rightleftharpoons\eta$ at 1540°, and it decomposes by a eutectoidal reaction, $\eta\rightleftharpoons\epsilon+\delta$, into the ϵ- and δ-phases at about 1180°. According to T. Takei and T. Murakami, the tritadimolybdide forms the ϵ-phase, and it is formed by the peritectic reaction: $\text{melt}+\eta=\epsilon$ between 1450° and 1500° on cooling, and it forms a eutectic with the α-phase. They also studied the lowering of the critical points of iron by molybdenum. H. Scott observed that molybdenum has but a slight effect on the temp. of transformation of martensite to troostite. V. N. Svechnikoff studied the γ-phase.

E. C. Bain's X-radiograms corresponded with hexagonal FeMo, and H. Arnfeldt observed that in the Fe–Mo system there is an intermediate trigonal phase with lattice parameters $a=4\cdot743$ A., and $c=25\cdot63$ A., or $c:a=5\cdot40$. The crystals have the composition of iron tritadimolybdide, Fe_3Mo_2. H. Lautsch and G. Tammann studied the microstructure of the alloys more or less carburized. W. P. Sykes observed that *BG* denotes the solubility curve of molybdenum in iron between 400° and 1440°. The eutectic is made up of iron tritadimolybdide and the sat. solid soln. of molybdenum in iron, and in alloys quenched from just below 1440°, it appears as a fine network, while with slower cooling, it has a distinctly lamellar structure. The solid soln. of molybdenum in iron is 24 per cent. Mo at 1440° and 7 per cent. at 600°. As the proportion of molybdenum rises above 35 per cent., massive areas of the tritadimolybdide appear. An alloy with 53 per cent. of molybdenum, when heated over 5 hrs. at 1450°–1500°, consists of only one phase, the tritadimolybdide. This alloy is porous, due to the vol. shrinkage accompanying the formation of this compound in the solid state. This alloy is non-magnetic, those with less molybdenum are magnetic. When alloys with 50 to 90 per cent. molybdenum are heated above 1540°, the tritadimolybdide dissociates into an iron-rich liquidus, and a solid soln. of iron in molybdenum. *DE* represents the solubility curve of iron in molybdenum. The line *MHN* is drawn through the Ar_4- and Ar_3-points during cooling. The point Ar_3 marks the change from γ-iron, with its face-centred cubic lattice, to α-iron, with its body-centred cubic lattice; and Ar_4 represents the change from δ-iron with its body-centred cubic lattice, to γ-iron, with its face-centred cubic lattice. The addition of 3 per cent. of molybdenum to iron lowers the Ar_4-point from 1400° to 1230°; and raises the Ar_3-point from 890° to 980°. The addition of molybdenum in iron thus tends to prevent the change from α- to γ-iron or from δ- to γ-iron in heating through Ar_3 or cooling through Ar_4 respectively; that is, additions of molybdenum to iron progressively restrict the range of temp. in which γ-iron is stable, until, with 4·0 to 4·5 per cent., the body-centred form prevails exclusively at temp. below the solidus. P. Oberhoffer observed a similar restriction of the range of γ-iron with 5 per cent. of silicon, but F. Wever placed it at 1·8 pet cent. of silicon. F. Wever also found the restriction occurs with about 2 per cent. of tin; E. Maurer, with 2·5 per cent. of vanadium; E. C. Bain, with about 14 per cent. of chromium; and W. P. Sykes, with about 6 per cent. of tungsten. T. Takei and T. Murakami found that with alloys having over 63 per cent. of molybdenum, there is an eutectoidal change, $\delta'=\delta+\eta$, at about

1500°. The A_2-arrest is slightly lowered by increasing proportions of molybdenum. S. Curie observed that the temp. of magnetic transformation on the heating curve is 720° to 730°, and the magnetic properties are regained on the cooling curve at 683° to 689°. H. C. H. Carpenter gave for the critical ranges on the cooling curve of molybdenum steels :

C	Mo	Initial Temp.	Critical ranges		
0·28	0·95	1020°	812°–870°	759°–744°	688°–658°
		1250°	836°–730° ;	617°–573° ;	546°–523°
0·57	9·25	900°	—	768°–724°	688°–618°
		1200°	—	783°–706° ;	592°–385°

Molybdenum is more powerful than tungsten in its action on iron. Less than 1 per cent. of molybdenum causes a widening and an alteration in the character of the critical ranges. Mild quenching in an air-blast caused the complete or almost complete suppression of the critical range. T. Swinden found that for alloys up to 8 per cent. molybdenum, if the initial temp. has not exceeded a certain minimum temp., normal points are obtained in the recalescence curves on cooling, and these are independent of the rate of heating, or time of soaking. The low temp. of recalescence is below the Ac_1-point with 8 per cent. molybdenum low-carbon steels. If the low temp. of recalescence has been exceeded, the normal Ar_1-point is lowered or split, and as the temp. increases, assumes a definite low position. There is in some cases an intermediate zone in which an equilibrium exists between the two points even with fairly slow heating, and a 2 hrs.' soaking. The position of the lowered recalescence temp. is a progressive function of the molybdenum-content, being more easily effected as the proportion of molybdenum increases, but a higher temp. and longer soaking is necessary to produce the full lowering effect. The temp. which first affects the point, and also that which produces the maximum lowering effect, is slightly higher as the carbon-content increases. The low temp. is not disturbed by slow cooling or arrested cooling at about 800° if the steel has been previously heated at 1200°. The recovery of the normal point is effected by repeated heating to below the lowering temp. It is not easily effected by a single slow heating and soaking. The normal Ac_1-point is found on heating, and no new point has been observed corresponding to the lowering temp. The subject was discussed by H. J. French, F. Lepersonne, and G. Burns.

E. Vigouroux obtained **iron tritadimolybdide,** Fe_3Mo_2, as an insoluble residue from alloys with 50 per cent. molybdenum. Its sp. gr. is 9·16 at 0°. It is attacked slowly by chlorine at ordinary temp., and vigorously at 250° ; oxygen, sulphur, and water-vapour react at a red-heat. Soln. of hydrochloric and hydrofluoric acids, as well as gaseous hydrogen chloride, have no appreciable action, but the compound is readily attacked by hot, conc. sulphuric acid, by dil. nitric acid, and by iodine suspended in water. Potassium hydroxide has no action in soln., but reacts readily in the fused condition. As indicated above, this compound was prepared by A. Carnot and E. Goutal ; and W. P. Sykes observed the conditions under which it is formed, Fig. 456. No other compound appears on the thermal diagram, but E. Vigouroux said that **iron hemimolybdide,** Fe_2Mo, of sp. gr. 8·90 at 0°, is obtained by the action of hydrochloric acid on alloys with less than 46·16 per cent. of molybdenum ; iron molybdide, FeMo, of sp. gr. 9·01 at 0°, from 54 to 63 per cent. alloys ; and **iron dimolybdide,** $FeMo_2$, of sp. gr. 9·41 at 0°, from 64 to 77 per cent. alloys. The existence of these three molybdides has not been confirmed. For the cementation of these steels, *vide supra.*

A. Carnot and E. Goutal found that molybdenum steels with 1·7–2·3 per cent. of carbon contained the **iron molybdenum carbide,** $Fe_3C.Mo_2C$. P. Williams prepared the same compound. J. O. Arnold and A. A. Read analyzed the residues obtained by treating molybdenum steels with acid, and found that with the 0·78 C and 2·43 Mo steel, the residue corresponds with 6FeC, Fe_3Mo_3C ; with the 0·75 C and 4·95 Mo steel, $7Fe_3C$, $3Fe_3Mo_3C$, 2C ; with the 0·71 C and 10·15 Mo steel,

Fe_3C, $3Fe_3Mo_3C$, C: with the 0·79 C and 15·46 Mo steel, Fe_3C, $8Fe_3Mo_3C$; and with the 0·82 C and 20·70 Mo steel, Fe_3Mo_3C. F. R. Morral and co-workers, and V. Adelsköld and co-workers observed the formation of the **molybdenum iron tritacarbide,** Fe_3Mo_3C. The observations of H. Lautsch and G. Tammann, and of W. P. Sykes, show that a part of the molybdenum in iron forms only one compound, and the remainder forms mixed crystals with the iron; in the presence of carbon, there may be formed the mixed crystals of iron and molybdenum —*molybdenoferrite*; iron molybdenum carbide; iron tritadimolybdide; and in hardened steels, molybdenum-austenite or martensite in which, with higher proportions of molybdenum, iron molybdenum carbide can be recognized; while, with annealed steels, intermediate forms between martensite and pearlite can also be recognized. L. Guillet found that the pearlitic steels have 0·20 per cent. of carbon and less than 2 per cent. of molybdenum, or 0·80 per cent. of carbon and less than 1 per cent. of molybdenum; and the carbide steels have a double carbide with over 2 per cent. of molybdenum and 0·20 per cent. of carbon, and over 1 per cent. of molybdenum with 0·80 per cent. of carbon. A. M. Portevin supposed that the double carbide is found in steels with over 5 per cent. of molybdenum and 0·2 per cent. of carbon; and with above 2 per cent. of molybdenum and 0·8 per cent. of carbon. H. le Chatelier supposed that the molybdenum is isolated in the mass of the metal as a solid soln.; and O. Boudouard, and C. A. Edwards made a similar assumption with respect to the existence of tungsten in tungsten steels; but measurements of the electrical resistance—*vide infra*—do not favour this hypothesis. C. A. Edwards supposed that the carbon exists as iron carbide. J. S. de Benneville prepared the complex iron **chromium molybdenum carbide,** $Fe_7(Cr_2Mo)_8C_4$, and called it *wahlite*. F. Roll, H. Sawamura, and F. L. Coonan found that molybdenum partly decomposes and partly preserves the cementite in cast iron. J. W. Donaldson studied the action of molybdenum in cast iron.

T. Swinden suggested that the molybdenum occurs in annealed steels as a compound of iron and molybdenum, and not in simple solid soln. When the steel is heated, the Fe_3C goes into soln. at Ac_1, and unless the lowering temp.—*vide supra*—is exceeded, is re-precipitated at the normal Ar_1-temp. on cooling. If the steel be heated beyond the lowering temp., the condition of the molybdenum compound behaves as if it passed into soln. The separation of Fe_3C from this soln. takes place at a lower temp. than the normal Ar_1. The actual temp. depends on the conc. of the molybdenum soln. When the steel has been cooling beyond the lowering temp., and then re-heated, the molybdenum gradually re-assumes its original condition if the temp. does not exceed that producing the lowering. When this change is complete, the normal Ar_1-temp. is regained in the cooling curve. T. Swinden also observed that specimens quenched from 800° contain normal martensite indicating that the carbide is partially soluble at this temp. Molybdenum steels quenched from 1200° are less easily attacked by acid, and in the case of certain steels with the higher proportions of carbon and molybdenum, they show white polyhedra. The structure of specimens heated to 1200°, and quenched at 600°, is essentially the same as that of those quenched at 1200°. Samples which have been air-cooled from 1200° show martensite and troostite, and the proportion of martensite is greater, the greater the proportion of carbon and molybdenum. J. O. Arnold said that a true molybdenum steel is formed when 18·3 per cent. of molybdenum and 0·7 per cent. of carbon are present. The 100 per cent. pearlite then consists of $24Fe+Fe_3Mo_3C$. The subject was discussed by G. W. Sargent, and E. L. Reed.

E. C. Bain discussed the X-radiograms; and E. P. Chartkoff and W. P. Sykes, the changes in the lattice parameters in solid soln. The scleroscopic and Brinell's hardnesses of molybdenum steels, measured by T. Swinden, are indicated in Table LXXVI. The normalized steel was obtained by heating it for 15 minutes at 900°, and free cooling in air. T. Swinden also examined the file hardness of molybdenum steels. W. P. Sykes found that the Brinell hardness of iron increases

continuously with the addition of molybdenum up to about 40 per cent. by weight. The hardness of molybdenum is increased at a more rapid rate by the addition of iron up to about 15 per cent. The hardness of some of the alloys, water-quenched from just below the solidus, is increased by as much as 250 per cent. by ageing at temp. between 600° and 700°. In tempering or ageing at certain given temp. the hardness reaches a maximum and then decreases as ageing is prolonged. The higher the temp. of the ageing above a certain minimum temp., the more rapidly the hardness increases, but the lower is the maximum hardness attained. A shrinkage in vol. occurs during the ageing process, and, in general, its maximum coincides with that of the maximum hardness developed by ageing. The subject was discussed by G. Grube and F. Lieberwirth, and M. Ballay; and E. K. Smith and H. C. Aufderhaar observed that the Brinell's hardness, and tensile strength of cast iron were increased by adding 0 to 3·1 per cent. of molybdenum, but the machinability was decreased. G. Tammann and V. Caglioti discussed the recovery of hardness after cold-work.

Observations on the mechanical properties were made by W. von Lipin, J. K. Smith, R. Helmhacker, P. Marsich, S. B. Ritchie, A. L. Colby, L. Campredon, A. Rys, R. A. Hadfield, H. J. French, W. N. Bratton, K. Taniguchi, J. V. Emmons, E. L. Henderson, J. Cournot and J. Challansonnett, E. C. Clapp and F. C. Devereaux, H. J. French and T. G. Digges, P. Prömper and E. Pohl, F. L. Coonan, E. K. Smith and H. C. Aufderhaar, W. Liestmann and C. Salzmann, E. E. Thum, R. C. Good, A. L. Norbury, E. Kothny, J. H. Küster and C. Pfannenschmidt, I. Musatti and G. Calbiani, C. H. Lorig and F. B. Dahle, K. H. Müller and E. Piwowarsky, J. E. Hurst, E. L. Henderson, W. H. Phillips, A. C. Prulière, E. Piwowarsky, P. Blum, H. Fleck, O. Smalley, A. Campion, A. M. Portevin, and L. Guillet. The subject was summarized by H. W. Gillett and E. L. Mack. According to L. Guillet, the pearlitic steels have a high tensile strength and elastic limit which increases regularly with the percentage of molybdenum; while the elongation and resistance to shock diminish a little, but preserve high values. The carbide steels have a tensile strength and elastic limit which increase with the percentage of molybdenum; the elongation and reduction of area are low; while the brittleness increases with the percentages of carbon and molybdenum. The effect of heat-treatment resembles that with the tungsten steels—*vide infra.* T. Swinden obtained the results indicated in Tables LXXVII and LXXVIII.

The rolled steels are not closely comparable, because of variations of treatment in the mill; but the influence of molybdenum in rendering the steel susceptible to cold-working is clearly shown. The annealed steels diminish in strength and ductility as the molybdenum increases from 1 to 8 per cent. This is very marked with steels having 0·9 per cent. or more carbon. The normalized steels are only slightly influenced by molybdenum. As the proportion of carbon increases, the influence of molybdenum is more marked. It produces an appreciable increase in tenacity with only a slightly reduced ductility. The effect of molybdenum on hardened and tempered steels is very marked, resulting in high tenacity with considerable elasticity. The most promising results are obtained with the series containing 1 and 2 per cent. molybdenum. T. Swinden observed no evidence of the softening of any steels by quenching as reported by L. Guillet for double carbide steels. W. P. Sykes found that the tensile strength, like the hardness, increases with ageing or tempering ; a decrease in ductility accompanies the increase in tensile strength. The development of secondary hardness in these alloys is accompanied by the precipitation of the compound Fe_3Mo_2. The particle-size of the separation remains sub-microscopic until the hardness has passed through its maximum value and has fallen off considerably. C. L. Clark and A. E. White measured the effect of temp. on the tensile strength. T. Swinden found that the bending tests show up the brittleness of the high-carbon annealed bars ; and, in general, they confirm the tensile tests. Molybdenum does not greatly increase the resistance of steels to alternating stresses with any heat-treatment. The annealed series gave fair results with a low percentage of carbon, but poor values with a high proportion of carbon notwithstanding the low tensile values. Crushing tests show that the molybdenum slightly stiffens the steel, but the effect is not marked. W. Giesen found that with molybdenum steel having 0 to 4 per cent. of molybdenum and 0·3 per cent. of carbon, or 0 to 2 per cent. of molybdenum and 0·95 per cent. of carbon, gave results approximating to those furnished by additions of tungsten so far as tensile strength, elastic limit, elongation, hardness, and brittleness, when the ratio of added molybdenum is to tungsten as 1 : 2·225. F. Robin observed that the addition of 1 to 2 per cent. of molybdenum in 0·8 per cent. carbon steels makes the resistance to crushing low, and it is about 5 kgrms. per c.c. at 1100°. The effect of molybdenum on cast iron, etc., was studied by F. L. Coonan, H. M. Boylston, and J. H. Jennings and E. L. Henderson.

T. Takei and T. Murakami observed an abrupt dilation in alloys with less than 2 per cent. of molybdenum ; this is due to the $\alpha \rightleftharpoons \gamma$ change. The dilation is not observed in alloys with over 4 per cent. of molybdenum. In the alloys containing more than 7·5 per cent. of molybdenum quenched at a high temp., an abrupt change at about 700°–720° is observable during heating, the magnitude of the dilation increases with the molybdenum-content. This change may also be attributed to the gradual deposition of the ϵ-phase from the supersaturated α-solid soln. F. Wüst and co-workers found the mean sp. ht. of molybdenum steel between 0° and $\theta°$ up to 1500°, to be $0{\cdot}06162+0{\cdot}0_4 1099\theta$, and the true sp. ht. at $\theta°$, is $0{\cdot}06162+0{\cdot}0_4 2198\theta°$.

According to T. Takei and T. Murakami, no marked change was observed in the effect of temp. on the electrical resistance of annealed specimens of iron-molybdenum alloys, except a slight bending and a break which is attributable to the change in solubility of the ϵ-phase. If, however, the specimens, consisting of the α- and ϵ-phases, are quenched from a high temp. they show an abrupt change in the electrical resistance on heating them at about 700°, and the greater the molybdenum-content, the more conspicuous is the change. This abnormal change corresponds with the deposition of the ϵ-phase, from a supersaturated α-solid soln. According to H. le Chatelier, the electrical resistance of steel is only slightly influenced by the addition of molybdenum, and this is taken to mean that the molybdenum is not dissolved in the iron. Some observations were made by A. M. Portevin ; and T. Swinden obtained the results indicated in Table LXXIX. A. M. Portevin gave 3·4 microhms per cm. cube for the increase in the resistance of iron produced by 1 per cent. of molybdenum. T. Swinden added that the influence of molybdenum on the annealed steels depends on the carbon-content. In the 0·20 per cent. carbon series, there is a slight increase with increasing proportions of molybdenum ; in the

0·45 per cent. carbon series, the resistance is unaffected; and with 0·9 to 1·20 per cent. carbon, there is a distinct decrease. Samples quenched at 800° give a resistance in agreement with the assumption that the carbon is in soln., and the molybdenum not in soln.; but samples quenched at 1200°, indicate that a considerable proportion at least of the molybdenum is in solid soln. G. Tammann and V. Caglioti discussed the recovery of the resistance after cold-work. E. L. Dupuy and A. M. Portevin found the thermoelectric force of molybdenum steel against copper, expressed in millivolts, to be:

C	0·19	0·16	0·14	0·29	0·77	0·81	0·81	per cent.
Mo	0·45	1·00	2·20	4·50	0·50	1·21	1·98	,,

G. Tammann and E. Sotter found that the electrode potentials of the alloys in $0{\cdot}1N\text{-}H_2SO_4$ show that they are electronegative to molybdenum with up to 65 per cent. of that element, and beyond that slightly electropositive.

S. Curie found that molybdenum increases the coercive force and residual magnetism of steel, so that molybdenum steels make excellent magnets. These steels lose their magnetic qualities between 700° and 750°, and regain them on cooling at a temp. rather lower than that at which the loss occurs on heating. T. Takei and T. Murakami's observations on the intensity of magnetization in different fields are summarized in Fig. 457. By the addition of molybdenum, the intensity of magnetization is gradually decreased; the amount of decrease is small in the range of alloys consisting of the α-phase alone, whereas in those consisting of the two phases, α and ε, the decrease is conspicuous. For annealed specimens, the intensity of magnetization decreases gradually with the rise of temp., and rapidly at the critical point, which is only slightly lowered by the addition of molybdenum. The change at the critical point decreases in amount as the molybdenum-content increases, up to 50 per cent., owing to the fact that the magnetic α-phase in the specimen decreases and the non-magnetic ε-phase increases. Quenched specimens, with over 6 per cent. of molybdenum, *i.e.* consisting of the two phases

α and ϵ, at room temp., show a higher intensity of magnetization in the heating curve than in the cooling—that is, the intensity of magnetization of the quenched specimen decreases on annealing, the amount of the decrease being much greater on increasing the molybdenum-content and raising the temp. of quenching. This fact may be explained as follows: As mentioned above, in an annealed state the intensity of magnetization of alloys gradually decreases in the case of those consisting of the α-phase alone as the molybdenum content increases, while in alloys consisting of the α- and ϵ-phases the decrease is conspicuous, owing to the increase of the non-magnetic ϵ-phase. If the specimen is quenched from a high temp., the α-phase increases in amount, dissolving the ϵ-phase in supersaturation, and hence, the intensity should be increased, owing to the decrease of the non-magnetic phase. If, however, the specimen is heated, the ϵ-phase is deposited from the supersaturated α-phase, and hence, the intensity should be decreased, owing to the increase of the non-magnetic phase. The amount of deposition is greater, as the molybdenum-content increases and the quenching temp. rises. The intensity of magnetization of these quenched specimens gradually decreases at first with the rise of temp., and an abnormal change, or an increase of the intensity, takes place at a temp. above 700°. The amount of the abnormal change increases as the molybdenum-content increases, and also with rise of quenching temp. From the change of microstructure of the quenched specimen on heating, it is definitely inferred that the abnormal change of magnetization is to be attributed to the deposition of the ϵ-phase—that is, if the quenched specimen is heated to about 800°, the ϵ-phase separates extensively, whereas no change is observable if the heating temp. is less than 650°. Since the magnetic critical point of the α-phase is gradually lowered with the increase of the molybdenum-content, it is probable that the critical point of the supersaturated α-phase would be lower than that in the sat. state, and hence, the subsequent heating of the quenched specimen, or the deposition of the ϵ-phase, should result in the rise of the critical point. Hence, the abnormal change observable on the heating of the quenched specimen may be attributed to the superimposed effect of the following two factors. The decrease in the magnetization begins at the lower temp. in the quenched specimen, owing to the lowering of the critical point. If, however, the deposition of the ϵ-phase occurs, the critical point rises and the magnetization should be increased. When the deposition is completed, the change of the intensity is that of the sat. α-phase and it rapidly falls at the critical point. Besides these changes, there is a small increase in the intensity of magnetization above 100°. This is attributed to the removal of strains acquired during quenching. The magnetic properties of molybdenum steels were studied by T. Takei, E. Gerold, and A. F. Stogoff and W. S. Messkin; and the effect of cold-work on the magnetic properties—*vide supra*, iron—by W. S. Messkin.

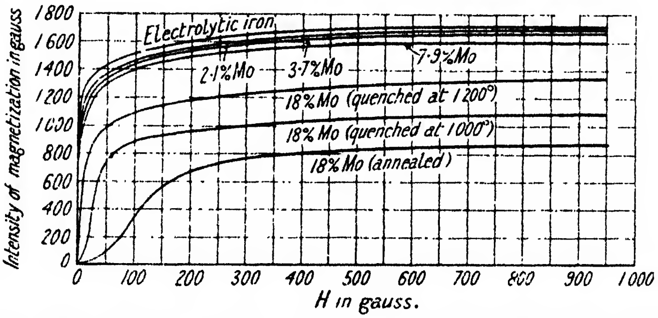

FIG. 457.—The Intensity of Magnetization of the Iron-Molybdenum Alloys in Different Magnetic Fields.

E. Martin studied the absorption of hydrogen and nitrogen by molybdenum steels. J. A. N. Friend and C. W. Marshall tested the effect of molybdenum on the corrodibility of steel, and concluded that (i) molybdenum up to 4 per cent. does not exert any marked influence on the corrodibility of steel by tap-water, salt soln., and dil. sulphuric acid. The results with 0·5 per cent. sulphuric acid are nearly the same as the mean of those with other corroding agents. The resistance of steel to corrosion by alternate wetting and drying, increases with the percentage of carbon, but increasing the proportion of molybdenum increases the corrosion. Hence, the presence of over 1 per cent. of molybdenum is undesirable where steels have to resist corrosion. L. Aitchison found that the addition of molybdenum to carbon steel results in a definite increase in corrodibility by tap-water, 3 per cent. sodium chloride soln., and 1 and 10 per cent. sulphuric acid, until a high proportion of molybdenum—approximately 15 per cent.—has been added. W. A. Dew and H. S. Taylor studied the adsorption of ammonia in the alloy; and S. Satoh studied the nitridization of these steels by heating them in ammonia at 560° to 580°. The corrosion of the alloys was studied by G. Tammann and E. Sotter, H. J. French, C. Duisberg, W. Oertel and K. Würth, W. Guertler and T. Liepus, F. Lieberwirth, and J. S. de Benneville. H. Endo, Fig. 459, found for the losses, in grams per sq. cm., during 5 hrs.' action, at ordinary temp., with alloys containing 0·27 to 0·34 per cent. of carbon, and

G. Grube and F. Lieberwirth's values for the number of milligrams of iron (dotted lines, Fig. 458), and of molybdenum (continuous lines) dissolved per sq. mm. in 24 hrs., at 20°, by 0·1*N*-HCl and 0·1*N*-H_2SO_4 per sq. cm. of surface, are summarized in Fig. 458. J. G. Thompson and co-workers studied the action of aq. soln. of urea and of ammonium carbonate. M. Wiessner studied some **copper-molybdenum-iron alloys**; R. Scherer, some **tungsten-vanadium-iron alloys**; F. T. Sisco and D. M. Warner, M. Baer, K. F. Starodubоff and F. M. Gorbacheva, H. Franz, K. H. Müller and E. Piwowarsky, A. C. Prulière, W. Rohn, and C. F. Würth, the **chromium-molybdenum-iron alloys**; W. H. Cunningham and J. S. Ashbury, **aluminium-chromium-molybdenum-iron alloys**; W. Guertler and T. Liepus studied the corrodibility of the **iron-molybdenum-vanadium alloys** (52 : 20 : 28); and W. Kahlbaum and L. Jordan, **vanadium-chromium-molybdenum-iron alloys**; A. Rys, H. J. French, and J. S. de Benneville prepared some molybdenum-chromium steels, and the corrodibility of the iron-chromium-molybdenum alloys was studied by H. C. Cross, C. N. Dawe, T. G. Digges, H. J. French and W. A. Tucker, M. A. Grossmann, W. Guertler and T. Liepus, W. Oertel and K. Würth, E. W. Pierce, V. and G. Prever, H. B. Pulsifer and O. V. Greene, and C. F. Würth. T. L. Robinson investigated the endurance qualities of these steels; and M. Okochi and co-workers found erosion to be severe in guns made from molybdenum steel.

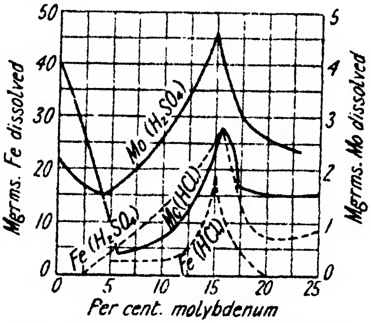

FIG. 458.—The Solubility of Iron-Molybdenum Alloys in Acids.

J. J. and F. de Elhuyar [26] prepared a dense, greyish-white, hard, **iron-tungsten alloy**, or *ferrotungsten*, in 1783; nearly half a century later, P. Berthier obtained an alloy approximating Fe_6W, which he said is a whiter grey colour than iron; is brilliant, hard, and more brittle than cast iron; has a lamellar structure, and contains bubbles or pores. H. de Luynes prepared various kinds of damasked steel with up to 1 per cent. tungsten. According to L. Gruner, M. Koeller and J. Jacob first prepared tungsten steel about 1855; and about this time, too, F. Mayr obtained tungsten steel on a commercial scale. In 1857, R. Oxland obtained ferrotungsten by heating wolframite with charcoal in a closed crucible; and adding the resulting powder of tungsten, iron, manganese, and carbon to molten iron or steel. In 1857–59, R. F. Mushet prepared ferrotungsten which he employed for making tungsten steels; and in 1860, A. Delvaux de Fenffe described the use of tungsten *par l'amélioration de l'acier et de la fonte de fer.* In 1860, M. Siewert, and F. A. Bernoulli described the properties of a number of tungsten alloys; and, in 1867–69, P. le Guen reported attempts made to use tungsten steel rails. Observations were reported by T. Kellermann, R. Volkmann, F. Kick, R. N. Riddle, J. E. T. Woods and J. Clark, and H. A. Levallois. In 1886, G. Heppe emphasized the need for studying the tungsten steels. He said that improved rails, railway axles, and cutting tools can be obtained by adding a small proportion of tungsten to steel. V. Leepin, in 1897, examined some mechanical properties of tungsten steels. The manufacture was described by G. Surr, C. R. Schröder, J. B. Nau, K. P. Grigorovitch, G. T. Holloway, W. Heym, G. and E. Stig, W. Borchers and R. W. Stimson, F. C. A. H. Lantsberry, E. C. Bain and Z. Jeffries, M. A. Grossmann, J. W. Weitzenkorn, H. K. Ogilvie, A. H. d'Arcambal, S. S. Steinberg, F. Peters, J. K. Smith, G. A. Meerson, H. W. Hutchin, R. C. McKenna, R. M. Keeney, J. W. Richards, J. Escard, C. McKnight, F. M. Becket, R. Cazaud, H. G. Batcheller and J. O. Kelley, W. H. Wahl, J. Castner, P. Girod, P. Oberhoffer, O. J. Steinhart, E. Vigouroux, P. Müller, W. Venator, A. Haenig, W. Giesen, J. Percy, P. Nicolardot, and R. A Hadfield; and the general uses and properties of the alloys were described by J. Ohly, W. Guertler, A. C. Ross, H. Alterthum, H. Behrens and A. R. van Linge, and E. Lievenie.

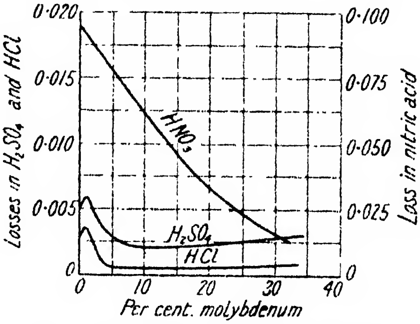

FIG. 459.—The Corrosion of Molybdenum Steels by Acids.

J. Laissus, G. Grube, G. Grube and K. Schneider, N. Ageeff and M. Zamotorin, and W. Geiss and J. A. M. van Liempt discussed the diffusion of tungsten in iron. H. List said that the two metals do not form true alloys. The preparation of ferrotungsten has been discussed in connection with the preparation of tungsten. Portions of the equilibrium diagram were studied by H. Harkort, who obtained alloys by melting ferrotungsten and iron in magnesia crucibles. He found that the temp. of the transformation of α-iron into β-iron was not influenced by the addition of tungsten; but the temp. of the transformation of β-iron to γ-iron rises rapidly from 871° for iron to 933° for an alloy with 10 per cent. of tungsten. Solid soln. were formed, and evidence was obtained of the separation of a compound of iron and tungsten from solid alloys rich in tungsten; the compound being in soln. when the alloys are quenched from a high temp. G. Grube and K. Schneider found that the diffusion coeff. of tungsten in iron at 1280°, 1330°, and 1440° are respectively $3{\cdot}2\times10^{-6}$, 21×10^{-5}, and 26×10^{-5} per sq. cm. per day. D. Kremer made some observations on the solid soln. of tungsten in iron, and of iron in tungsten. K. Bornemann constructed a hypothetical diagram based largely on H. Harkort's observations; and K. Honda and T. Murakami proposed a possible equilibrium diagram based largely on a microscopical study of the alloys. This was discussed by A. Hultgren, and modified by S. Ozawa. The modified diagram is shown in Fig. 460, where it is assumed that **iron hemitungstide,** Fe_2W, is formed in accord with the suggestion of K. Honda and T. Murakami, and H. Harkort. With up to about 10 per cent. of tungsten, the f.p. is raised a little and then gradually lowered. The alloy with 33 per cent. of tungsten freezes at 1510°. The solubility curve of tungstide in ferrite is connected with the A_3-transformation, and at ordinary temp., it corresponds with about 9 per cent. tungsten. A. M. Portevin obtained a lower value for the solubility. The A_2-transformation point, at 790°, is not affected by the tungsten. The line is dotted in Fig. 460 because it does not represent a change of phase. W. P. Sykes found rather different results; they are summarized in Fig. 461. Iron holds about 33 per cent. of tungsten in solid soln. at 1525°, and about 8 per cent. at 600°. The 33 per cent. alloy melts about 10° below the m.p. of iron. An alloy with 33 per cent. or less of tungsten contains large polyhedral grains of the solid soln., and if cooled very slowly, another phase is formed. This same phase appears if this alloy be heated for some time near 1200°; it appears scattered through the solid soln.; and it is probably **iron tritaditungstide,** Fe_3W_2. H. Harkort represented this compound as a hemitungstide, Fe_2W–*vide supra*. The curve *BG* represents the solubility of tungsten or the tritaditungstide. When the tungsten exceeds 33 per cent., this tungstide appears in specimens quenched from the solidus; the alloy with 49 to 51 per cent. iron appears to be the eutectic, of f.p. 1525° to 1527°. Long needles of the tungstide are formed in an excess of solid soln. with alloys having 33 to 49 per cent. of tungsten. With higher proportions of tungsten, there is a rapid rise in the liquidus, so that an alloy with 55 per cent. of tungsten did not fuse until 1600°. The compound can be formed by heating the alloy for, say, 20 hrs. at 1550°–1575°. As the compound forms in the solid soln., there is a considerable shrinkage which makes the alloy more or less porous. If the compound be heated to 1650° or over, it is decomposed. The 62 per cent. alloy is not magnetic after heating for 30 hrs. at 1550°. The solubility of iron in tungsten at 1600° is about 1·20 per cent. The critical point Ar_4 is lowered from 1400° to 1200°, and Ar_3 raised from 890° to 980° by the addition of 5·5 per cent. of tungsten. F. Stäblein said that the A_3-transformation cannot be detected when over 5 per cent. of tungsten is present. S. Takeda found an ϵ-phase corresponding with W. P. Sykes' tritaditungstide; the eutectic of the ϵ- and δ-phases lies at 33 per cent. of tungsten; and the peritectic reaction in which the ϵ-phase is formed occurs with alloys having over 43 per cent. of tungsten, as in S. Ozawa's diagram. Indications of a phase *x* were obtained; it may be formed pericectically from the melt and tungsten or a ζ-phase. T. Murakami and S. Takeda studied the formation of ferrite in tungsten steels. According to H. Harkort, as the tungsten-content increases, there is a corresponding decrease in the amount of γ-iron, *i.e.* the face-centred cubic iron; and when the proportion of tungsten exceeds 6 per cent., only the body-centred cubic lattice is present at any temp. S. L. Hoyt, and N. H. Aall studied this subject.

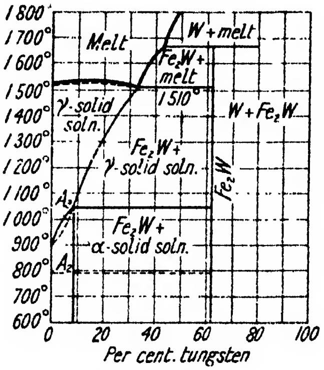

FIG. 460.—Equilibrium Diagram of the Iron-Tungsten Alloys.

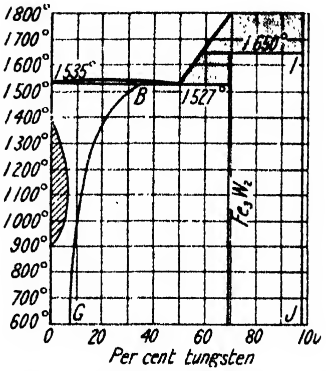

FIG. 461.—Equilibrium Diagram of the Iron-Tungsten Alloys.

A. Carnot and E. Goutal found that when **tungsten** steels are treated with dil. acids, there remains undissolved **iron tritatungstide,** Fe_3W. This same compound was assumed by T. Swinden to occur in the **tungsten steels.** J. O. Arnold and A. A. Read supposed that iron hemitungstide, Fe_2W, occurs in steels, and this compound was assumed by K. Honda and T. Murakami, and S. Ozawa to be formed—Fig. 461. H. Behrens and A. R. van Linge found octahedral crystals of Fe_2W in ferrotungsten. T. Poleck and B. Grützner observed trigonal, hard, silver-grey prisms of **iron ditungstide,** FeW_2, were formed in the crevices of a lump of iron-tungsten alloy derived from Bohemian wolframite. E. Vigouroux obtained iron tritaditungstide, Fe_3W_2, as a residue when dil. hydrochloric acid acts on tungsten steel; and W. P. Sykes' diagram, Fig. 461, shows the conditions under which it can exist in the steel. E. Vigouroux said that the compound forms brilliant plates of sp. gr. 13·89 at 0°; it is not attracted by a magnet; it is readily attacked by chlorine at 350°; by oxygen, or the alkali carbonates at a bright red-heat; by potassium hydrosulphate at a dull red-heat; while aqua regia, sulphuric acid, and fused potassium chlorate have very little action. J. S. de Benneville, E. Vigouroux, and P. Berthier reported products corresponding with Fe_4W, Fe_5W, and Fe_6W, but there is nothing to show that they are chemical individuals. The subject was discussed by N. H. Aall, and W. Zieler.

E. C. Bain's X-radiograms of the ferrotungstens corresponded with hexagonal carbide, FeW. H. Arnfeldt observed at least two intermediate phases in the ferrotungstens. One of them has a hexagonal structure, and when it is in equilibrium with the iron phase its lattice is defined by the parameters $a=4·727$ A. and $c=7·704$ A.; $c/a=1·630$. Its composition corresponds to the formula Fe_2W. There are four groups of Fe_2W in the unit cell. It seems to be unstable at higher temp., and has a decomposition temp. lying between 1000° and 1150°. Another intermediate iron-tungsten phase has a trigonal lattice with the parameters $a=4·731$ A. and $c=25·76$ A.; $c/a=5·44$. The unit cell probably contains 40 atoms. Crystals of this phase have been isolated and they have a composition corresponding with Fe_3W_2. A. Carnot and E. Goutal found that when dil. hydrochloric acid acts on tungsten steels with 2·0 to 2·2 per cent. of carbon, and 6·6 to 7·8 per cent. of tungsten, in the absence of air, there is formed **iron tungsten carbide,** $Fe_3C.WC$; and P. Williams obtained the complex carbide, $2Fe_3C.3W_2C$, by heating tungsten carbide and iron in an electric furnace. The crystalline powder is magnetic, and has at 18° a sp. gr. 13·4. It is attacked by fused potassium hydroxide, and is insoluble in cold, conc. hydrochloric acid. A. Westgren and G. Phragmen found octahedral crystals of Fe_4W_2C in ferrotungsten; and F. R. Morral and co-workers, and V. Adelsköld and co-workers observed the formation of **tungsten iron tritacarbide,** Fe_3W_3C. W. Zieler, and F. Rapatz studied these carbides. J. O. Arnold and A. A. Read assumed that tungsten steels contained the complex carbide, $Fe_3C.WC$. W. A. Wood and co-workers found that the X-radiograms indicated the presence of tungsten carbide and of the complex carbide, Fe_4W_2C, but no cementite. S. Ozawa observed no evidences of this in his study of the ternary system. L. Guillet, K. Däves, and P. Oberhoffer and K. Däves studied the solubility curve of tungsten in the iron-carbon alloys. A. Hultgren assumed that the complex carbides, FeWC, and Fe_2W_2C, can exist in the system. The latter is stable in the presence of a moderate proportion of carbon, while the former is easily decomposed into the carbide, WC, and austenite. Low-carbon steels are supposed to contain Fe_nW. Cementite is supposed to dissolve a certain amount of the carbide, WC, and the carbide W_3C is supposed to exist only in the tungsten-carbon alloy, but not in tungsten steels. Sudden changes in the physical properties of tungsten steels are correlated with changes of composition involving the passage from one side to the other of this limiting curve. The appearance of so-called double carbides of iron and chromium or of iron and tungsten, observed by different workers, is attributed to the same cause. Small amounts of tungsten in steel raise the melting-point, but larger amounts depress it. For the cementation of these steels, *vide supra,* observations. The subject was studied by S. Takeda, E. Houdremont and co-workers, and E. L. Reed. J. S. de Benneville prepared the complex **iron chromium tungsten carbide,** $Fe_7(Cr,W)_6C_4$, and called it *garrisonite.*

O. Böhler concluded that tungsten lowers the m.p. of iron. S. Ozawa, and S. Takeda studied the thermal changes of the ternary system. Tungsten affects the position of the recalescence points of steel as indicated by W. P. Sykes in connection with the equilibrium diagram, Fig. 461. F. Osmond observed that with steels carrying up to 1·53 per cent. of tungsten, and up to 0·13 per cent. of carbon, the positions of the Ar_3- and Ar_2-points remain normal; while Ar_1 is lowered as the tungsten increases, provided the steel has been heated to a sufficiently high temp. He therefore concluded that tungsten has no appreciable action on the allotropic changes of iron, but it causes the carbon change to occur at a lower temp. than the normal one. J. O. Arnold found that with a steel carrying 0·08 per cent. of carbon and 1·41 per cent. of tungsten, the Ac_3-point was absent, Ac_2 occurred at 729°, and Ac_1 was absent; and on cooling from 1150°, Ar_3 was faint at 834°—a little below its normal position; Ar_2 occurred at 729°; and Ar_1 at 590°—about 50° below normal. F. Osmond then noted that with steels having 0·13 to 0·46 per cent. of carbon, and 0·20 to 8·33 per cent. of tungsten—manganese about 0·25 per cent.—that if the initial temp. is not above 850°, the curve resembles that with steels having no tungsten; if the initial temp. exceeds 1040°, the Ar_1-point is sharply lowered, while the Ar_3- and Ar_2-points do not move; if the initial temp. is 1300°, Ar_3 and Ar_2 are lowered in turn, and tend to rejoin Ar_1; while under certain conditions, Ar_1 divides into two portions. O. Böhler found that a steel with 0·85C, and 7·78W had two critical points—about 700° and 550°. The former was visible if the initial temp. did not exceed 1100°, and the latter appeared only if 1000° was passed. Both critical points appeared in the interval, and both were said to correspond with the formation of pearlite. The tungsten facilitates this duplication of the points, and as the proportion of tungsten increases, a higher initial temp. is needed for the doubling, and at the same time, the temp. of the second recalescence point is lowered. In high-speed steels, the chromium and tungsten were said to lower the second recalescence point below ordinary temp., and thus the softening of the metal due to the formation of pearlite is avoided. H. Pommerenke and R. Deivert, H. Scott, P. Dejean, E. Maurer and W. Haufe, W. Zieler, and A. Merz discussed this subject. F. Osmond showed that with hypereutectoid or supersaturated steels, both tungsten and chromium impede during cooling the segregation of the cementite to such a degree that the rate of cooling can be neglected. The transformation points are lowered during cooling, even slow cooling, more and more as the original content is raised above that of the eutectoid. If the lowering is sufficient, the transformations remain more or less incomplete, and quenching is no longer necessary. The proportion of carbon dissolved is then a function of the temp. of heating and indirectly of the chemical composition. The homogeneous distribution of the carbon, however, is not instantaneous—the dissolution on heating and its segregation on cooling are difficult. If the temp. is not high enough, areas of unequal carburization are produced, and if cooling then commences, each fraction acts as if it were alone, and has a recalescence temp. dependent on the carbon-content, so that the recalescence temp. may appear doubled; and the result is dependent on the initial temp. H. Scott found that tungsten has but a slight effect on the temp. of the transformation of martensite to troostite. H. Sawamura, and F. Roll observed that tungsten promotes the graphitization of cast iron.

H. C. H. Carpenter found that when a steel containing 0·63C and 0·94W is cooled from 1000°, the ranges occur in their normal positions, but when cooled from 1250°, there is a slight lowering of Ar_1 to 664°, and there is a prolonged range from 801° to 706°. The alloy is restored to its original state at 1000°. The heating curve is also dependent on the free-heating for it shows the lower range from 696° to 716° only after being heated to 1250°. When a steel with 0·63C and 10·56W is cooled from 1207°, the beginning of the critical range is not lowered, but the lower limit drops about 260°. The upper range, $Ar_{2,3}$, is quite distinct. The drop in temp. occurs only with the lower limit, thus widening the range. The results are the same whether the alloy be cooled at once from the given temp., or after soaking for a long time at that temp., showing that not many minutes are necessary for equilibrium to be attained. Fairly wide differences in the rate of cooling gave similar results. H. C. H. Carpenter concluded that the action of tungsten or molybdenum consists in hindering or preventing changes in the iron-carbon alloys which result in the softening of the material. Air-quenched high-speed alloys consist almost entirely of white polyhedra resembling austenite. T. Swinden found that below a certain initial " lowering temp.," all the steels examined have the same critical points as carbon steels. In steels below 0·35 per cent. carbon, heating beyond this initial temp. lowers Ar_1 to a definite low point; Ar_2 is practically unaffected; and Ar_3 is gradually suppressed in its normal position, but appears again below Ar_2 forming the upper maximum of the low point. With between 0·35 and 0·9 per cent. carbon, Ar_1 is first lowered, and then increased; heating displaces $Ar_{3,2}$ towards Ar_1; beyond 0·9 per cent. carbon, the $Ar_{3,2,1}$-point is lowered as a whole by heating beyond the lowering temp., and produces a single low point. As the carbon increases, a higher initial temp. is needed for the critical lowering to be effected. The low point is practically constant at 570° for 3 per cent. tungsten steels. The rate of cooling does not affect the position of the low point after lowering has once taken place. The range of the recalescence is not merely widened, but the critical point is at a distinctly lower temp. At Ac_1, on heating, a change of a similar nature to the carbon change occurs; and at the critical lowering temp., a further change in constitution occurs, the reverse of which is at the low point. No recalescence occurs at the critical lowering temp. The microstructure, cooling curves, and hardness of the tungsten steels confirm these conclusions, and indicate that the critical lowering temp. marks a definite reaction in which the tungsten is involved.

As a working hypothesis, H. C. H. Carpenter attributed the low point in tungsten steels to a special carbide containing iron, and either tungsten or manganese, or both; and C. A. Edwards concluded that the low point is not the Ar_1 or the iron carbide change depressed by tungsten, but is due to the slow formation at 1200° of a tungsten carbide which has a critical temp. quite independent of Ar_1. T. Swinden concluded that the similarity in the form of the cooling curve from 1200° to the curve from 900°, the maximum intensity of the low point at 0·9 per cent. carbon, and the general evidence of the microstructures indicate that the low point is not due to the deposition of a tungsten carbide or of a double or triple carbide. The low temp. change in the 3 per cent. tungsten steels is really a separation of cementite from decomposing martensite. It is assumed that iron tungstide, Fe_3W, is formed in the mass and thus passes into soln. at the lowering temp., and the carbide, Fe_3C, is dissolved in this soln. The iron tungstide does not separate until the low point is reached, and the carbide, Fe_3C, immediately follows. The increased electrical resistance beyond the lowering temp. is due to the increase in the proportion of dissolved impurity. S. N. Brayshaw discussed the range of the Ac_1-arrest; and W. Eilender and co-workers, the temper hardness.

L. Guillet found that tungsten steels with 0·20 per cent. of carbon are pearlitic with less than 9 per cent. of tungsten, and show carbide formation with over that proportion of tungsten; while the steels with 0·80 per cent. carbon are pearlitic with less than 4·5 per cent. of tungsten and show carbide formation with over that proportion of tungsten. Quenching exerts the same effect on pearlitic steels as it does on ordinary carbon steels, but the difference which exists between the properties of the steel as annealed, and as quenched, is the more marked as the proportion of tungsten becomes greater. Quenching at 850° produces in steels containing a double carbide an exceedingly fine martensitic structure, and leaves a portion of the carbide undissolved, if the percentages of carbon and tungsten are fairly high. The higher the quenching temp. above 850°, the lower the proportion of carbide remaining unaltered by quenching. Quenching raises the tensile strength, elastic limit, and hardness. Steels containing the double carbide are superficially affected by liquid air-quenching; somewhat coarse needles of martensite are formed when the steel is heated to near 100° and subsequently cooled in air. Annealing slightly softens all tungsten steels, and furthers the formation of grains of carbide. By suitably case-hardening a pearlitic tungsten steel, it is possible to cause the double carbide to appear even when the percentage of carbon in the outer layer is below 0·85 per cent. J. O. Arnold said that a true tungsten steel is formed, with 100 per cent. pearlite, when 11·3 per cent. of tungsten and 0·72 per cent. carbon are present. The pearlite consists of 26Fe+WC. J. P. Gill and L. D. Bowman, P. Oberhoffer and K. Däves, and K. Däves studied the structure of these steels.

R. A. Hadfield observed that the fracture of cast, and of forged, unannealed pieces with a low content of carbon up to 0·20 per cent. changes when about 1·49 per cent. of tungsten has been added, when it becomes finely crystalline. The fine grain increases with increasing proportions of carbon and tungsten, so that when the carbon exceeds about 1 per cent., the fracture becomes silky, and this peculiar fracture is not possessed to the same degree, if at all, by other steels. The molten metal is only slightly less fluid than ordinary steel. The malleability when hot is fairly good, but not equal to that of ordinary commercial steel, and some difficulty was experienced in forging some of the bars with a rather low proportion of manganese. The presence of tungsten—as well as of manganese, chromium, silicon, aluminium, and nickel—in an iron alloy greatly hinders or prohibits the welding of the metal. C. F. Burgess and J. Aston discussed the working properties of the iron-tungsten alloys.

A. Westgren and A. Almin calculated from the X-radiogram data that the vol. per atom of alloys of iron and the contraction are as follow:

Tungsten . . .	0	13·3	40	100 atom per cent.
Volume per atom . .	11·70	12·42	12·48	15·45 A³.
Contraction . . .	—	4·3	5·5	—

A. Osawa and S. Takeda studied the X-radiograms of the alloys and their carbides. Z. Nishiyama found the lattice parameter, *a*; the sp. gr.; and the elastic modulus, *E* kgrms. per sq. cm., at 13·6° to 15·6°, to be:

W . .	1	2	3	4	5	6	7	7 per cent.
a . .	2·861	2·866	2·866	2·866	2·868	2·863	2·869	2·869 A.
Sp. gr. .	7·9112	7·9577	7·9895	8·0430	8·1005	8·1008	8·1495	8·2119
$E\times10^{-6}$.	2·164	2·157	2·153	2·174	2·101	2·134	2·085	2·150

—*vide infra.* E. C. Bain, and E. P. Chartkoff and W. P. Sykes measured the lattice parameters of the solid soln. R. A. Hadfield found the sp. gr. of an alloy with 0·15 C and 0·20 W to be 7·676; with 0·21 C and 1·49 W, 7·683; with 0·28 C and 3·40 W, 7·792; with 0·46 C and 8·33 W, 8·109; and with 0·78 C and 16·18 W, 8·602. W. Brown found with 0·16 C, 0·11 Mn, and 1·0 W, the sp. gr. and sp. vol. were respectively 7·9365 and 0·12600; with 0·28 C, 0·28 Mn, and 3·5 W, 8·0645 and 0·12400; with 0·38 C, 0·20 Mn, and 7·5 W, 8·2918 and 0·12060; and with 0·76 C, 0·28 Mn, and 15·5 W, 8·7720 and 0·11400. With up to 15 per cent. of tungsten, therefore, the sp. vol. decreases by 0·0009 c.c. per 1 per cent. of tungsten. A. S. Townsend found the sp. gr. of tungsten steels to vary with the proportion of contained tungsten in the following manner:

Sp. gr. .	8·60	8·63	8·66	8·69	8·72	8·75	8·78	8·80
W . .	15·92	16·53	17·14	17·76	18·37	18·98	19·59	20·00 per cent.

with an error of ±0·30 per cent. F. Stäblein found that the sp. gr. of the tungsten-iron alloys increases by 0·048 for every 1 per cent. of added tungsten. C. Benedicks and co-workers, J. O. Arnold, and B. Simmersbach made some observations on this subject. C. Benedicks studied the sp, vol.

R. A. Hadfield made some observations on the hardness of tungsten steels quenched from 750°, 950°, and 1200° in cold water. Observations were also made by C. A. Edwards, W. Zieler, O. Böhler, H. Scott, G. Mars, K. Taniguchi, etc. W. P. Sykes observed that Brinell's hardness increases continuously with the addition of up to about 50 per cent. of tungsten. The hardness of some alloys when water-quenched from 1500° is increased as much as 130 per cent. by annealing at 600°–700°. In the annealing at a given temp., a maximum hardness is attained, and this decreases as the annealing is prolonged. The higher the temp. of annealing above a certain minimum temp., the more rapidly the hardness increases, but the lower the temp. at which maximum hardness is attained. The development of the secondary hardness is accompanied by the separation of iron tritaditungstide. *Vide infra*, Table LXXXII, for some data. F. Osmond observed that a steel with 0·48 C and 6·0 W, remained soft when slowly cooled from a white-heat, and had an arrest between 505° and 485°, but when heated at 555°, it became glass-hard. L. Guillet found that with pearlitic steels, the hardness increases rapidly as the proportion of tungsten is raised; and with the carbide steels, the hardness increases as the proportion of carbon is raised. No self-hardening was observed, but T. Swinden observed that self-hardening occurred with a 3 per cent. tungsten steel, and a high initial temp. S. N. Brayshaw found that a 1·19 C and 0·57 W steel, when quenched from 731°, which is below the hardening temp. 738°, did not increase in hardness, but other steels heated above the hardening temp. for 10 mins., and then kept from 30 to 240 mins. below the hardening temp. and quenched in water, were hardened. Thus, with the first heating at 760°, and the second at 731° for 30, 120, and 240 mins., the Brinell's hardnesses were respectively 600, 477, and 241, and the scleroscopic hardnesses respectively 103, 88, and 53; again, with the first heating at 890°, and the second at 725°, for 30, 120, and 240 mins., the Brinell's hardnesses were respectively 418, 207, and 187; and the scleroscopic hardnesses respectively 82, 51, and 38. The transformation from the hard to the soft state is completed within a range of six degrees of the hardening temp.; the hardening temp. is represented by an arrest on the heating curve; if the quenching temp. is over 20° or 30° above the hardening temp., the steel becomes softer. E. G. Herbert, W. P. Sykes and A. C. Ellsworth, H. B. Pulsifer, and L. Grenet discussed the hardening of these steels. G. Tammann and V. Caglioti discussed the recovery of the hardness after cold-work. E. C. Bain and Z. Jeffries suggested the following explanation of the red-hardness of these steels:

> The changes which cause the martensite in carbon steel to soften are grain-growth of the ferrite and growth of the carbide particles above critical size. Similar changes in high-speed steel take place only at a red-heat. The outstanding reasons for the retention at red-heat of fine grains in the ferrite of high-speed steel are the increased resistance to growth, due to the elements in atomic dispersion in the ferrite and the copious presence of obstructing carbide particles. The reason for retention at red-heat of carbide particles of critical size is the great stability of the iron-tungsten carbide and the large size of the tungsten atom. The great stability of this double carbide favours its formation to the exclusion or elimination of other carbides when the necessary atoms are available. The large size of the tungsten atom prevents its diffusion in the ferrite space-lattice until a temperature corresponding to a red-heat is reached. The double carbide is an intermetallic compound, which owes its existence entirely to crystallization. The formation of a particle of this carbide, therefore, requires a number of tungsten atoms, which must be supplied by diffusion through the ferrite lattice. The precipitation and growth of the double carbide in quenched high-speed steel at a dull red-heat is, therefore, somewhat comparable to the precipitation and growth of cementite in quenched carbon steel below 300°.

A. M. Portevin found that the hardness of tungsten steel increases with the quenching temp., and with the time of heating at this temp. Thus:

Per cent.		Minutes heated	Hardness when quenched from			Hardness when annealed
Carbon	Tungsten		800°	950°	1050°	
0·09	5·30	2	216	263	—	158
		30	284	289	—	
0·06	13·54	2	192	183	291	180
		30	212	200	315	
0·70	10·29	2	260	501	—	223
		30	473	600	—	
0·66	15·03	2	414	664	766	265
		30	670	695	--	

—*vide infra*, magnetization. The so-called *tungsten carbide steels*, produced by the cementation of tungsten steels, are valued for their hardness. They were discussed by R. D. Prosser, L. L. Wyman and F. C. Kelley, C. M. Thompson, C. Sellers, T. G. Digges, M. Nakamura, and J. L. Gregg and C. W. Küttner.

In his experiments on the effect of alloying different metals with steel, R. F. Mushet, about 1868, observed that while ordinary steel is hardened by abrupt cooling from a red-heat, as it is quenched in water, some bars of steel alloyed with tungsten seemed to have the property of becoming hard after heating, without the usual quenching. Indeed, the unquenched tungsten steel was harder without the usual quenching than ordinary steel which had been quenched. Hence, R. F. Mushet investigated this alloy with the idea of producing a superior tool steel which could be employed for cutting at speeds above those at which ordinary steel tools become overheated by friction near the cutting edge, with a consequent drawing of the temper, the rubbing away of the edge, and the ruin of the tool. It was soon found that the cooling of the bars of the tungsten steel exposed in a draught of air gave a better steel than if cooled where there was no draught; and still better results were obtained by cooling the metal in an air-blast. The composition of one of R. F. Mushet's steels is C, 2·0; W, 5·0; Cr, 0·5; Mn, 2·5; and Si, 1·3 per cent., and a steel of this character is sometimes known as a **Mushet steel.** The steels were then called **self-hardening steels,** and also **air-hardening steels.** M. A. Grossmann and E. C. Bain, and D. M. Giltinan discussed the history of these steels. O. M. Becker gives the following for the percentage composition of self-hardening steels:

	C	W	Cr	Mn	Si	P	S
High .	2·4	11·6	3·4	3·5	1·04	0·080	0·050
Low .	1·1	4·5	0·07	0·08	0·16	0·016	0·004
Mean .	1·8	7·3	1·6	1·8	0·56	0·032	0·015

One sample was reported with 4·58 per cent. molybdenum. The excellence of the steel is dependent on the care exercised in subjecting it to the required heat-treatment when it is being prepared. F. W. Taylor, and others observed that the capacity of these self-hardening steels for cutting at high speeds is considerably enhanced when subjected to a heat-treatment at temp. which would ruin ordinary steels. The superheated steels, in fact, stood up to their work much better than when given the usual treatment. In fact, it was found that the heat-treatment could be carried up to nearly the m.p. and it would give better results than when the temp. of the heat-treatment is lower. Beyond 925°, a slight increase in the hardening temp. raises the cutting power in an extraordinary way. Hence the term **high-speed steels,** and **rapid steels.** The high-speed steels are partially self-hardened. O. M. Becker gave for the composition of high-speed steels:

	C	W	Mo	Cr	V	Mn	Si	P	S
High .	1·28	25·45	7·6	7·20	0·32	0·30	1·34	0·029	0·016
Low .	0·32	14·23	0·0	2·23	0·00	0·03	0·43	0·013	0·008
Mean .	0·75	19·00	3·5	4·00	0·30	0·13	0·22	0·018	0·010

The vanadium was found in three of the steels analyzed. The difference between the self-hardening and the high-speed steels is more of degree than kind, so that the Mushet steel becomes a high-speed steel if it has been subjected to the superheating process. In ordinary steel, the austenitic structure can be obtained only under special conditions, because it changes so rapidly to the martensitic structure. Martensite, however, passes into pearlite comparatively slowly. The martensitic structure is obtained by suddenly quenching the metal from a bright red-heat. Martensite is hard and brittle, so that for the sake of durability some hardness is sacrificed by tempering the metal so as to let it down to any degree towards the pearlite stage where the metal is soft and tough. The presence of tungsten hinders the passage from austenite to pearlite, so that in order to obtain the pearlite structure in the presence of, say, 7 per cent. of tungsten, the cooling must be extremely slow. Martensite is not stable in ordinary steel unless the metal is kept cool. In the presence of over 7 per cent. of tungsten, the stability of martensite becomes so great that the steel can be heated above the ordinary tempering heats before the martensite begins to change into pearlite.

J. H. Andrew and G. W. Green, A. H. d'Arcambal, J. O. Arnold and co-workers, G. Auchy, H. W. Baker and A. H. Gibson, R. K. Barry, O. M. Becker. A. E. Bellis, C. Benedicks, C. H. Benjamin, C. P. Berg, F. Bischoff, P. Blum, O. Böhler, W. V. Brandt, S. N. Brayshaw, L. P. Breckenridge and H. B. Dirks, G. R. Brophy and R. H. Harrington, W. Brown, A. Campion, H. C. H. Carpenter, J. Pölzguter and W. Zieler, H. Pommerenke and R. Dewert, F. Rapatz, F. Rapatz and H. Kallen, F. Rapatz and H. Pollack, F. Reiser, E. W. Rettew, E. L. Rhead, E. D. Rogers, H. W. Rushmer, K. Sasagawa, G. Schlessinger, E. Schulz and co-workers, H. Scott, F. Seiler, B. F. Shepherd, E. Sievers, O. Smalley, E. K. Smith and H. C. Aufderhaar, J. Spüller, A. Stockall, M. Vasvari, J. Wagner, F. Walker, J. W. Weitzenkorn, W. H. Wills, A. J. Wilson, A. D. Wilt, W. Wrazei, W. Zieler, and E. Zingg and co-workers made observations on the mechanical properties of tungsten steels. V. Ehmcke studied the influence of silicon and manganese on the properties of high-speed steel.

F. Robin studied the acoustic properties of tungsten steels. F. W. Harbord said that additions of up to 1·5 per cent. of tungsten had no appreciable effect on the mechanical properties of mild steel. Z. Nishiyama's observations on the elastic modulus are indicated above. L. Guillet observed that the pearlitic tungsten steels had a tensile strength and elastic limit which becomes higher in proportion as the percentage of tungsten increases, while the elongation, reduction of area, and resistance to shock diminish as the proportion of tungsten rises. With the carbide steels, the tensile strength and elastic limit vary little with the proportion of tungsten, if anything they diminish. They become higher as the proportion of carbon increases. W. P. Sykes found that the tensile strength is affected by annealing very like the hardness, and that a decrease in ductility accompanies an increase in tensile strength. T. Swinden's results on normalized steel are indicated in Table LXXX. The tests show the toughening influence of tungsten as the

TABLE LXXX.—MECHANICAL PROPERTIES OF TUNGSTEN STEEL.

Percentage composition		Elastic limit (tons per sq. in.)	Maximum stress (tons per sq. in.)	Elongation (per cent. in 2 in.)	Reduction of area (per cent.)	Compression (per cent. under 100 tons per sq. in.)	Alternating stress (alternations)

proportion of carbon increases. The compression is rather less than is usual with steels without tungsten. Tungsten imparts no beneficial influence to the resistance of steel to repeated impact. An average boiler-plate gives about 350 alternations. K. Honda and T. Terada gave for the coeff. of elasticity, *E*, of tungsten steel from $1{\cdot}928\times10^{12}$ with a load, 1758 grms. per sq. mm., to $1{\cdot}945\times10^{12}$ with a load of 11,523 grms. per sq. mm. The coeff. of rigidity is $0{\cdot}608\times10^{12}$ at 14·0°. For the effect of magnetization on the elastic constants, *vide infra.* W. Giesen observed that pearlitic steels with 0 to 15 per cent. of tungsten and 0·3 per cent. of carbon, or 0 to 8 per cent. of tungsten and 0·95 per cent. of carbon, show an increase in tensile strength, limit of stretch, and breaking load with increasing proportion of tungsten, but the ductility diminishes. The hardness is generally a little greater than carbon steels with the same proportion of carbon. The brittleness remains unchanged even when the proportion of tungsten is 15 or 18 per cent. in the presence of respectively 0·3 and 0·95 per cent. carbon. With this high proportion of tungsten, the only properties that vary are elastic limit, and ductility, which increase but slightly, and breaking load, which rises with the content of carbon and tungsten. Pearlitic steels with 0·25 per cent. carbon and over 9 per cent. tungsten, or 0·85 per cent. of carbon and over 4 per cent. tungsten, increase in hardness as the proportion of tungsten rises. Tungsten steels with double carbide attain sufficient hardness only when the carbon content is high, but the great fragility remains the same. C. L. Clark and A. E. White measured the effect of temp. on the tensile properties; V. Ehmcke studied the effect of nickel and manganese on high-speed steels. R. A. Hadfield observed no abnormal behaviours when the steel is cooled to —182°. The observations of K. Honda and T. Matsushita on the modulus of elasticity and rigidity of tungsten steels, in dynes per sq. cm., are summarized in Figs. 462 and 463. The dotted curves refer to steels heated to 1100° and quickly cooled, and the maximal values due to the presence of carbide, as in the conductivity-concentration curves. F. Pölzguter and W. Zieler studied the effect of annealing on the properties of tungsten steels.

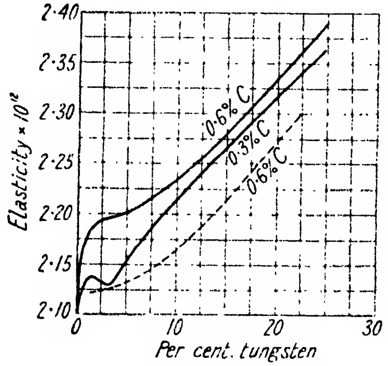

FIG. 462.—The Elasticity of Tungsten Steels.

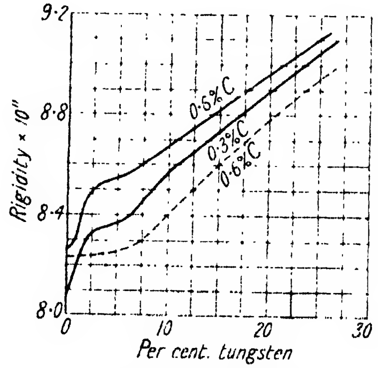

FIG. 463.—The Rigidity of Tungsten Steels.

K. Honda and T. Matsushita measured the coeff. of thermal expansion, and the results at 100°, 500°, and 850° are shown in Fig. 464. The values at 100° and 500° resemble the conductivity curves (*q.v.*). Here there are two maxima, one corresponding with the presence of the double carbide. F. Stäblein found that the mean coeff. of thermal expansion decreases with increasing proportions of tungsten; and the heat conductivity is but little affected by increasing proportions of tungsten. The electrical and thermal conductivity curves are shown in Fig. 465. The samples were annealed at 900° and then slowly cooled to room temp.

Generally speaking, a metallic compound has a less conductivity for electricity and heat than one of its components; thus cementite, tungsten carbide, and the double carbide all possess much less conductivity than pure iron. Hence, as the content of tungsten increases, the conductivity of the tungsten steels increases in virtue of the diminution of cementite, and decreases owing to the increasing content of tungsten carbide, and of double carbide and tungstide. The variation of the conductivities of the tungsten steels with the conc. of tungsten is then the resultant of these effects. But in steels whose tungsten-content is less than 5 per cent., the quantity of the double carbide is large as compared with other compounds, and therefore the variation of the conductivities is principally effected by the double carbide. The quantity of the carbide increases from zero, reaches a maximum at 1·84 per cent. of tungsten, and then decreases; hence, with the addition of tungsten, the conductivities must at first rapidly and afterwards slowly decrease, until they reach a minimum at 1·84 per cent. of tungsten and then slightly increase. These theoretical conclusions are in exact agreement with the observed facts. The steady decrease of the two conductivities after reaching a small maximum, as actually observed, is attributed to the increasing content of tungsten carbide and tungstide at the cost of pure iron. In the series of tungsten steels containing 0·3 per cent. of carbon, the quantities of the carbides are only half as large as in the former series. Hence, the minimum and maximum in the conductivity-concentration curves in this series must be much less conspicuous than in the last case; this conclusion also agrees with the observed facts. W. Brown found that the sp. ht. of a 0·16 C, 0·11 Mn, and 1·0 W steel is 0·1162; 0·28 C, 0·28 Mn, and 3·5 W, 0·1136; 0·38 C, 0·20 Mn, and 7·5 W, 0·1100; and 0·76 C, 0·28 Mn, and 15·5 W, 0·1041. There is an increase in the sp. ht. of steel by 0·0028 by the addition of 1 per cent. of tungsten, and with 3·5 per cent., the sp. ht. is the same as that of iron; while with the addition of 15 per cent., the sp. ht. is lowered 0·0093. F. Wüst and co-workers gave for the mean sp. ht. between 0° and θ° up to 1500°, $0{\cdot}03325+0{\cdot}000001 07\theta$; and for the true sp. ht. at θ°, $0{\cdot}03325+0{\cdot}00000214\theta$.

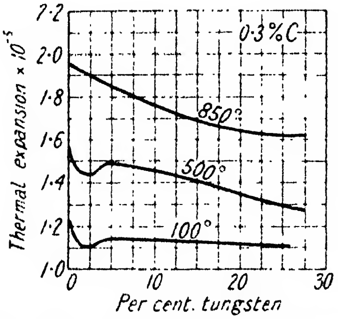

FIG. 464.—The Thermal Expansion Curves of Tungsten Steels.

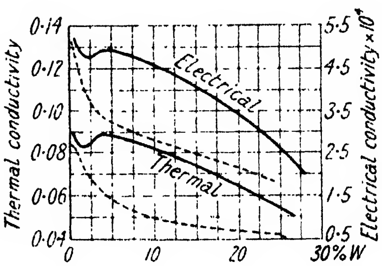

FIG. 465.—The Thermal and Electrical Conductivities of Tungsten Steels.

Observations on the electrical resistance, *R*, of tungsten steel were made by W. F. Barrett and co-workers, L. Guillet, O. Boudouard, etc. W. F. Barrett and co-workers gave 1·1 microhms, and A. M. Portevin, 1·5 microhms per cm. cube for the increase in the resistance of iron produced by 1 per cent. of tungsten. F. Stäblein found that the sp. resistance increased linearly with up to 7 per cent. of tungsten, and then remained nearly constant. A. M. Portevin gave for the resistance, *R* microhms per cm. cube, for steels with less than 0·28 per cent. of carbon:

W . .	0·41	0·93	1·75	6·90	11·89	14·37	20·71	27·05 per cent.
R {normal .	12·8	13·5	15·8	25·3	20·9	22·6	23·1	20·7
R {quenched .	13·8	14·3	17·1	23·4	24·5	24·6	25·3	25·8

For the electrical conductivity, *vide* Fig. 465. The results agree with C. Benedicks' formula with up to 7 per cent. of tungsten, indicating that the tungsten is in solid soln. With 0·8 carbon steels :

W . .	0·40	0·95	2·75	4·68	9·99	14·75	19·25 per cent.
R normal .	22·4	20·9	24·3	28·1	26·9	26·5	25·3
R quenched .	39·1	39·6	40·9	41·2	39·5	32·3	31·0

The agreement with C. Benedicks' formula with up to 5 per cent. of tungsten is taken to mean that this amount of tungsten is in solid soln. H. le Chatelier found :

	0·6 C, 5·0 W				0·76 C, 2·7 W.			
Quenching .	760°	800°	850°	1100°	730°	780°	850°	1100°
R . .	21·0	29·4	31·5	37·8	25·9	29·6	31·5	35·2

The increased resistance on quenching beyond the lowering temp. agrees with the assumption that a tungsten compound passes into soln. This was also observed by T. Swinden, who obtained :

C . . .	0·144	0·218	0·27	0·48	0·53	0·57	0·89	1·07 per cent.
W . . .	3·25	3·24	2·92	3·11	3·18	3·17	3·08	3·09 ,,
R annealed .	17·31	17·50	—	18·87	18·40	18·56	17·64	16·97
R normalized .	16·68	17·63	17·63	19·12	18·46	19·98	18·76	18·43
R hardened .	19·24	19·33	20·20	23·87	25·64	26·68	36·6	38·70

G. Tammann and V. Caglioti discussed the recovery of the resistance after cold-work. P. W. Bridgman studied the press. coeff. of the resistance. E. L. Dupuy and A. M. Portevin found the thermoelectric force of tungsten steel against copper, expressed in millivolts, to be :

C . . .	0·18	0·11	0·20	0·22	0·86	0·66	0·81	0·71%
W . . .	0·41	1·75	14·37	20·71	0·40	0·95	9·99	14·74%
Annealed −80° .	9·00	7·60	7·60	7·85	1·80	2·50	4·90	2·70
Annealed 100° .	6·30	5·24	6·40	6·30	−0·08	0·50	3·00	0·60
Hardened −80° .	8·40	6·70	7·80	7·90	−1·60	1·10	2·80	0·00
Hardened 100° .	5·70	4·75	7·40	7·25	−4·15	−1·70	1·30	−1·40

S. Curie found that tungsten increases the coercive force and residual magnetism of steel. On heating, it still loses its magnetic properties between 700° and 750°, and regains them on cooling, but at a rather lower temp. than that at which the loss occurs on heating. L. W. Wild, A. Abt, S. Saito, C. C. Trowbridge, C. Chistoni and G. G. de Vecchi, E. Gumlich, R. L. Dowdell, J. Würschmidt, E. A. Watson, S. Evershed, G. Hannack, A. M. Parkin, T. Spooner, K. G. Brecht and co-workers, N. I. Spiridovich, and B. Hopkinson made observations on the magnetic properties of tungsten steels. W. F. Barrett observed that as the carbon and tungsten increased, the coercive force increased, while the maximum induction, for $H=45$, decreased ; thus :

		Intensity of Magnetization		
C	W	Maximum	Remanent	Coercive force
—	0·00	1335	778	1·66
0·22	1·20	1320	568	3·23
0·28	3·40	1305	998	5·73
0·38	7·47	1266	1081	9·02
0·76	15·65	920	766	13·92

The retentivity or remanence of the steel with about 7·5 per cent. tungsten steel is high, in agreement with the observation that the tungsten is specially well suited for making permanent magnets. R. A. Hadfield said that one peculiar effect of tungsten in high-carbon steel is the great increase in retentiveness ; but with steels low in carbon the effect is not so marked. This is taken to mean that the action of tungsten is indirect in causing the carbon present to become very intimately combined. Tungsten in the presence of low-carbon steel interferes with the permeability much less than chromium, nickel, and other elements. Probably, therefore, tungsten steel with high carbon, more readily permits the steel to become permanently magnetized, so that in its presence the intimate union of carbon and iron in the quenched steel enables the imparted magnetic energy to be retained. T. Swinden made a series of observations on approximately 3 per cent. tungsten steel, normalized by heating it to 950° for 15 mins. and cooling freely in air; annealed by heating 3 hrs. at 950°, and kept between 930° and 960° for 90 mins. and cooled over 8 hrs. in the muffle; hardened, by heating to 900° and quenching in water; and tempered at 60°–75° for 14 hrs. A selection from the results is summarized in Table LXXXI. In Table LXXXI, A. denotes annealed; N., normalized; H., hardened; and T., tempered. As the proportion of carbon increases, the maximum induction decreases, and the maximum remanent intensity is unimpaired by the 3 per cent. of tungsten. The remanent magnetism is higher than for quenched carbon steels. With lightly annealed tungsten steels, the coercive force is almost identical with that of comparable carbon steels. S. Curie observed that with steels with a higher proportion of tungsten, the coercive force is increased irrespective of carbon. F. Stäblein found that the coercive force of iron-tungsten alloys rises sharply with up to between 5 and 10 per cent. of tungsten, reaching a well-defined maximum at 15 per cent. of tungsten. The subject was discussed by F. W. Harbord; and W. F. Barrett and co-workers obtained better results for magnetic steels when manganese was absent. T. Swinden found that annealed, 3 per cent. tungsten steels gave hysteresis losses very little different from carbon steels, while with the normalized steel, the losses were higher, and still higher with hardened steel. J. O. Arnold inferred that in iron containing 0·1 to 0·9 per cent. of carbon, and quenched, the permanent magnetism is directly proportional to the hardening carbon. The ratio of the remanent and permanent magnetism increases steadily with up to 0·53 per cent. carbon with the annealed and normalized

TABLE LXXXI.—MAGNETIC PROPERTIES OF TUNGSTEN STEEL ($H = 150$ C.G.S. UNITS).

bars; the tempered steel gave a uniform increase up to 0·9 per cent. carbon; and the hardened steel gave a maximum with 0·4 per cent. carbon. In general, a steel which is physically hard has a high coercive force and a high remanent magnetic intensity. G. Mars discussed this subject, and his results for tungsten steel are summarized in Table LXXXII, the data for the magnetization refer to arbitrary units on the magnetometer, and to steels quenched, from the temp. named, in water at 10° to 15°. He also obtained results for chromium-tungsten steels. These steels were also examined by L. Guillet, F. Osmond, and W. Brown. U. Adelsberger discussed the hysteresis losses. The magnetic properties of the tungsten steels were examined by J. Trowbridge and S. Sheldon, H. Scott, W. Siemens, and C. W. Siemens. R. L. Sanford and W. L. Cheney observed the maximum induction of oil-quenched tungsten steel to be 11,200, and the coercive force, 68·0. W. A. Wood found that the coercive force may be reduced to a fifth of its optimum value at about 950°, and it can be restored by heating to 1250°. The hardness varies in the same way. The decrease in magnetic quality and hardness at about 900° is due to the disappearance of lattice distortion, and the recovery at 1250° is due to the re-introduction of the distortion. Lattice distortion is the main factor in the spoiling and recovery of tungsten magnet steels.

TABLE LXXXII.—THE HARDNESS AND MAGNETIZATION OF TUNGSTEN STEELS.

Composition				Hardening temp.	Brinell's hardness	Magnetization		
C	Si	Mn	W			Just after magnetizing	After 8 days	Percentage loss
1·15	0·20	0·23	0·68	780°	600	69·5	68·5	2·9
1·16	0·19	0·20	1·20	750°	744	76·5	76·0	1·3
0·64	0·25	0·26	1·12	820°	713	76·5	73·5	3·9
0·62	0·22	0·20	1·96	800°	782	85·5	84·5	1·8
1·20	0·28	0·29	3·22	740°	782	66·5	65·5	4·5
0·57	0·18	0·26	5·47	930°	782	90·5	90·5	0
1·25	0·27	0·30	8·65	930°	782	61·0	58·5	4·1
1·25	—	—	30·0	850°	578	19·0	—	—

K. Honda and S. Shimizu found that the intensities of magnetization, I, with different field-strengths, H, at −186° were:

H	1·37	5·89	12·40	28·8	62·7	272·4	570
I	13	64	254	1035	1236	1468	1557

and at 30·7°:

H	2·16	6·91	10·35	25·8	111·2	333	557
I	21	104	376	1064	1326	1463	1509

K. Honda and S. Shimizu measured the magnetostriction of tungsten steel. K. Honda and T. Terada found the change in the coeff. of elasticity, $\delta E/E$, by magnetization is small, gradually increasing as the strength of the magnetic field increases; $\delta E/E \times 10^2$ rises from 0·08 with $H=245$, to 0·10 with $H=380$. The magnetostriction or elongation, $\delta l/l$, by magnetization increases at first rapidly, then slowly, and finally decreases. With a load of 1693 grms. per sq. mm., $\delta l/l \times 10^6$ rose from 0·03 to 1·39 as H changed from 10·0 to 24·9, and from 1·39 to 3·72 as H changed from 24·9 to 167·2, and it fell to 3·28 as H rose to 399. With a load of 5762 grms. per sq. mm., $\delta l/l \times 10^6$ rose from 0·03 to 1·05 as H increased from 8·9 to 25·0; it then rose to 2·51 as H was raised to 166·0, and fell to 1·93 as H changed to 397. The increase in the rigidity, $\delta k/k \times 10^2$, with magnetization is small, rising from zero with $H=136$ to 0·51 with $H=429$. The change in Poisson's ratio, $\delta\sigma/\sigma \times 10^2$, rose from zero with $H=100$ to 0·3 with $H=300$. The change of magnetization, δI_i, with initial loading, and δI_c, with cyclic loading, for loads in tension, T grms. per sq. mm., is :

	T	1625	4837	8092 grms. per sq. mm.
$H = 4{\cdot}08$	δI_i	0·4	2·6	6·5
	δI_c	0·2	0·4	0·7
$H = 341$	δI_i	−0·3	−1·5	−2·8
	δI_c	−0·3	−1·7	−3·4

K. Honda and T. Terada also found that with a constant tension the magnetization increases rapidly in low fields, and gradually approaches saturation. They also examined the effect of a twist, and of a combined twist and tension on the magnetization. In all cases the reciprocal nature of the changes of strains by magnetization and of the changes of magnetization by strain were established. For instance, magnetic elongation under constant tension, and of magnetization under constant tension ; of elongation by tension under a constant field, and the change of magnetization by tension under a constant field ; of magnetic twisting under a constant couple, and magnetization under a constant twist ; and of the change of rigidity under a constant field ; and the change of magnetization by twist under a constant field.

E. Martin studied the absorption of hydrogen and nitrogen by tungsten steels ; and L. Losana and G. Reggiani, the corrosion of tungsten steels. According to R. A. Hadfield, the percentage losses in weight which occurs after the metal has been immersed for 21 days in 50 per cent. sulphuric acid, were :

C	0·15	0·21	0·28	0·38	0·76	0·78 per cent.
W	0·20	1·49	3·40	7·47	15·65	16·18 ,,
Loss	5·01	3·50	2·25	4·50	5·75	5·50 ,,

when the percentage loss with ordinary steel was 3·97 ; with mild steel, 2·09 ; and with 99·80 per cent. iron, 4·52.

L. B. Pfeil observed a three-layer scale—*vide supra* - is formed when tungsten steel is heated for several hours at 1000° in air. The tungsten is about twice as concentrated in the innermost layer as it is in the original steel ; tungsten also occurs in the middle layer, but very little is present in the outer layer. Some tungsten oxide is volatilized, but not enough to explain the impoverished outer layer. C. Chappell said that the presence of 3 per cent. of tungsten has practically no effect on the corrodibility of carbon steels by sea-water. Y. Utida and M. Saito found the gain in weight, in grams per sq. cm., when the tungsten steel with about 0·07 per cent. of carbon is heated for an hour at 1100° ; and the loss in weight, in grams per sq. cm., when the metal is immersed in 10 per cent. acid for 24 hrs. :

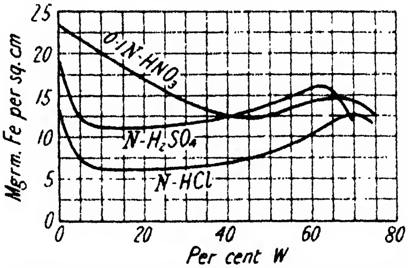

FIG. 466.—Corrosion of Iron-Tungsten Alloys by Acids.

Tungsten	0	0·40	0·73	2·85	4·63	6·63	8·24 per cent.
At 1100°	0·0212	0·0397	0·0344	0·0291	0·0221	0·0227	0·0306
HNO_3	0·9380	0·5890	—	0·5642	0·5207	0·4545	0·3175
HCl	0·0712	0·1427	0·1222	0·0576	0·0335	0·0183	0·0117
H_2SO_4	0·0990	0·9796	0·0638	0·0476	0·0328	0·0278	0·0172

H. Endo's results, shown in Fig. 466, represent the losses, in grams per sq. cm., in 5 hrs. at ordinary temp., with alloys containing 0·50 to 0·56 per cent. of carbon, and the given amounts of tungsten. The results of G. Grube and K. Schneider showed that the greatest attack occurs with the alloy corresponding with the compound Fe_3W_2. C. F. Burgess and J. Aston found that the progress of the corrosion of alloys of tungsten and iron, expressed in grams per sq. dm., by

20 per cent. sulphuric acid for an hour; and by exposure to weather conditions for 162 days from July to February, expressed in kgrms. per sq. metre, is as follows:

W .	0·406	0·925	2·334	3·553	5·982	9·849	13·641	23·866 per cent.
Acid .	0·363	0·088	0·086	0·332	0·304	0·398	0·365	0·183
Air .	0·371	0·302	0·302	0·308	0·293	0·195	0·329	0·215

L. Aitchison found for the loss in weight per 100 sq. cm. of tungsten, with nearly 3 per cent. of tungsten:

C	0·47	0·20	0·58	0·88	1·08 per cent.
NaCl 3 per cent. .	1·56	1·68	1·83	1·04	1·70
H_2SO_4 1 per cent. .	2·16	2·87	6·4	3·69	3·98
10 ,, .	2·80	5·37	4·95	5·13	4·83

and for steels with nearly 0·7 per cent. of carbon:

W . .	2·36	5·37	9·74	14·96	21·5	26·3 per cent.
Tap-water .	0·970	0·930	0·976	1·100	0·940	0·970

S. Satoh studied the nitridization of these steels by heating them in ammonia at 560° to 580°; and O. Bauer, J. S. de Benneville, C. Duisberg, R. A. Hadfield, and W. H. Hatfield studied the retarding effect of tungsten on the corrosion of steel. F. Osmond studied the corrosion of a Mushet's chromium-tungsten steel with 1 per cent. sulphuric acid. G. Mars, and O. Bauer also made observations on this subject. Y. Utida and M. Saito found that tungsten decreases corrosion, but L. Aitchison said that it does not appreciably reduce corrosion when it is present in the carbide phase.

E. Maurer and W. Haufe discussed some **tungsten-silicon-iron alloys**; and J. Swan, the effect of silicon on some tungsten magnet steels; H. J. French, W. Kahlbaum and co-workers, A. Schevchenko, and H. Pommerenke and R. Dewert, the **chromium-tungsten-vanadium steels.** According to E. Maurer and co-workers, the addition of chromium increases the solubility of tungsten in steel. A. Schevchenko, and L. Guillet prepared **tungsten-chromium steels** containing from 0·124 to 0·849 per cent. of carbon, 0·94 to 20·44 per cent. of chromium, and 1·98 to 20·3 per cent. of tungsten. The structures which the hypoeutectoidal tungsten-chromium steels can assume are: pearlite, martensite, martensite and carbide, carbide with a background probably of sorbite, and carbide with a background of γ-iron. The influence of tungsten may be superadded to that of chromium with the production of martensite. The most frequently occurring structure is that with grains of carbide more or less numerous on a background of what is thought to be sorbite. When tungsten is added to a pearlitic chromium steel, it adds its influence to the chromium to form martensite; if an excess be added, martensite is not formed, but troostite or sorbite. If the percentage of carbon reaches 0·5, a carbide, probably a triple carbide, is formed. If tungsten be added to a martensitic chromium steel, the steel remains martensitic so long as the proportion of tungsten is small; if otherwise, carbide is formed with a background of probably sorbite. The addition of tungsten to a chromium steel already containing carbide has the effect of increasing the proportion of carbide only. Quenching at 850° transforms pearlitic steels into martensitic steels, and partly so with steels containing carbide. When a tungsten-chromium steel containing carbide is quenched from 850°, in water at ordinary temp., the amount of carbide is somewhat diminished, but the carbide does not all disappear; if the steel contains troostite, it becomes martensitic, but with steels containing high proportions of carbon and tungsten, part of the troostite persists; if the steel is martensitic, it remains so, but a little γ-iron may be formed; and if it contains γ-iron, that constituent remains. If steels be heated to 1250°, the longer the period of heating, previous to quenching, the greater the proportion of carbide which is destroyed. Half an hour's heating at 1200° was sufficient to cause the carbide to disappear in all the cases examined. Similar effects can be obtained by heating the steel for a longer time at a lower temp. Annealing has no perceptible effect on the microstructure, excepting that the carbide, if present, becomes a little better defined. Cooling in liquid air, or subjecting the steel to stresses, produced no change in the microstructure. The case-hardening of all the carbide steels increases the proportion of carbide, and a martensitic steel containing carbide undergoes in the case-hardened portion a transformation into troostite or sorbite; whilst martensitic steels not containing carbide have, after case-hardening, carbide embedded in a background of troostite. J. S. de Benneville, K. Honda and T. Murakami, and A. Michel and P. Bénazet studied the structure of the chromium-tungsten steels. A. E. White and C. L. Clark found that a steel with 7·93 per cent. of chromium, and 7·70 per cent. of tungsten, quenched from 1232°, had the highest proportional limit yet recorded at 538°, namely, 100,000 lbs. per sq. in.

L. Guillet found that the mechanical tests on the normalized steels show that with the pearlitic steels, the tensile strength, elastic limit, and resistance to shock are raised, and the elongations are lowered. The martensitic steels have a high tensile strength and elastic limit, and a low elongation; they are also hard and brittle. Steels containing both carbide and martensite have a high tensile strength, a low elastic limit, and a medium elongation; they are hard and brittle. Similarly also with steels containing carbide and sorbite. Here the mechanical properties vary but little with the proportions of the various elements present, except the elastic limit which slowly increases as the carbon and chromium increase, and is reduced when the proportion of tungsten is high. Steels containing carbide, and polyhedra of γ-iron, have a low tensile strength, elastic limit, elongation, and reduction of area, while the brittleness is high. On quenching from 850°, when the proportions of chromium and tungsten are fairly constant, the hardness increases as the percentage of carbon is raised; when the proportion of tungsten alone varies, the hardness reaches a maximum with 8 per cent. tungsten—carbon $>$0·73 per cent.; and when the proportion of chromium alone varies, the hardness is reduced as the percentage of chromium increases owing to the fact that it becomes increasingly difficult to dissolve the triple carbide. When the steel is quenched from 1200°, the hardness of all steels containing carbide is increased owing to the dissolution of the carbide, and prolonging the period of heating before quenching increases the hardness to a maximum. A similar result is obtained at a lower temp. if the duration of heating be prolonged. The more energetic the quenching medium, the lower the degree of hardness owing to the presence of γ-iron. Annealing at a high enough temp., 900° to 1200°, increases the grains of carbide and induces extreme brittleness, lowers the tensile strength and elastic limit, and reduces the elongation and reduction of area. W. Kahlbaum and co-workers, E. Maurer and W. Haufe, and W. Schneider and E. Houdremont studied the mechanical properties. F. Robin found that the high-speed, sorbitic, chromium-tungsten steels offer the highest resistance to crushing. This resistance rises rapidly at reduced temp., and at −185° is very high; a fall in resistance occurs at about 500°; and at high temp. the curve is almost linear—at 1100° the resistance is nearly double that of mild steel. The subject was discussed by L. Grenet. F. Robin discussed the acoustic properties of the chromium-tungsten steels; but observed no specially noteworthy characteristics. C. F. Würth also examined the effect of tungsten on the corrodibility of chromium steels. L. Guillet, and W. Kahlbaum and L. Jordan discussed the nitridization of the **chromium-tungsten-vanadium-iron alloys.** J. S. de Benneville, and J. V. Emmons studied the **molybdenum-tungsten-iron alloys.**

The **iron-uranium alloys** have not been closely investigated. Uranium, like molybdenum and tungsten, is considered to be an alloying element; and it also forms carbides, and possibly enters into combination with the cementite of steel.[27] A. Stavenhagen and E. Schuchard prepared the alloys by the thermite process, and F. Peters by electrometallurgical processes. Uranium is readily oxidized, and, according to G. K. Burgess and R. W. Woodward, is liable to leave its oxide in the steel. H. W. Gillett and E. L. Mack also found that it segregates badly. Up to 2 per cent., it has no marked effect on the critical ranges of steel; nor does it increase the tendency to hardening to any great extent. E. L. Reed studied the subject. H. S. Foote said that 0·60 per cent. is advantageous, and E. P. Poluskin added that while it increases the strength and toughness of steel, it does nothing which cannot be as well accomplished by less costly elements. Alloys with over 40 per cent. of uranium are decomposed by water. There may be present uranium, the carbides UC, $Fe_3C.U_2C_3$, U_2C_3, Fe_6U, and the oxide U_3O_8. H. S. Foote observed no useful effect with cast iron. The alloys were discussed by F. F. Mueller and R. W. Harris, J. M. Flannery, P. A. Heller, J. Ohly, I. Musatti and G. Calbiani, H. S. Foote, E. V. Britzke and co-workers, P. Blum, P. Girod, A. Haenig, H. Fleck, P. Oberhoffer, E. Lievenie, H. J. French and W. A. Tucker, G. and E. Stig, W. Borchers and R. W. Stimson, H. C. H. Carpenter, O. J. Steinhart, J. Johnson, R. M. Keeney, J. W. Richards, J. Escard, A. F. Braid, G. J. Horvitz, F. M. Becket, R. P. Neville and J. R. Cain, and H. W. Gillett and E. L. Mack. F. Roll showed that uranium favours the graphitization of cast iron. J. Laissus discussed the diffusion of uranium in iron. S. Satoh studied the nitridization of these steels by heating them in ammonia at 560° to 580°.

Soon after the discovery of manganese in the eighteenth century, S. Rinman[28] obtained an impure **iron-manganese alloy,** or ferromanganese, by melting grey pig-iron with an equal weight of manganese ore. The alloy was brittle; the fracture, white; and the manganese deprived the iron of its usual magnetic properties. W. Sowerby stated that old Persian steel blades were made from a kind of manganiferous iron-stone, tempered in oil; and in Spain, the Toledo blades were also manufactured from a manganiferous iron-stone. T. Bergman gave for his analyses of Swedish iron and steel:

	Ferrum crudum (cast iron)		Ferrum cusum (forged iron)		Chalybs (steel)	
	Min.	Max.	Min.	Max.	Min.	Max.
Silicon . . .	1·0	3·4	0·05	0·3	0·3	0·9
Carbon . . .	1·0	3·3	0·05	0·2	0·2	0·8
Manganese . .	0·5	30·0	0·50	30·0	0·5	30·0
Iron . . .	63·3	97·5	99·50	99·4	68·3	99·0

This, said D. Mushet, attracted the attention of the manufacturers of iron and steel at the beginning of the nineteenth century, and attempts were made to alloy manganese with iron. The use of manganese in the manufacture of iron and steel was patented by W. Reynolds in 1799; by J. Wilkinson in 1808; by J. M. Heath in 1839; and by R. F. Mushet in 1856. A legal case arising from the infringement of J. M. Heath's patent was discussed by T. Webster, and J. Percy. D. Mushet thus summarized his observations on the subject:

> I was now satisfied that ores of manganese might be smelted with success along with our common argillaceous iron-stone in the blast-furnace, with a considerable augmentation of metallic produce; and much pleased to have discovered the fact that iron alloyed with manganese, in certain proportions (22 per cent.), ceases to be obedient to the magnet. This fact alone renders it extremely probable that the presence of manganese is not essential to the formation of good steel; and that those irons analyzed by T. Bergman, contain no notable quantity, seeing that the strongest and most durable magnets are made from steel manufactured from such iron.

C. J. B. Karsten said that manganese is a very common companion of iron, but the most he had observed was 1·85 per cent. To-day, the manganese finds its way in Bessemer and open-hearth steels during the addition of the decarburizer, and, as emphasized by A. L. Baikoff, it can be regarded as a normal constituent of steels. One important result of the addition of manganese is to remove sulphur, so that the greater proportion of the manganese added passes into the slag as manganese sulphide. According to E. F. Law, that remaining in the steel is readily recognized by covering the surface with gelatin mixed with an acidic soln. of a cadmium salt. The acid attacks any exposed manganese sulphides, liberating hydrogen sulphide, which produces yellow cadmium sulphide in the gelatin. In 1865, H. Bessemer emphasized the use of manganese in iron; in 1865, W. Henderson manufactured ferromanganese with 25 to 35 per cent. manganese; and in 1871, F. Kohn discussed the prôduction of alloys of iron and manganese, with particular reference to the manufacture of spiegeleisen. The manufacture of manganese steel by W. Henderson's process was taken up by A. Pourcel in the Terr-Noire Co. in France in 1867; and in 1876, F. Gautier predicted:

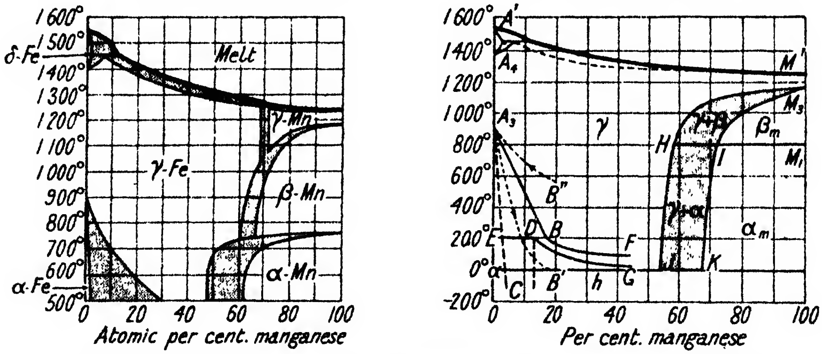
> The judicious combination and treatment of the different elements which are at the disposal of the metallurgist will attract more attention in the future, as only little is known on this question at present. Amongst the elements which may be most readily used for admixture is manganese; it is found plentifully and is a most active element.

Great improvements in the manufacture of manganese steels, and a detailed examination of the properties of the metal were made by R. A. Hadfield in 1888 and subsequent years. In consequence, there is now available a great deal of information on the strength and weakness of these alloys. The subject has been discussed by H. M. Howe, and others. The manufacture and uses of manganese iron, steels, etc., were discussed by R. J. Anderson, E. S. Bardwell, L. J. Barton, C. Benedicks, E. Büttgenbach, R. Cazaud, D. Clark and J. Coutts, H. I. Coe, E. F. Cone, E. Decherf, S. H. Dolbear, B. Egeberg, J. Escard, T. Fujiki, F. L. Garrison, W. H. Greene and W. H. Wahl, C. D. Grier, K. P. Grigorovich and V. S. Yemelyanoff, W. Guertler, A. Hänig, J. H. Hall, W. Hampe, J. Harden, W. Heym, G. Hofer, J. H. Hruska, W. G. Imhoff, E. Indenkempen, J. E. Johnson, M. Kauchtschischwili, R. M. Keeney and J. Lonergan, R. M. Keeney and co-workers, E. F. Kern, B. G. Klugh, R. Korten, V. G. Kotelnikoff, E. Kothny, E. F. Lake, W. S. McKee and J. M. Blake, G. P. Messenger, E. Monaco, P. Oberhoffer, F. Peters, J. W. Richards, P. H. Royster, H. K. von Schiele, G. P. Scholl, F. Schroedter, E. L. Shaner, O. Simmersbach, O. J. Steinhart, G. and E. Stig, S. R. Stone, G. Surr, R. R. Tatlock and R. T. Thomson, H. Thaler, E. E. Thum, P. M. Tyler, W. Venator, F. M. Walters, J. D. Weeks and G. L. Stone, C. M. Weld, and R. S. Wile. W. R. Hulbert used the thermite process. The methods of preparing ferromanganese were indicated in connection with manganese. F. Sauerwald, and A. N. Campbell prepared alloys electrolytically. G. Oishi, F. Körber and W. Oelsen, and G. Tammann and W. Oelsen studied the distribution of manganese between the slag and molten steel.

According to R. A. Hadfield, manganese steel is not as liable to honeycomb as ordinary steel, and the counter-agent silicon is unnecessary. The molten metal is very fluid, and it can be run in thin sections; but it cools more rapidly than ordinary steel, and its contraction is greater. Hence its tendency to piping and settling, both in ingots and castings, unless proper head or runners are employed. The steel is manufactured by ordinary processes. Highly heated or molten ferromanganese is added to molten decarbonized iron or mild steel. The proportion of carbon should not exceed 1 per cent. or the product will be inferior. About 0·5 per cent. of the manganese is oxidized during the preparation of the steel – *vide infra*. According to R. A. Hadfield, when less than 0·10 per cent. of manganese is added to decarbonized iron, it is very difficult to roll or forge the ingots, but above this they become malleable; mild steel with 0·2 per cent. of manganese is unsound, and rises in the ingot moulds, the honeycombs, however, close up on being forged, rolled, or otherwise reduced. As the proportion of manganese is increased, the material becomes sounder, but on exceeding 1 per cent., the steel becomes tender, the elongation is much reduced, and the material is of doubtful commercial value. The steel becomes brittle and rotten with about 2·5 per cent.; and with between 2·5 and 7·5 per cent. manganese, the cast material is brittle, like glass; and although ductile when hot, it can, when cold, be reduced to powder by a hand-hammer.

When the cast material is heated, and hammered or forged, it gains considerably in strength, and the grain of the bar is coarse and white; but if re-heated, and cooled in air, it acquires a close-grained texture, and this self-hardening manganese steel is suitable for turning tools and cutters. When the proportion of manganese passes beyond 7·5 per cent., the peculiar brittleness and hardness begin to disappear, and the steel becomes hard enough to compete with chilled iron for articles to resist wear and tear. The increase in toughness continues up to about 14 or 15 per cent., when a decrease in toughness but not in transverse strength occurs. Beyond 20 per cent. manganese causes a rapid decrease in toughness. In the hot forging of the manganese steel, there is a tendency for surface oxidation, so that some carbon is burnt off. N. Czako said that steel with a high percentage of manganese can be welded. The working qualities of the alloys were discussed by C. F. Burgess and J. Aston, H. P. Evans, and W. S. McKee.

A. Fry, J. Cournot, N. Agéeff and M. Zamotorin, and F. C. Kelley discussed the diffusion of manganese in solid iron; and W. F. Holbrook and co-workers, in molten iron. According to M. Levin and G. Tammann, the f.p. curve indicates the absence of any compound of iron and manganese; there is only an unbroken series of solid soln. of the two metals. Under the microscope, there seem to be two structural elements, but this is due to the fact that during rapid cooling, equilibrium is not established between the liquid alloy and the solid soln., so that crystals richer in iron separate first and then become surrounded by others richer in manganese. The magnetic permeability of the 100 per cent. iron alloy disappears at 950° and returns at 750°; that of the 90 per cent. iron disappears at 820° and returns at 715°; and that of the 80 per cent. iron disappears at 750° and returns at 720°. G. Rümelin and K. Fick also studied the equilibrium diagram; and P. Goerens combined the two sets of results in the one diagram. E. Oehman also examined the alloys by means of the X-radiograms and summarized his results in Fig. 467. The ranges of stability of the various solid soln. are indicated. The face-centred, cubic γ-iron, and the face-centred, tetragonal γ-manganese are said to form a continuous series of solid soln., but there may be a break at about 70 at. per cent. manganese where the cubic structure becomes tetragonal—*vide infra*. The vol. per atom is a linear function of the composition, and increases from 11·32 A³. for pure γ-iron, to 12·56 A³. for pure γ-manganese. The solubility of iron in β-manganese increases from 0 per cent. at 1191°, the transformation point of γ-Mn$\rightarrow\beta$-Mn, to 35 at. per cent. at 730°, by saturating the alloy with iron, the lattice parameter decreases from 6·305 A. to 6·251 A. The transformation point of β-Mn$\rightarrow\alpha$-Mn is but little affected by iron. The solubility of iron in α-Mn is very little affected by the temp. At 490°, it amounts to about 37 at. per cent., and at 690°, to 34 at. per cent. By the dissolution of 36 at. per cent. of iron, the lattice parameter changes from 8·904 A. to 8·864 A. The vol. per



Figs. 467 and 468.—Equilibrium Diagrams of the Binary System: Fe–Mn.

atom for β-manganese is 12·53 A^3., and for α-manganese, 12·17 A^3. The β-Mn$\rightarrow$$\alpha$-Mn transformation is accompanied by a considerable change of vol. The lattice dimensions of α-manganese are smaller per atom than those of the other modifications, and it is also less affected by the introduction of iron atoms in the lattice. The break in the solid soln. series between α-manganese and γ-iron extends over the range of 15 at. per cent. The break in the solid soln. between β-Mn and γ-Fe is narrow—at 800° it amounts to about 4 per cent. The ϵ-phase with a close-packed, hexagonal lattice extends over 12 to 23 at. per cent. manganese, and probably to 30 at. per cent. manganese. The ϵ-phase is not stable over 500°. The ϵ-phase with 22·9 per cent. manganese has a space-lattice with $a=2·541$ A., $c=4·106$ A., and $a:c=1:1·616$. There is a considerable decrease in vol. in passing from γ-Fe to the ϵ-phase. The solubility of manganese in α-iron is very small. The break between the γ-Fe and the α-Fe phases increases as the temp. falls, and the limits cannot be followed beyond 500°, and beyond 30 at. per cent. The system was also studied by V. N. Krivobok. A. Osawa found that the hexagonal, close-packed lattice observed by T. Ishiwara has the axial ratio $a:c=1:1·61$, and corresponds with iron pentitamanganide, Fe_5Mn. Manganese quenched from 1200° has a face-centred, tetragonal lattice with the axial ratio $a:c=1:0·961$, and alloys with 7·96 to 38·62 per cent. of iron, similarly treated, have the face-centred, tetragonal lattice with $a:c$ varying from $1:0·96$ to $1:1$. Five phases were observed in the iron-manganese system: the body-centred phase extending from 91 to 100 per cent. iron; the hexagonal phase extending from 78 to 84 per cent. of iron; and α- and β-manganese extending from 0 to 35 per cent. The solid soln. made by γ-iron, and γ-manganese occurs throughout the whole series of alloys at a high temp.

T. Ishiwara's results are summarized in Fig. 468. The alloys with less than 17 per cent. of manganese undergo the $\gamma\rightarrow\alpha$ or the A_3-transformation at positions corresponding with the dotted curve A_3B'; but, on the heating curve, with the dotted curve A_3B''. Hence, as shown by H. Esser and P. Oberhoffer, the progressive addition of manganese to iron results in the progressive lowering of the A_3-transformation, and there is also a steady increase in the temp. hysteresis of the transformation. The true boundary curve is estimated to be represented by A_3B. The curve A_3C represents the solubility of manganese—about 3 per cent.—in iron at the temp. indicated. A. Sauveur said that, in accord with the work of C. R. Wohrman, a solid soln. of 3 per cent. manganese in γ-iron may occur at a high temp., and that the resulting manganese-austenite breaks up on slow cooling into α-iron, which may retain some manganese in soln., and of a pearlitic constituent—manganese pearlite. T. Ishiwara, however, said that the alleged pearlitic structure is not present in carbon-free alloys; and when it is present, it corresponds with the structures belonging to the iron-carbon system with alloys containing over 17 per cent. of manganese; another transformation, γ to h-solid soln., begins on cooling at 140° to 20° and ends at about 50° to −60°, and on heating, it begins at 100° to 230° and ends at 170° to 280°. The mean temp. of the γ–h transformation are represented by the curves BF and DG. The γ–h transformation occurs with alloys containing 17 to 30 per cent. of manganese. The alloys at first show a remarkable change in vol., which finally diminishes and becomes inappreciable; the alloys also, at first, have a Widmannstätten structure, characteristic of the h-state; and finally, a uniform austenitic structure. The γ–h transformation is reversible; and the boundary curve of the γ–phase is closed by the curve A_3BF. Alloys with a concentration between E and B should show two transformations, the peritectoid change γ–h, and the A_3 change γ–α. Alloys with between 55 and 68 per cent. of manganese consist of the γ and α_m solid soln. in the range of temp. below about 800°, and of the γ and β_m solid soln. above this temp. The heterogeneous alloys with both phases are bounded in the region JHM_3IK. An alloy with 68 per cent. of manganese furnishes a uniform solid soln. α_m, and when heated it passes into the β_m state, a change accompanied by an abrupt expansion. When further heated, this alloy passes into the upper portion of the JHM_3IK-region, and afterwards enters the field of the γ-solid soln. At high temp., iron and manganese are miscible in all proportions to form the γ-solid soln. Iron has a face-centred, cubic lattice at these temp., and manganese has a face-centred, tetragonal lattice at temp. above M_3. Hence, there is nothing to show that these elements correspond with one another to give rise to a homogeneous solid soln. A. Osawa showed that the axial ratio $c:a$ of the tetragonal lattice of manganese is less than unity, but it gradually increases with the addition of iron, finally to merge into that of the face-centred, cubic lattice. The subject was also discussed by H. Esser and P. Oberhoffer, E. L. Reed, W. Schmidt, T. Murakami and M. Mikami, and C. H. M. Jenkins and M. L. V. Gayler. J. A. M. van Liempt said that it is doubtful if the X-radiograms support the view that iron and manganese form a continuous series of solid soln.

According to W. S. Potter, in the cooling of steel containing 10 to 20 per cent. manganese, and 1 per cent. carbon, γ-iron begins to freeze at about 1370°, and is for the most part frozen at about 1270°. The eutectic freezes at 1125°–1080°, or perhaps at a little higher temp. with low-carbon and manganese mixtures. The mechanical break-up of austenite begins at 850° to 825°. Carbides separate between the grains at 710° to 650°. The magnetism increases at 550° to 525° with further carbide separations between the grains, and there is a further mechanical separation at 430° to 420°. In heating, if the steel is originally austenitic, there is a preliminary break-up at 350°, a further break-up at 450° to 470°, and a complete break-up at 575°, with the separation of magnetic carbides of iron or manganese at 475° to 575°. In rolled steel, separated carbides begin to re-dissolve at about 725°, and this is completed at 850° to 870° with the re-formation of austenite. Slight re-separation of carbides occurs along the grain outlines as the m.p. of the eutectic is approached, beginning at about 1025°, and continuing to 1100° or over. This is most noticeable in ingot metal, and taken together with the fact that the outlines of the original freezing structures persist in the cast steel at temp. below 1125° or thereabout, the remarkable tenderness of ingots between 1025° and 1125° is made clear. In cast ingot steel, the melting of the eutectic occurs at 1120° to 1140° if the heating is slow; and at about 1100° to 1130° if the heating be rapid. The complete re-solution of constituents and a re-formation of grains with the first formation of uniform austenite occurs above 1150°. Cementite re-separates out extensively at about 1250°. The mass melts at 1350° to 1375° or lower, depending on its composition. The subject was discussed by J. S. Lloyd, N. H. Aall, B. Kjerrmann, J. Strauss, J. H. Hruska, V. N. Krivobok, O. von Keil and F. Kotyza, E. C. Bain and co-workers, J. H. Hall, J. H. Andrew and H. A. Dickie, and H. Scott and J. G. Hoop. P. Schafmeister and R. Zoja found that the proportions of carbon in the eutectoid decreases with increasing proportions of manganese, being 0·83 per cent. carbon with 1 per cent. of manganese; about 0·77 with 2 per cent. of manganese; and about 0·71 with 3·1 per cent. manganese. The percentage of ferrite in the steels decreases with the rate of cooling, and with an increase in the proportions of manganese. The effect produced by the cooling is greater the higher is the percentage of manganese. H. A. Schwartz and A. N. Hird observed that manganese when present of the order of magnitude of 0·25 per cent. freezes out with the austenite; any sulphide freezes out at the beginning, and may be entrapped with the ledeburite eutectic.

The manganese carbides were discussed in connection with the carbides, **5**. 39, 20. J. O. Arnold and A. A. Read said that part of the iron in iron carbide is replaced by manganese in steels with a high proportion of manganese to form a **manganese iron carbide**; and J. E. Stead also made similar observations with respect to the carbide residue remaining after a manganese steel had been dissolved in dil. acid. F. Mylius and co-workers also obtained a complex carbide from steel; and A. Carnot and E. Goutal stated that when over 74 per cent. ferromanganese is treated with dil. acid, it furnishes the complex carbide $Fe_3C.4Mn_3C$; that 60 to 74 per cent.

ferromanganese furnishes $Fe_3C.2Mn_3C$; and that 30 to 60 per cent. ferromanganese yields $2Fe_3C.Mn_3C$. The last carbide crystallizes in large plates during the cooling of ferromanganese blocks. J. O. Arnold and A. A. Read observed that in steels with up to 4 per cent. manganese, the carbide residues are simply mixtures; possibly a true double carbide, $3Fe_3C.Mn_3C$, is present in steels with 11·21 to 13·38 per cent. manganese; and in steels with over 15 per cent. manganese, the carbide $2Fe_3C.Mn_3C$, or a mixture of carbides, is present. It was inferred that at ordinary temp. the manganese carbide is less stable than the iron carbide because, according to C. Benedicks, and O. Ruff and E. Gersten, the iron carbide of cementite is endothermal, and that of manganese carbide is exothermal. Carbon is assumed to have a stronger affinity for iron at the high temp.; and, conversely, at the low temp., the manganese is easily displaced by iron from manganese carbide. F. Wüst found that the effect of manganese is to impart exceptional stability to the solid soln., so that beyond *afd*, Figs. 467 and 468, no double phases occur, but only homogeneous solid soln. H. Lütke considered that manganese does not affect the percentage of carbon in solid soln. until more than 49 per cent. of manganese is present. H. Scott found that manganese has a marked effect on the temp. of transformation of martensite to troostite. A. Matsubara and J. Takubo found that cathodic polarization of iron pyrites in dil. sulphuric acid causes the ionization of one or both atoms of sulphur, which then combine with the hydrogen ions present to form hydrogen sulphide. If the material is first made the anode, subsequent cathodic polarization gives rise to an abnormal amount of hydrogen, and certain natural specimens behave similarly without previous treatment. The current yield is, in general, smaller when much hydrogen is evolved. F. Roll observed that manganese in cast iron makes the cementite more stable.

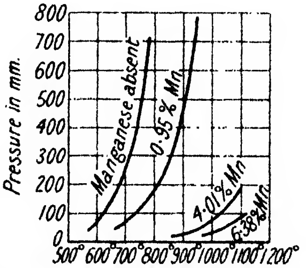


FIG. 469.—The Effect of Manganese in Iron on the Equilibrium: $2CO = CO_2 + C$.

The influence of carbon monoxide on solid soln. of iron and manganese was studied by R. Schenck and H. Semiller. The results for the press., *p* mm., of the gas at different temp. are as follow: (i)

	634°	672°	691°	722°	734°	774°	779°
p .	83	131	195	298	341	562	657

(ii) with an alloy of 0·95 per cent. of manganese, 96·6 per cent. of iron, and 2·15 per cent. of carbon:

	629°	679°	731°	751°	820°	900°	959°
p .	28	41	86	101	180	396	802

(iii) with an alloy of 4·01 per cent. of manganese, 93·0 per cent. of iron, and 2·99 per cent. of carbon:

	853°	911°	965°	1010°	1088°	1093°
p . . .	17	28	46	74	162	170

and (iv) with an alloy having 6·38 per cent. manganese, 93·2 per cent. of iron, and 1·32 per cent. of carbon:

	943°	956°	981°	1031°	1086°	1093°	1110°
p. .	15	20	20	34	62	68	96

The results are plotted in Fig. 469, and they show the lowering which the equilibrium point undergoes at any given temp., say 950°, with increasing proportions of manganese. This lowering is relatively great for even small proportions of manganese. For the cementation of manganese steels, *vide supra*, cementation; and for observations of E. Adamson, A. Allison, J. H. Andrew, J. O. Arnold and F. K. Knowles, O. Bauer and K. Sipp, H. H. Beeny, S. S. Beliaeff, P. P. Berg and M. S. Pshonik, E. Maurer and W. Bischof, A. F. Braid, J. R. Cain, A. Campion, E. Decherf,

and J. R. Cain, A. L. Norbury, P. Oberhoffer and H. Schenck, G. Oishi, E. Oughterbridge, E. Piwowarsky, A. Pohl, W. E. Remmers, R. T. Rolfe, D. Saito and K. Nishiwara, H. Schenck, J. Shaw, N. W. Shed, G. Sirovich, A. E. M. Smith, S. C. Spalding, E. R. Taylor, E. Thews, B. Thomas, O. Wedemeyer, E. A. Wheaton, F. Wüst and co-workers, etc., on the effect of manganese on cast iron, steel, etc., *vide supra.*

The polyhedral crystals of the ferrite in manganese steel are illustrated by Figs. 470 and 471 (×100). Their outlines are not so rounded as in the case of the ferrite of, say, electrolytic iron. The steel illustrated in Figs. 472 and 473 contained 10 per cent. of manganese, and 1·15 per cent. of carbon; that in Fig. 470, was quenched from 1200°; and that in Fig. 471, was slowly cooled from that temp. The ferrite of alloy steels contains the special constituents—*e.g.* manganese-forming *manganoferrite*—in soln., and in this respect is related to martensite. The polyhedral form is best developed by cooling the steel from a high temp.; and the changes which occur in the heat-treatment of the alloy steel are in some respects rather simpler than with ordinary steels. Both diagrams show the polyhedral crystals with cleavage cracks, and in the slowly cooled sample, the carbide separations accumulate between the grains. The steel illustrated in Fig. 472 (×400) contains 20·43 per cent. manganese, and 1·08 per cent. of carbon; after forging, it was heated 45 mins. at 1020°, slowly cooled, and kept for 200 days at 200°. The steel illustrated by Fig. 473 (×1200) contains 20·98 per cent. of manganese, and 1·2 per cent. of carbon. After forging, it was heated 45 mins. at 1020°, and slowly cooled. The remarkable twinning of the crystals is clearly shown. According to C. R. Wohrman, the Widmanstätten structure and martensitic patterns with the iron-manganese alloys result from the breaking up of a solid phase into two. The latter structure is finer, less well defined, and less regular than the former. On thorough annealing there is formed an aggregate consisting of a ferritic constituent, an intermetallic compound rich in manganese. An eutectoid of the two (6 per cent. Mn) is also believed to exist, at first martensitic and then pearlitic. H. M. Howe and A. G. Levy discussed the hypothesis that the deformation lines in manganese steel are slip-bands, though it is possible they may be due to twinning. T. W. Hogg found crystals of titanium cyanonitride in ferromanganese.

F. Osmond observed that the curve representing the effect of manganese on the A_3-transformation of steel merges into the curve representing the martensite-pearlite transformation when 2·5 to 3·5 per cent. of manganese is present. The transformation with a steel having 4 per cent. manganese lies between 200° and 300°; with a steel having 5 per cent. manganese, it is near 100°; and with one having 7 per cent. manganese, it is below 0°. Unlike ordinary steel, therefore, alloys with over 7 per cent. of manganese, when heated above 700°, show no recalescence when cooled down to ordinary temp.—*vide supra*, martensite. R. A. Hadfield examined the heating and the cooling curves of a forged steel with 1·26 per cent. carbon, and 13·38 per cent. manganese, and of a cast steel with 1·16 per cent. carbon, and 10·88 per cent. manganese, and obtained no evidence of the existence of critical points when cooled down from or heated up to about 1300°. There is not the slightest evidence of any internal change of structure during heating or cooling. The same results are obtained if the material is cooled slowly, or quickly by quenching in water. This in spite of the fact that the physical properties are markedly influenced by the rate of cooling. Thus, by slowly cooling manganese steel, it remains brittle and non-magnetic, but by quick cooling, the material becomes very ductile, and non-magnetic. R. A. Hadfield continued:

> Whereas with all ordinary as well as hardening or self-hardening steels, the critical points are of considerable importance in guiding heat-treatment, with manganese steel, the heating and cooling curves are apparently of no value in this respect, and do not give any clue to the extraordinary change of structure which goes on in this material when it is transferred from its original and brittle state into that condition in which it possesses ductility unequalled by any other alloy of iron and steel.

R. A. Hadfield and B. Hopkinson found that a steel containing 1·26 per cent. of carbon, and 13·38 per cent. of manganese, becomes magnetic when heated several hours at 500°, and it loses its magnetism rapidly at about 700°. The heating curves show a heat absorption corresponding with this change. The range 650° to 750°, thus corresponds with the critical range in which ordinary carbon steel loses its magnetism. The reverse transformation—non-magnetic to magnetic—is so slow that it cannot be detected on the cooling curve. It is probable that as the temp. falls the alloy has a tendency to assume its equilibrium state in which it becomes magnetic, but the change is too slow for the alloy to acquire a state of stable equilibrium. The effect of manganese is to retard the attainment of equilibrium, rather than to produce any marked shift of the position of the critical range. R. A. Hadfield and B. Hopkinson added that the attainment of equilibrium in manganese steel at temp. below the change point, is opposed not only by resistances of the nature of fluid viscosity, which can be overcome by a very small force if continued long enough, but it is also opposed by a resistance of the nature of solid friction, which requires a force of a definite amount to be exerted before motion takes place at all. Thus, magnetic manganese steel at 650° ultimately attains a magnetism about twice as great as that reached by the non-magnetic variety heated at the same temp. Hence, the final condition at this temp. is different according as it is approached, so to speak, from above or below; and, so far as it is possible to judge from observed facts, these two limiting conditions could never be brought into coincidence, however much the heating were prolonged. E. Gumlich observed that a steel with 12·4 per cent. manganese began its magnetic transformation at −8°, and ended it at −109°. If this steel be re-heated, it loses its magnetism between 600° and 700°. Hence, between 0° and 600°, the same steel can be either magnetic or non-magnetic. Steels with 14·4 and 15·7 per cent. of manganese did not become magnetic at the temp. of liquid hydrogen.

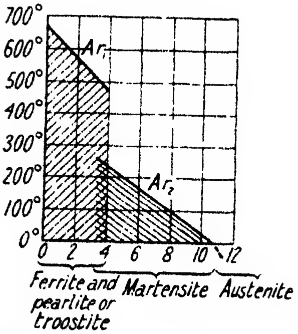

Fig. 474. — Constitution of Manganese Steel—0·3 to 0·4 per cent. Carbon.

L. Guillet observed that with a steel containing 0·20 per cent. of carbon, the pearlite structure obtains when the proportion of manganese is less than 5 per cent.; the martensite-troostite structure, with alloys having 5 to 12 per cent. of manganese; and the polyhedral γ-iron structure, with alloys having over 12 per cent. manganese; whereas with a steel having 0·80 per cent. carbon, the pearlitic structure occurs with alloys having less than 3 per cent. manganese; the martensite-troostite structure with alloys having between 3 and 7 per cent. manganese; and the polyhedral γ-iron structure with alloys having over 7 per cent. manganese. Free cementite occurs with alloys having over 1·65 per cent. carbon. This proportion of carbon in ordinary carbon steels was considered by F. Osmond to give the maximum proportion of austenite. According to A. M. Portevin, by annealing, followed by very slow cooling of steels containing 7 per cent. manganese, and 0·5 to 1·0 per cent. carbon, it is possible to obtain lamellar pearlite with martensite. With a steel containing 12 per cent. manganese, and 1 per cent. carbon, by very slow cooling the co-existence of lamellar pearlite and austenite, separated by a thin border of troostite, can be obtained. By ordinary annealing the whole becomes austenitic. Using a steel containing 9·8 per cent. manganese, and 0·66 per cent. carbon, by slow cooling it was possible to find the complexes troostite-pearlite-martensite-austenite, the martensite arising from a polymorphic transformation of the austenite. P. Dejean found that steels containing 0·3 to 0·4 per cent. of carbon, and 0 to 3·5 per cent. of manganese are pearlitic, and give the point Ar_1; those with 3·5 to 11 per cent. manganese are martensitic, and give the point Ar_2; and those with intermediate proportions 3·5 to 4·0 per cent. manganese, show both critical points, and consist of martensite and troostite. As the proportion of carbon rises to 0·7 to 1·0 per cent., the intermediate zone becomes of importance, since, with equal proportions of manganese, the temp. of the point Ar_1 rises, and that of Ar_2 falls, and finally, by suitable cooling, it is possible to produce the point Ar_1 in steels for which the point Ar_2 is below 0°, and the steels are troostitic and martensitic, Fig. 474. According to H. Meyer, the presence of manganese lowers the temp. of Ar_3 at which ferrite separates, thus:

Mn . .	0·1	0·2	0·3	0·4	0·5	0·6	0·7	0·8	0·9	1·0 per cent.
Lowering Ar_3	5°	10°	15°	20°	26°	32°	38°	45°	52°	60°

H. I. Coe observed that the manganese arrests the carbon in lowering the primary freezing, so that with 13 per cent. of manganese, the f.p. is 40° lower than with the corresponding iron-carbon alloy. The effect of manganese on the critical temp. is as follows:

TOTAL CARBON	MANGANESE	SILICON	FIRST ARREST	SECOND ARREST	PEARLITIC CHANGE
3·14	0·025	0·01	1285°	1139°	700°
3·15	3·75	0·27	1270°	1141°	645°
3·37	7·95	0·17	1247°	1140°	525°
3·47	13·60	0·22	1204°	1140°	—
3·84	16·80	0·26	1160°	1141°	—
4·00	21·63	0·33	1140°	1130°	—
4·05	28·80	0·41	—	1125°	—
4·45	32·42	0·42	1133°	1125°	—

As pointed out by F. Wüst, the pearlitic change is thus materially affected by manganese, so that with 8 per cent. of manganese it can scarcely be detected. J. O. Arnold said that manganese does not form a true steel having 100 per cent. pearlite. F. Wüst and H. Meissner observed that in the presence of 1·5 per cent. of silicon, and 2·7 to 3·9 per cent. of carbon, below 0·3 per cent. of manganese favoured the separation of graphite, but with 0·3 to 2·5 per cent. of manganese, no perceptible effect on the condition of the carbon was observed. H. I. Coe observed that in the presence of silicon, the effect of manganese on the pearlitic change in cast iron is more marked. Thus, the addition of 4·45 per cent. of manganese, in the absence of silicon, changed the pearlitic arrest from 700° to about 600°, whereas in the presence of silicon, the arrest was lowered to 350°. Large proportions of manganese, even in the presence of silicon, keep the solid soln. of combined carbon more stable, and favour the production of hard, white cast iron. A. Merz, J. A. Jones, F. Kjerrman, H. S. Rawdon and F. Sillers, H. Scott and J. G. Hoop, G. Tammann, and J. J. A. Jones discussed the Ac_1-range in manganese steels; R. Austin, H. M. Boylston, A. Allison, W. Eilender and H. Diergarten, F. M. Walters and C. Wells, M. Hamasumi, Z. Shibata, V. N. Krivobok and co-workers, P. Schafmeister and R. Zoja, H. S. Rawdon and F. Sillers, H. Sawamura, C. R. Wohrman, H. Schenck, P. Oberhoffer and co-workers, T. Swinden, F. Giolitti, E. Killing, A. L. Feild, C. H. Herty and J. M. Gaines, K. Hilgenstock, B. M. Larsen, H. E. Field, F. W. Lürmann, T. Naske and A. Westermann, A. K. Silin, and J. O. Arnold and G. B. Waterhouse, the deoxidizing or desulphurizing action *vide* the action of oxygen on iron. L. Goldmerstein tried manganese and other fluorides for removing phosphorus, sulphur, etc., as fluorides.

According to W. S. Potter, during the cooling of steels with 1 to 2 per cent. of carbon and 10 to 20 per cent. of manganese, γ-iron begins to freeze out at about 1370°, and is for the most part frozen at about 1270°; the eutectic freezes at 1125° to 1080°—and at a rather higher temp. with low-carbon and manganese mixtures. The mechanical break-up of austenite occurs at about 850° to 825°; carbides separate between the grains at 710° to 650°; the magnetism increases at 550° to 525° with a further separation of carbide between the grains; and there is a further separation of carbide at 430° to 420°. In heating a steel, originally austenitic, there is a preliminary break-up at 350°, a further break-up at 450° to 470°, and a complete break-up at 575°, with the separation of magnetic carbides of iron or manganese at 475° to 575°. In rolled steel, the separated carbides begin to be re-dissolved at about 725°, and this is completed at 850° to 870° with the re-formation of austenite. There is a slight re-separation of carbides along the grain outlines as the m.p. of the eutectic is approached, beginning at about 1025° and continuing to 1100° or over. This is very marked with ingot metal; and, considering that the outlines of the original freezing structures persist in the cast steel at temp. below about 1125°, this explains the tenderness of ingots between 1025° and 1125°. In cast ingots, the melting of the eutectic occurs at about 1120°

to 1140° if the heating is slow, and at about 1100° to 1130° if the heating be rapid. The complete re-solution of the constituents, and new grain-formation with the production of austenite occurs above 1150°; cementite separates extensively above 1250°; and the mass melts at 1350° to 1375° or less, according to its composition.

B. M. Larsen showed that manganese tends to extend the temp. range of stability of γ-iron or austenite; manganese forms a carbide more stable than cementite; and manganese atoms cannot well diffuse through the iron space-lattice at ordinary annealing temp. at which carbon atoms diffuse freely. In steels containing more than 1 per cent. of manganese, dendritic segregation causes a marked dendritic pattern in cast sections, and a fibrous pattern in rolled or forged bars. The proportion of manganese is higher in the dendritic fillings. Heat-treatment up to 1100° is ineffective, but an hour's heating at 1300° causes the manganese to diffuse to a uniform concentration throughout. As a cast bar with 1 to 3 per cent. of manganese cools through the critical range, the Ar_3-point is attained first by the lower manganese axes of the dendrites. If the cooling rate is below 5° to 7° F. per minute, the carbon tends to segregate in the high-manganese fillings between the dendrites. With a total carbon-content of 0·3 per cent. or less, a dendritic pattern is formed by the pearlite or sorbite areas in cast sections, and a marked banded structure in rolled or forged bars; the ferrite areas always correspond to the dendritic axes. Phosphorus and arsenic tend to cause these same patterns, but as these elements raise the Ar_3-point of pure iron, the ferrite areas formed correspond to the dendritic fillings. Above the Ar_3-point, the carbon atoms are probably uniformly distributed in the γ-iron lattice. With an increasing percentage of manganese, a manganese-cementite tends to form, perhaps containing an increasing proportion of mols. of Fe_2MnC. Up to 2 per cent. manganese, finer-grained pearlite and sorbitic areas are formed. Above 2 per cent. manganese, the carbides separate in a fine-grained distributed structure that may be linked together through the manganese atoms scattered through the iron space-lattice. The eutectoid point of pure iron-carbon alloys containing about 0·9 per cent. carbon appears to widen with an increase in the amount of manganese into a eutectoid range which, with 3 per cent. of manganese, extends from 0·6 to 0·92 per cent. carbon. This apparent eutectoid range is probably the result of a very small temp. interval between the Ar_3- and Ar_1-points in the given range of carbon-content. H. M. Howe did not agree with T. Mukai that manganese causes the retention of carbon in the non-hardened state, and he summarized the effects of sudden cooling on manganese and carbon steels as follows:

	CARBON STEEL	MANGANESE STEEL	EFFECTS
Hardness	Large increase	Slight increase	Alike
Per cent. total combined carbon.	Large increase	Moderate increase	Alike
Specific gravity	Decrease	*Nil* or increase	Opposite
Size of grain	*Nil* or decrease	Increase	Opposite
Separation components . .	Decrease	Increase	Opposite
Ductility	Large decrease	Large increase	Opposite
Tensile strength	Increase	Increase	Alike

In 1878, E. Mallard showed that the crystal form is dependent on the proportion of manganese, and that with 52 to 55 per cent. the crystal form changes. B. Rathke showed that the crystals rich in manganese are hexagonal, or pseudohexagonal, and those with smaller proportions are rhombic prisms. F. Wever observed that with manganese steels ranging from 19·08 per cent. manganese and 0·30 per cent. carbon to 2·06 per cent. manganese and 1·90 per cent. carbon, the lattice parameter, a, of austenite varied from 3·597 to 3·643 A.; the sp. vol. from 0·1262 to 0·1288 for high and low manganese respectively; and $a=3{\cdot}578+0{\cdot}00050[\mathrm{Mn}]+0{\cdot}00645[\mathrm{C}]$, where the symbols represent atomic percentages. V. N. Svetchnikoff, and T. Mukai studied the microstructure of the manganese steels; M. L. V. Gayler, the constitution; and for the observations of E. Persson and E. Oehman, and Z. Nishiyama on the X-radiograms of these alloys, *vide* manganese. E. C. Bain,

M. Gensamer and co-workers, J. B. Friauf and M. Gensamer, and V. N. Krivobok and C. Wells discussed this subject. W. Schmidt's X-radiograms of the iron-manganese alloys showed that the α-solid soln. is present up to 20 per cent. of manganese, when the lattice parameter, a, increases from 2·857 A. for iron alone, to 2·871 A. for iron with 20·1 per cent. of manganese. Alloys with 16 to 60 per cent. of manganese contain the γ-solid soln., with a cubic, face-centred lattice having a=3·586 A. for iron with 15·7 per cent. of manganese to a=3·616 A. for iron with 55·85 per cent. manganese. Alloys with 60 to 98 per cent. of manganese have the structure of β-manganese, with a lattice parameter increasing from 6·24 A. for 62·7 per cent. of manganese, to 6·28 A. for 87·25 per cent. manganese; alloys with more manganese have the structure of α-manganese. In the alloys with 12 to 29 per cent. of manganese, there is an ϵ-phase having a hexagonal, close-packed lattice, with a=2·532 A. to 2·543 A., and c=4·061 A. to 4·082 A., according to the manganese-content. The way the lattice parameters change shows that no definite chemical individual, as a compound of iron and manganese, exists. Since the α-, γ-, and ϵ-phases can co-exist in the same alloy, one of them must be metastable in the range 12 to 29 per cent. of manganese. No transition points were observed by thermal or dilatometric analysis. For E. Oehman's observations on the X-radiograms, *vide* manganese. H. Perlitz discussed the distance apart of the atoms. Z. Nishiyama found the lattice parameter a; the sp. gr.; and the elastic modulus, E kgrms. per sq. cm., at 14·8° to 15·6°, to be:

Mn .	0	0·5	1·0	1·5	2	3	4	6	8 per cent.
a . .	2·866	2·863	2·865	2·864	2·867	2·873	2·871	2·867	2·872 A.
Sp. gr. .	7·8596	7·8555	7·8404	7·8416	7·8430	7·8402	7·8292	7·8163	7·8003
$E \times 10^{-6}$.	2·151	2·128	2·138	2·125	2·128	2·122	2·108	2·072	2·044

R. A. Hadfield found the sp. gr. of cast, 13·75 per cent. manganese steel to be 7·83, and when drawn into wire, 7·81–7·83. W. Brown found for the sp. gr., and sp. vol.:

C .	0·20	0·24	0·41	0·36	0·15	1·20	0·26	1·54 per cent.
Mn .	0·50	1·00	2·25	4·00	5·40	7·00	13·00	18·50 ,,
Sp. gr.	7·8456	7·8354	7·7983	7·8352	7·8411	7·9028	7·9970	7·9075
Sp. vol.	0·12746	0·12762	0·12823	0·12763	0·12753	0·12654	0·12605	0·12646

so that with up to 2 per cent. manganese, the sp. vol. increases 0·00026 c.c. for 1 per cent. manganese, and with 2 to 18·5 per cent. manganese, the sp. vol. decreases 0·00015 c.c. per 1 per cent. manganese. J. O. Arnold, H. A. Dickie, A. Osawa, H. Meissner, H. Tomlinson, and O. Simmersbach discussed this subject. C. Benedicks and co-workers studied the sp. vol. E. Gumlich found the sp. gr. gives an abrupt increase when 8 to 10 per cent. of manganese has been added, Fig. 476, and that the sp. gr., with p per cent. manganese, up to 1 per cent., decreases in accord with $7{\cdot}873-0{\cdot}008p$. F. Wever gave for the sp. vol., v, of manganese steel, $v=0{\cdot}1246+0{\cdot}0004[\mathrm{Mn}]+0{\cdot}0041[\mathrm{C}]$, where the symbols represent atomic percentages. The results of K. Tamaru are summarized in Fig. 475; and those of C. Benedicks, in Fig. 186. H. I. Coe found that the shrinkage curve of the manganiferous, white cast irons showed minima corresponding with the formation of carbides: Fe_3C; $8Fe_3C.Mn_3C$; $2Fe_3C.Mn_3C$; and $3Fe_3C.2Mn_3C$; and with grey cast irons the increasing shrinkage with increasing proportions of man-

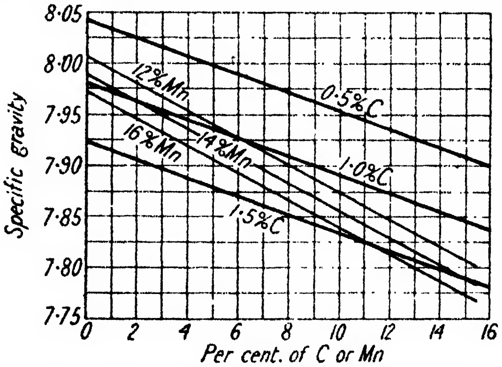

FIG. 475.—Specific Gravities of Manganese Steels.

ganese is more uniform. Some peculiarities observed by R. A. Hadfield in connection with the hardness of manganese steels have been indicated above. R. A. Hadfield pointed out that the hardness varies considerably in degree. It is most intense in cast material containing 5 to 6 per cent. of manganese, for no tool will face or touch this steel; a gradual decrease in hardness occurs as manganese is added, so that when the proportion has attained 10 per cent., the softest condition is reached; an increase in hardness again occurs as the proportion of manganese rises to 22 per cent., when the hardness is not so great as it was with 5 per cent. By heating at 831° a specimen with 1·17 per cent. carbon, and 12·46 manganese for 10 days, the steel became magnetic, and its Brinell's hardness decreased from 532 to 241. H. I. Coe found variable results with the scleroscopic hardness of manganiferous, white cast irons. The hardness rises from 57 to 80 as the proportion of manganese rises to about 6 per cent., there is then a fall to a minimum 52 with about 11 per cent. of manganese, a rise to a maximum of 66 with 16 per cent. manganese; a fall to 60 with about 18 per cent. of manganese, and a very gradual rise from 70 as the proportion of manganese exceeds 22 per cent. With grey cast irons, there is a maximum of 40 with 1·5 per cent. manganese, a fall to 52 with 2·7 per cent. manganese, a sudden rise to 52 with 4 per cent. manganese, and a slower rise with higher proportions of manganese. M. Hamasumi, and K. Taniguchi studied Brinell's hardness of these alloys. The results of L. Guillet are summarized in Fig. 477. The hardness of pearlitic tungsten steel is approximately the same as that of the corresponding carbon steels; the martensitic steel shows the maximum hardness, and the steel with the polyhedral structure is softest. T. Murakami and K. Hatsuta, T. Kase, H. A. Dickie, H. O'Neill, A. Osawa, and A. Wahlberg also measured the hardness of the manganese steels. R. A. Hadfield found for low-carbon, manganese steels, the values for Brinell's hardness:

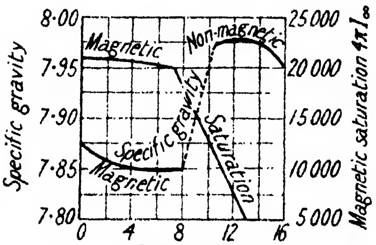

FIG. 476.—The Specific Gravity of Manganese Steel.

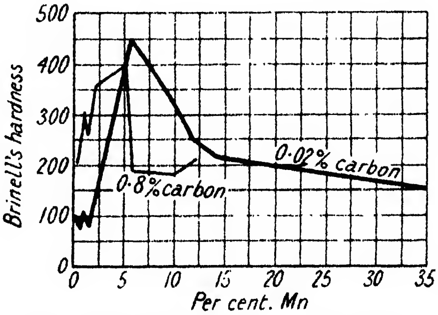

FIG. 477.—Brinell's Hardness of Manganese Steel.

Mn . .	1·10	3·13	4·10	5·50	10·50	12·90	15·90	19·85 per cent.
Hardness .	143	430	418	418	444	302	192	235

The value for iron alone is about 90; and for the hardest steel known, 800, or perhaps a little higher. With high-carbon, manganese steels:

Mn . . .	1·16	3·10	4·98	10·07	15·11	19·59 per cent.
Hardness. . .	650	600	286	179	196	192

W. Giesen said that pearlitic steels with 0 to 7 per cent. of manganese and 0 to 5 per cent. of carbon, or 0 to 5 per cent. of manganese and 0·95 per cent. of carbon, differ very little from ordinary steels with the same carbon-content, in respect to tensile strength, ductility, yield-point, elongation, hardness, and brittleness. Martensitic and troostitic steels with 7 to 15 per cent. of manganese and 0·3 per cent. of carbon, or 5 to 9 per cent. of manganese and 0·95 per cent. of carbon, have a high limit of about 165,000 lbs. per sq. in. for the stretching and breaking strains; the ductility and brittleness are very low, and the hardness is extremely high. Generally, a manganese steel consisting of martensite, exhibits a great brittleness and high tensile strength; and if the structure is polyhedral, the hardness is very great. Steels with the γ-iron structure having 7 to 18 per cent. of manganese and 0·3 per cent. of carbon, or 5 to 11 per cent. of manganese and 0·95 per cent. of carbon, have a high ductility, low elastic limit, low brittleness, and medium breaking strength. A steel with 5·5 to 11 per cent. manganese is more brittle and harder than one in which the manganese-content is higher or lower. It is rare to find that the hardness and brittleness of steels high in manganese are diminished, instead of increased, by quenching, but this does occur with a manganese steel low in carbon when the manganese reaches 19·5 per cent., and with 7·5 per cent. manganese in high-carbon steels. F. Robin studied the acoustic properties of manganese steels. The martensitic steels show a fall in resonance up to 300°, when the metal is aphonic.

Observations on the mechanical properties of manganese steel were made by K. Amberg, P. Bardenheuer and G. Schitzkowsky, C. F. Burgess and J. Aston, L. Campredon, A. Capron, C. L. Clark and A. E. White, H. I. Coe, A. L. Colby, V. Deshayes, H. A. Dickie, V. Ehmcke, F. L. Garrison, H. Guédras, L. Guillett, R. A. Hadfield, J. H. Hall, J. H. Hall and G. R. Hanks, J. J. Hall, G. A. Hawkins and co-workers, J. H. Hruska, G. R. Johnson, J. A. Jones, W. Kahlbaum and L. Jordan, W. J. Keep, V. N. Krivobok, G. Lang, A. Ledebur, E. Leuenberger, E. Lievenie, H. C. Loudenbeck, P. Marsich, R. P. Neville and J. R. Cain, A. M. Portovin, W. S. Potter, F. Rapatz and H. Pollack, H. W. Roberts, A. D. Ross, R. Scherer, W. Schneider and E. Houdremont, A. Schulze, H. J. Schuth, H. Souther, J. F. Springer, A. Stadeler, B. Stoughton and W. E. Harvey, J. Strauss, V. N. Svetchnikoff, E. E. Thum, H. Tomlinson, T. D. West, M. H. Wickhorst, and F. Wüst and H. Meissner.

H. I. Coe observed that the addition of the first 5 per cent. of manganese to white cast iron produces no appreciable change in brittleness, but increases up to 13 per cent. make the metal more brittle. With higher proportions of manganese, the metal becomes stronger, and with 19 per cent., there is an increase in toughness. With 30 per cent. and over, the metal partakes of the nature of spiegeleisen and becomes weak and brittle. Z. Nishiyama's observations on the elastic modulus are indicated above. R. A. Hadfield observed that the cast manganese steel is so brittle that it does not seem to be a steel at all. This cold-short material, however, is ductile when hot, and can then be drawn into any desired size. The brittleness is intensified by the peculiar crystallization of the cast samples. When forged, there is a marked increase in strength, but the steel is still brittle. The grain of the forged steel is coarse and open. If re-heated and cooled quickly in air, a fine, close grain is produced, and this is the state of the metal which is made into boring cutters, and other tools. The tensile strengths, in kgrms. per sq. mm., and the percentage elongations of forged steel and of steel heated to a high temp. and cooled in air, oil, or water, are indicated in Table LXXXIII. J. O. Arnold and F. K. Knowles obtained the results indicated in Table LXXXIV, and they consider that they prove that, although the influence of carbon is considerable, the dominating factor is the presence of manganese. M. Hamasumi measured the tensile strength of the alloys; and C. L. Clark and A. E. White, the effect of temp. on the tensile strength. A. M. Portevin found that when the percentage of manganese increases from 0·5 to 5 per cent., the resistance to shear and the elastic limit increase until the former is 61 kgrms. and the latter 46 kgrms., but the contraction on shearing diminishes slightly. Steels with over 5 per cent. manganese show a nearly constant resistance to shear of nearly 50 kgrms., the elastic limit remains low, between 10

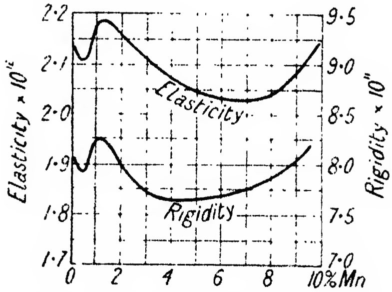

FIG. 478.—The Elasticity and Rigidity of Manganese Steel.

and 20 kgrms., and the contraction on shearing has high values ranging from 20 to 30. The first class of steels are pearlitic and troostitic, and the second class have γ-iron. So long as the steels are simply pearlitic, the resistance to shear and elastic limit are small, but they attain comparatively high values with 5 per cent. manganese. T. Matsushita's results for the elastic modulus and rigidity of manganese steel; in dynes per sq. cm., are summarized in Fig. 478. R. A. Hadfield examined the effect of reducing the temp. to —182° on the mechanical properties of manganese steel. With 0·08 C and 3·50 Mn, the tenacity is increased and all ductility is lost. The metal does not appear to be modified when the temp. returns to normal. Steels with 0·41 C and 2·23 Mn, and 1·66 C and 11·53 Mn all behaved normally. A steel with 1·23 C and 12·6 Mn had a slightly raised tensile strength and suffered a 2·5 per cent. decrease in elongation. The cooling to —182° thus embrittles or de-toughens the material. When the steel is cooled to —182° and allowed to return to normal temp., the de-toughening is merely temporary, for the steel exhibits an increase in toughness. When quenched in liquid air from 620° to —182°, the steel is toughened as if it had been cooled to ordinary temp., showing that the toughening occurs in the fall of the first 150°–250°. In no case did the steels at —182° show any change in magnetic properties. F. Robin found that the resistance of manganese steels to crushing resembles that of nickel steels (*q.v.*) with the corresponding structure. For C. L. Clark and A. E. White's observations on the proportional limit, *vide* Fig. 481, nickel-chromium steels.

TABLE LXXXIII.—EFFECT OF HEAT-TREATMENT ON TENSILE STRENGTH AND ELONGATION OF MANGANESE STEEL.

Percentage composition			Tensile strength				Elongation			
				Quenched in				Quenched in

A. Schulze studied the coeff. of thermal expansion of the iron-manganese alloys between 20° and 100°. T. Matsushita's results for the coeff. of thermal expansion are shown in Fig. 479. The continuous lines refer to pearlitic or martensitic steels, and the dotted lines to austenitic-martensitic steels. The hysteresis loop at the critical temp. widens as the proportion of manganese increases. J. A. N. Friend and R. H. Vallance gave $0{\cdot}0_4183$ for the coeff. of expansion of manganese steel between 10° and 100°. Observations were made by A. M. Portevin and P. Chévenard, and M. Gensamer and co-workers. A. Schulze gave 0·03 for the coeff. of thermal conductivity. W. S. Potter found the sp. ht. of manganese steels to range from 0·15 at ordinary temp. to 0·20 at 1200°. W. Brown gave :

C .	0·20	0·24	0·41	0·36	0·15	1·20	0·26	1·54	per cent.
Mn .	0·50	1·00	2·25	4·00	5·40	7·00	13·00	18·50	,,
Sp. ht.	0·9258	0·8987	0·9007	0·9128	0·9189	0·9357	0·9796	0·9884	

so that the sp. ht. first decreases up to 1 per cent. manganese, and then increases 0·0006 per 1 per cent. of manganese up to 18 per cent. A. Eucken and H. Werth measured the sp. ht. of manganese-iron alloys, and the values for the at. hts. under constant press. and constant vol., and for Debye's constant $\ominus$—the x of **1.** 13, 15—are as follow :

50 per cent. Mn	T° K .	15·65°	18·37°	46·93°	88·65°	115·80°	173·13°	205·46°

F. Wüst and co-workers represented the mean sp. ht. between 0° and θ° up to 1070°, by $0{\cdot}12037+0{\cdot}0_4 2541\theta$; between 1130° and 1210°, by $0{\cdot}17700-7{\cdot}41\theta^{-1}$; and between 1230° and 1250°, by $0{\cdot}19800-3{\cdot}8\theta^{-1}$; where the true sp. ht. between 0° and 1070° is $0{\cdot}12037+0{\cdot}0_4 5082\theta$. H. Klinkhardt studied the sp. ht. of manganese steels. Manganese suffers an allotropic change between 1070° and 1130° which has a thermal value of 24·14 Cals. R. A. Hadfield showed that the thermal conductivity of manganese steel is less than that of ordinary steel ; A. Schulze gave for a 10 per cent. manganese steel, $\lambda=0{\cdot}03$; and W. S. Potter found the thermal conductivity up to 600° is about one-third of that of ordinary steel. T. Matsushita's results for the thermal conductivity, in c.g.s. units, and electrical conductivity, in mhos, of manganese steel are summarized in Fig. 480.

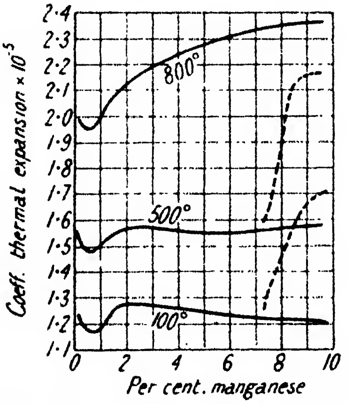

FIG. 479.—Thermal Expansion of Manganese Steels.

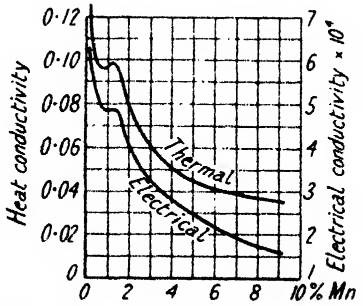

FIG. 480.—Thermal and Electrical Conductivities of Manganese Steel.

J. T. Littleton found the reflecting power, R, the coeff. of extinction, k, and the index of refraction, μ, for light of wave-length 5893, and an alloy with 50, 75, and 100 per cent. manganese, to be respectively, R=61·0, 62·5, and 64·0; k=3·70, 3·77, and 3·88; and μ=2·42, 2·43, and 2·41. S. Shimura and K. Wada studied the spectral analysis of the alloys; and H. Pincass, the spectra of the Fe-Mn catalyst.

W. F. Barrett, and J. H. Partridge found that the electrical resistance of steel is increased by the introduction of manganese, so that manganese steel can be used for making resistance coils; and E. Hopkinson observed that a steel with 13·95 per cent. manganese had a resistance eight times as great as that of iron. W. F. Barrett said that the increased resistance with rise of temp. is 0·136 per cent. per degree, while with iron, the increase is 0·5 per cent. W. S. Potter said that the resistance of manganese steel is roughly 3·4 times that of Bessemer steel. According to H. le Chatelier, the resistance of steel increases 5 microhms for each per cent. of manganese; and the resistance of magnetic steel with a high proportion of manganese is much less than the same steel in the non-magnetic state. Observations were made by T. Matsushita, H. A. Dickie, and H. Tomlinson. O. Boudouard saw that the proportion of carbon does not affect the resistance of manganese steel, and that the resistance, R microhms per cm. cube, attains a maximum with 12 to 13 per cent. of manganese; thus:

Mn .	0·43	2·15	6·14	10·51	12·92	14·40 per cent.
R .	15·5	25·4	59·8	73·1	75·8	72·5

K. Tamaru found that the electrical resistance of rods slowly cooled from 1050° increase at first linearly with increasing proportions of manganese, Fig. 481; the increase is rapid between 3 and 5 per cent. Mn, and then again linearly with the increase of manganese. This rapid increase is caused by the increasing content of austenite intermingled with ferrite. The linear increase of resistance above 5 per cent. of manganese-content shows that the resistance of austenitic steel increases linearly with the content of manganese; hence, when this linear portion of the curve is extrapolated to manganese-content zero, the corresponding ordinate gives the electrical resistance of austenitic carbon steel containing 0·5 per cent. of carbon at room temp., its sp. resistance being $32{\cdot}7\times10^{-6}$ ohm. The linear portion below 3 per cent. of manganese shows the electrical resistance of pearlitic steel; it intersects with the ordinate at a point 20×10^{-6} ohm when extrapolated to manganese zero, this value being sp. resistance of pearlitic steel containing 0·5 per cent. of carbon, and in good agreement with the result found by H. Masumoto. E. Gumlich represented the resistance of alloys with p per cent. manganese—up to 9 per cent. Mn— by $R=0{\cdot}1+0{\cdot}05p$; and with over 10 per cent. of manganese, by $R=0{\cdot}506\times0{\cdot}007(p-10)$. There is a break in the resistance curve, R microhms per cm. cube; and also in the curve showing the percentage decrease in the temp. coeff. of the resistance of manganese steel slowly cooled from 800°. T. Matsushita's results for the electrical conductivity, in ohms, of manganese steels are shown in Fig. 482. H. le Chatelier gave 5·0 microhms per cm. cube for the increase in the

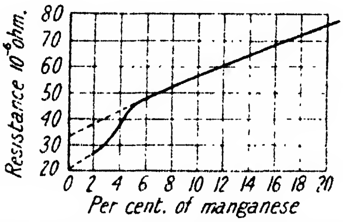

FIG. 481.—Electrical Resistance of Manganese Steels.

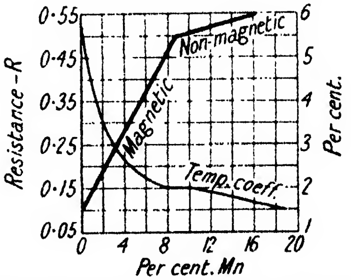

FIG. 482.—Electrical Resistance Curve of Manganese Steels.

resistance of magnetic, and 3·5 microhms for non-magnetic steels by the addition of 1 per cent. of manganese; W. F. Barrett, and E. Gumlich and P. Goerens gave 5·0; G. Lang, and T. Matsushita, 5·5. H. Tomlinson found that the electrical resistance is decreased by annealing hard-drawn wires, and that the resistance is increased by a longitudinal pull, and by longitudinal magnetization.

G. Tammann and E. Vaders found the e.m.f. of the cell Fe : 0·1*N*-$MnCl_2$: $Mn_nFe_{(100-n)}$, where *n* represents the percentage by weight:

n	19·53	29·37	36·58	58·94	69·24	78·89	100 per cent.
E immediately	0·035	0·290	0·260	0·248	0·475	0·465	0·520 volt
E after 40 hrs.	0·005	0·080	0·050	0·120	0·160	0·130	0·300 ,,

A. N. Campbell discussed the anodic behaviour of 77·9 per cent. ferromanganese in *M*-soln. of manganese sulphate, nitrate and chloride, and in ferrous sulphate. Passivity was absent in soln. of ferrous chloride with a slight excess of acid. At ordinary temp., passivity was found to occur in all the soln., but it was not complete; it was specially marked with manganese sulphate soln. The potential of the visible oxygen discharge from a neutral electrolyte at the ordinary temp. is about +2·15 volts (abs.). This is near the potential required for the formation of permanganate in an electrolyte of manganese sulphate. The passivity is destroyed at 25°, and also by activating the anode by charging it with hydrogen or by etching it with sulphuric acid. The passivity is reduced by a superposed alternating current. In *N*-potassium hydroxide electrolyte at 15° and 75° there is no formation of manganate, and nothing enters into soln.; but heavy slimes are formed. In other cases, both components entered into soln.; the efficiency is often less than 100 per cent., possibly owing to soln. being followed by immediate precipitation. Under a gas discharge the anode disintegrates, and ferromanganese is thus useless as an insoluble anode. C. Wells and J. C. Warner, and M. de K. Thompson and R. B. Morrissey studied the potential of ferromanganese.

E. Sedström, and J. Galibourg studied the thermoelectric properties of the alloys. E. L. Dupuy and A. M. Portevin found that the thermoelectric force against copper, in millivolts, with steels having 0·84 to 0·96 per cent. of carbon, is as follows:

Mn		0·40	1·03	3·08	12·09 per cent.
Annealed	−80°	−0·30	−0·70	−2·60	−9·60
	100°	−3·10	−2·80	−4·70	−11·80
Hardened	−80°	−0·00	−5·40	—	−10·00
	100°	−2·00	−6·65	—	—

As indicated above, S. Rinman, and D. Mushet noticed that manganese diminishes or destroys the magnetic properties of steel even when there is eight or nine times as much iron as manganese present. R. A. Hadfield added that the material behaves in the same manner in its forged or cast state, and water or oil quenching makes practically no difference. J. Hopkinson observed that the small quantity of manganese present enters into what must be regarded, for magnetic purposes, as the molecule of iron, and completely changes its properties. Twelve per cent. of manganese annihilates the magnetic properties of iron. J. A. Ewing and W. Low said that even under the magnetic forces amounting to 10,000 c.g.s. units, the resistance which 13·95 per cent. manganese steel offers to magnetization suffers no break-down in any way comparable to that which occurs with wrought-iron, cast iron, or ordinary steel, at a very early stage in the process of magnetization. On the contrary, the permeability is approximately constant under large and small forces, and may be therefore concluded as being only fractionally greater than that of copper, brass, or air. As indicated above, R. A. Hadfield noted that the magnetization disappears at 700°; and when the non-magnetic steel is heated several hours at 500°, it becomes magnetic. W. F. Barrett found that when the magnetization of ordinary iron is represented by 100,000, that of manganese steel is 20, and its susceptibility or induced magnetization is about as low as that of zinc or other non-magnetic metals. Observations were made by H. A. Dickie, L. T. O'Shea, H. Tomlinson, R. A. Hadfield and co-workers, W. F. Barrett, A. Abt, A. D. Ross, J. J. Porter, E. Griffiths, etc. S. Hilpert and W. Mathesius, T. Matsushita, J. H. Partridge, F. Goltze, H. F. Parshall, P. Kapitza, E. Gerold, and C. F. Burgess and J. Aston gave for the magnetic induction of alloys of manganese and iron the results indicated in Table LXXXV. The annealed alloys show a marked decrease in permeability with increasing proportions of manganese. Annealing at 675° improves the permeability, but a second annealing at 1000° lessens it. Quenching restores the 4·51 per cent. alloy to its best condition obtained by a first annealing at 675°. The values for coercive force and retentivity, Table LXXXVI, follow closely the fluctuations in the permeability.

W. Mathesius investigated and measured the magnetization, the coercive force, and the saturation of manganese steels with 0·45 to 20·8 per cent. of manganese, and 0·21 to 2·18 per cent. of carbon, after they had been subjected to different heat-treatments. The results are summarized in Table LXXXVII. E. Gumlich represented his observations on manganese steels with 0·23 per cent. carbon, and quenched from 800°, by Fig. 476; the discontinuity in the curve corresponds with that obtained for the sp. gr., and for the sp. resistance, Fig. 482. The magnetic state was obtained by cooling the specimens to —193°, and the non-magnetic state by cooling or quenching from Ac_2. The sp. gr. of the non-magnetic steel is much greater than that of the magnetic; and the sp. resistance of the non-magnetic steel is less than that of the magnetic. R. A. Hadfield and co-workers found the magnetic susceptibility increases as the proportion of carbon diminishes (manganese constant); and with carbon constant, the effect of manganese is small. The mass susceptibility increases as the [C]/[Mn] ratio decreases. The mass susceptibility of manganese steels ranges from 17×10^{-6} to 259×10^{-6}, so that the alloys are paramagnetic. With the [C]/[Mn] ratio constant, 2·57 to 19 per cent. of nickel raises the susceptibility in the ratio 23 : 67 ; 0·74 per cent. of tungsten raises the susceptibility in the ratio 18 : 29 ; 3·5 per cent. of chromium raises the susceptibility 10 per cent. ; 2·5 per cent. of copper raises the susceptibility of a manganese-nickel steel 19 per cent. ; and the addition of silicon to a manganese steel makes the steel more ferromagnetic. No relation between the sp. gr. and mass susceptibility or composition was observed.

R. A. Hadfield studied the temp. of the critical magnetic change in the alloys. With over 16 per cent. manganese the alloys have no magnetic transformation, but with the magnetic alloys there is a transformation at 767° to 776° on cooling, and 765° to 780° on heating. H. K. Onnes and co-workers studied the magnetic properties of these steels at a low temp. E. Gumlich assumes that there are two allotropic states involved. He found that non-magnetic, high per cent. manganese steel becomes magnetic with a martensitic structure when dipped in liquid air.

E. Gumlich obtained the hysteresis loop shown in Fig. 483 for steel with 12·4 per cent. manganese, and 0·23 per cent. carbon. The magnetization of the steel cooled to −78° is comparable with that of a feebly magnetic steel; and the improvement observed in heating the steel for 24 hrs. at 800° in vacuo is attributed to the surface oxidation by traces of residual air in the vessel.

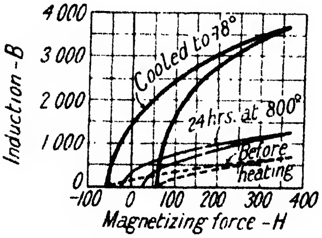

FIG. 483.—Hysteresis Loop of 12·4 per cent. Manganese Steel.

G. Mars, discussing the low magnetic properties of the manganese steels, said that the magnetism depends not so much on the kind of molecule present as on the structure of the molecule, *i.e.* not on the chemical nature of the body, but on the space left free between the molecules, or on the form of this space. This intermolecular space, which is assumed to be filled with æther, and which acts as the magnetic medium, is, in the case of iron, cobalt, and nickel, of such a nature that it causes a mechanical disturbance of the metal mols., the effect of which is to produce magnetic attraction or repulsion. This intermolecular space of a magnetic metal is changed when the metal is alloyed with another magnetic or non-magnetic metal. Thus, even when two magnetic metals, like iron and nickel, are melted together, the result may be non-magnetic metal; whereas two non-magnetic metals, like manganese and aluminium, may give a strongly magnetic alloy— *e.g.* the Heustler alloys. Consequently, the magnetism of one and the same magnetic metal may be reduced by heating it to a certain temp., because the mols. are thus driven farther apart, and the cohesion between them is reduced; again, any treatment which disturbs the arrangement in space of the mols. of a magnetic metal *e.g.* cold-working—may alter considerably the magnetism of the metal. A. Schulze measured the magnetostriction of alloys. Observations were also made on the effect of the magnetic intensity and concentration on the magnetostriction of iron-manganese alloys.

R. Dubois observed that a ferromanganese, with about 80 per cent. of manganese, disintegrated on exposure to air. G. Tammann and E. Vaders, and A. N. Campbell studied the passivity of these alloys. B. H. Thwaite found that steels with 0·684 and 12·55 per cent. manganese, and respectively 0·16 and 0·067 per cent. of carbon, were attacked by dil. nitric acid (1 : 9), so that the former lost 0·1475 and the latter 0·1735 grm. per sq. cm. when exposed for the same time. The increase in corrodibility of steel when manganese is present was also noted by P. Berthier, C. W. von Siemens, T. Turner, E. Heyn and O. Bauer, G. J. Snelus, C. F. Burgess and J. Aston, C. H. Desch and S. Whyte, L. Aitchison, R. Finkener, and A. S. Cushman. R. A. Hadfield and J. A. N. Friend found that in the absence of sulphur, manganese is not a particularly objectionable element in steel. L. B. Pfeil observed that a three-layer scale—*vide supra*—is formed when manganese steel is heated to 1000° for a few hours in air. With a 0·71 and a 3 per cent. manganese steel, the manganese in the innermost layer was about two-thirds of that present in the original steel, whilst in the middle and outer layers a little more manganese was present than was contained in the original steel. Usually, with other alloy steels, more foreign element is contained in the innermost layer than in the middle layer. E. Heyn and O. Bauer noted that with cast iron containing 3·5 C, 2·5 Si, and 0·07 P and S, and exposed to tap-water, the relative corrodibilities were:

Mn . . .	0·46	0·70	0·99	1·90	2·83	3·08 per cent.
Corrosion . .	100	92	100	94	96	89

C. F. Burgess and J. Aston found that the corrosion of manganese-iron alloys in grams per sq. dm., on exposure for an hour to 20 per cent. sulphuric acid, and the corrosion in kgrms. per sq. metre per year, on exposure to the weather for 162 days from July to February, were:

Mn . .	0·505	1·000	2·000	3·000	10·419
Acid . .	0·560	0·520	0·725	1·110	0·352
Air . .	0·268	0·390	0·302	0·327	0·435

Y. Utida and M. Saito measured the loss in weight, in grams per sq. cm., when manganese steels with about 0·05 per cent. of carbon are immersed for 24 hrs. in 10 per cent. acid:

Manganese . . .	0	0·95	4·36	8·41	13·75	16·55 per cent.
HNO_3	0·9380	0·5090	0·6464	0·7720	0·8263	0·7570
HCl	0·0712	0·2191	0·5015	0·5520	0·8930	0·8570
H_2SO_4	0·0990	0·1854	0·3055	0·5999	2·5850	3·0120

W. Guertler and T Liepus, J. Aston, E Maurer, O. Bauer, R. Dubois, O. W. Storey, E. A. and L. T Richardson, R. A. Hadfield, C. Duisberg, H. G. Haase, V. V. Kendall and E. S. Taylerson, and C. H. Charles studied the corrodibility of the iron-manganese alloys. S. Satoh studied the nitridization of these steels by heating them in ammonia at 560° to 580°. H. Endo's results, Fig. 484, represent the loss in grams per sq. cm., during 5 hrs.' action, at ordinary temp. on alloys with 0·47 to 0·52 per cent. of carbon, and the proportions of manganese indicated. R. A. Hadfield and J. A. N. Friend found with steels containing 0·10 to 0·9 per cent. of manganese, a slight increased resistance to corrosion by tap-water, and wet and dry tests occur with carbon up to about 0·5 per cent. From this point upwards, the manganese affords, generally, a slight protection which is decided in the wet and dry tests, but is not invariable with sea-water tests. The manganese raises the corrodibility by sulphuric acid; and E. A. and L. T. Richardson observed that manganese enhances the effect of copper in iron in resisting the attack of the alloy by corrosive influences. K. Hilgenstock studied the action of hydrogen sulphide and of sulphur dioxide on red-hot ferromanganese. R. Schenck and A. Kortengräber studied the dissociation press. of alloys in nitrogen. J. A. N. Friend noted the effect of manganese in masking the increased corrodibility caused by the addition of carbon to steels. C. H. Desch and S. Whyte observed no definite influence in the corrosion of manganese steels in 5 per cent. sodium chloride. The manganese was preferentially dissolved. L. Aitchison found that the losses of weight in grams per 100 sq. cm. are:

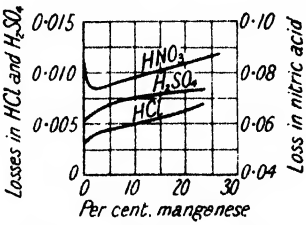

FIG. 484.—The Corrosion of Manganese Steels by Acids.

C	0·28	0·48	0·76	0·87 per cent.
Mn	0·94	0·91	1·01	0·83 ,,
NaCl 3 per cent. . .	1·82	1·94	2·50	1·88
H_2SO_4 { 1 per cent. .	8·16	9·70	4·67	7·08
H_2SO_4 { 10 per cent. .	8·05	8·80	12·3	6·12
Tap-water . . .	0·900	0·960	1·43	0·872

R. A. Hadfield and J. A. N. Friend also measured the effect with tap-water; L. Aitchison, C. Chappell, and R. A. Hadfield and J. A. N. Friend, sea-water; R. A. Hadfield and J. A. N. Friend, the effect when alternately wet and dry; and in 0·5 per cent. sulphuric acid. C. Chappell also observed the effect of dil. sulphuric acid. R. A. Hadfield and J. A. N. Friend thus summarized their observations:

> (1) The addition of from 0·03 to 1·63 per cent. of carbon to iron containing less than 0·2 per cent. of manganese results in (*a*) a steadily increasing rate of corrosion both in tap-water and sea-water, slight maxima being observed in the neighbourhood of 0·6 to 0·8 per cent. carbon; (*b*) an initial fall in corrosion, with a rapid rise to a maximum with 1·05 per cent. of carbon; (*c*) a rapid rise in corrosion to a maximum with 0·8 per cent. of carbon when exposed to the action of dil. sulphuric acid. There is some difference in the behaviour of steel towards all the corroding media in the neighbourhood of the eutectic composition, either a tendency to increased corrosion, or a decided increase in corrosion. (2) The addition of 0·7 per cent. manganese to all the steels resulted in (*a*) a very slightly increased corrosion in tap-water, sea-water, and in wet and dry tests, with a carbon-content up to

0·4 to 0·5 per cent. From this point upwards, the manganese, in general, affords a slight protection which is very decided in the wet and dry tests, but is not invariable in the sea-water tests. (*b*) An enormously increased corrosion in dil. sulphuric acid. This is important, since in commercial steels the manganese frequently ranges from 0·2 to 0·7 per cent., and the latter are therefore unsuited to acidic corroding media. A point of maximum corrosion occurs with a smaller per cent. of carbon than in steels with less manganese. (3) By increasing the proportion of manganese to 2 per cent. upwards, (*a*) the corrodibility of the steel in neutral soln. is greatly increased, particularly when the carbon-content exceeds 0·5 per cent. (*b*) The corrodibility in dil. sulphuric acid is greatly augmented.

N. Parravano [29] studied the ternary **iron-manganese-copper alloys,** and his results are summarized in Fig. 485. The gap in the binary copper–iron system is reduced by the addition of manganese, so that with 50 per cent. manganese, the solid solubility is complete. The continuous lines are liquidus curves, the dotted lines, solidus curves. F. Ostermann examined the manganese-copper steels, with 0·1 to 1·0 per cent. of carbon. The iron and copper are miscible in all proportions when 20° above the liquidus line. When carbon is added a two-layer system is formed in which most of the carbon collects in the layer rich in iron; on introducing manganese, the two-layer system is changed back to a single-layer phase. E. L. Nichols studied the electrical resistance of the iron-manganese-copper alloys. A number of these alloys had the remarkable property of decreasing in resistance each time that they were subjected to a change of temp.; an alloy containing 80·82 per cent. of copper and 19·12 per cent. of ferromanganese, when heated and cooled from 100° to 20°, diminished in resistance with each operation, the diminution being still perceptible at the end of the seventh cycle. On being then raised to a red-heat and allowed to cool, a still more marked diminution in the resistance of the above alloy was found to have taken place. The temp. coeff. of this alloy was positive, and continued to increase as the heating and cooling process was repeated. With an alloy consisting of 70·65 parts of copper and 29·35 parts of ferromanganese, a similar behaviour was observed. After being brought into a condition of stability such that further heating and cooling through a range of 80° had but little permanent effect upon its conductivity, it still showed, when hard-drawn, an appreciable negative temp. coeff. It was then annealed three times at red-heat, the sp. resistance and temp. coeff. being determined for the range of 20° to 100° after each annealing. The results were as follow:

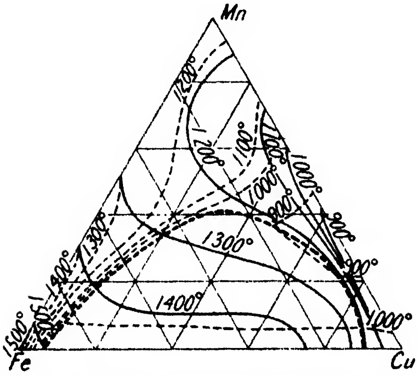

FIG. 485.—The Ternary System: Mn–Fe–Cu.

		Resistance			
		20°	100°	20°	Temperature coefficient
Hard		46·10	45·99	46·09	−0·000024
Annealed	once	45·10	45·18	45·09	+0·000021
	twice	44·07	44·33	44·06	+0·000068
	thrice	42·70	43·58	42·74	+0·000192

A number of similar alloys showed, when hard-rolled, a temp. coeff. very near to zero, sometimes positive, sometimes negative. After annealing at 300° to 400°, a well-defined negative coeff. was produced. It was found that the positive coeff. produced by annealing could be reduced again by rolling the alloy. With 10 per cent. of ferromanganese, the change of resistance is less than 1 per cent. for 100°. Alloys containing from 15 to 20 per cent. of ferromanganese have exceedingly small temp. coeff., the coeff. at 18 per cent. being practically zero. The coeff. may be made to undergo a considerable alteration by varying the temper of the metal.

The marked influence of temper upon the conductivity of these alloys renders it difficult to determine the precise law of the change in sp. resistance with the composition. It would, however, appear from the results that the resistance increases nearly in direct proportion to the percentage of ferromanganese.

T. W. Hogg prepared some **iron-manganese-aluminium alloys,** and observed that the alloy from 5·56 lbs. aluminium, and 50 lbs. of 82 per cent. ferromanganese, after standing twelve months, is completely disintegrated. G. Craig suggested that the disintegration is due to oxidation. The alloy was magnetic. Both manganese and aluminium reduce or destroy the magnetic property of iron, but raise the magnetic property when both are present. The mechanical properties were studied by P. E. McKinney.

L. Guillet studied the **manganese-silicon steels** with 0·104 to 0·620 per cent. carbon, 0·457 to 2·310 per cent. silicon, and 0·450 to 14·760 per cent. manganese. E. Kothny also studied a couple of these alloys. Steels with about 2 per cent. of manganese, 0·1 of carbon, and 0·5 to 1·5 of silicon, and also those with 0·5 per cent. carbon, 0·5 manganese, and up to 1·8 silicon, are pearlitic, with the grains of ferrite the closer the higher is the proportion of silicon. The other steels have polyhedra of γ-iron in some cases—*e.g.* 0·2 C, 2 Mn, and 1·5 Si—with fairly well-marked cleavage planes, and a few needles of martensite on the borders. Quenching from 850° renders the pearlitic steels martensitic. The γ-iron steels remain polyhedral, though the 0·2 C, 2 Mn, and 1·5 Si steel becomes wholly martensitic; this steel also becomes martensitic on annealing at 950° to 1200°, and when cooled in liquid air. The other steels were not changed by cooling in liquid air. The ferrite of the pearlitic steels becomes coarser on annealing, while the other steels remain unchanged. No precipitation of carbon was observed. The case-hardening of the pearlitic steels leaves a core of pearlite, a zone of troostite, and an outer zone of γ-iron. If carried far enough, pearlite and cementite are formed on the exterior. The mechanical tests on the normal steels show that silicon raises the tensile strength and elastic limit, and lowers the elongation, reduction of area, and resistance to shock. The variation in the elastic limit of the γ-iron steels was small. As silicon alters the mechanical structure, corresponding alterations occur in the mechanical properties, but the addition of silicon is, in general, injurious to manganese steels. Quenching raises the tensile strength and elastic limits, but reduces the elongation, reduction of area, and resistance to shock. Annealing softens all the steels excepting that with 0·2 C, 2 Mn, and 1·5 Si. G. Burns, B. Stoughton and W. E. Harvey, E. W. Colbeck and D. Hanson, G. H. Keulegan and M. R. Houseman, G. A. Hawkins and co-workers, W. Riede, S. Heuland, A. B. Kinzel, K. T. Kürten, W. Venator, and E. Mallard discussed the iron-manganese-silicon alloys. P. Nicolau examined their thermo-electric properties. F. Kohlhaas patented a *manganese-silicon-titanium steel*—0·9 to 1·0 C, 0·4 to 0·7 Si, 9·8 to 10·3 Mn, and 0·2 to 1·4 Ti.

L. Guillet prepared **manganese-chromium steels** with 0·128 to 0·923 per cent. carbon: 1·92 to 14·02 manganese; and 2·87 to 5·25 chromium. The microstructure shows that these steels may contain (i) pearlite (or troostite) if the proportions of manganese and chromium are not too high; (ii) martensite—with or without carbide; and (iii) polyhedra of γ-iron—with or without carbide. The alterations in structure show that the effect of chromium is superadded to that of the manganese, and when the proportion of chromium is high, a carbide is formed. Quenching renders the steels with pearlite wholly martensitic, it may render some with polyhedral γ-iron martensitic, and it may cause cleavage-planes to appear in some of the polyhedra. Annealing has very little effect on the martensitic or troostitic steels, but it produces transformations in the γ-iron, rendering it martensitic or troostosorbitic—*vide* the nickel chromium steels. Cooling in liquid air has very little influence. Stressing in the cold converted the steel with γ-iron and martensite into a martensite steel. The case-hardening of the martensitic steel left a central core of martensite, then a zone of troostite intermixed with martensite, and then a thin zone of γ-iron. In general, the mechanical properties correspond with the structure. The normal martensitic steels have a high tensile strength and elastic limit, a low elongation and reduction of area, high brittleness, and an enormous hardness. The troostitic steels have less strongly marked properties, while those with γ-iron have a high tensile strength but low elastic limit, a fairly high elongation, a high resistance to shock, and a medium hardness. The presence of carbide diminishes the resistance to shock. The changes in the mechanical properties which occur on quenching correspond with the microstructure. The hardness, tensile strength, and elastic limit generally increase; the elongation, reduction of area, and resistance to shock are reduced. Steels with γ-iron are softened by quenching—the elastic limit is reduced, and the resistance to shock is increased. Annealing has, in general, but little effect on the mechanical properties, though in some cases the hardness, tensile strength, and elastic limit are raised, while the elongation, and reduction of area, and resistance to shock are reduced. F. M. Beckett, J. M. Becket, A. B. Kinzel and W. B. Miller, and C. L. Clark and A. E. White studied the mechanical properties of these steels. W. Rohn found that the corrodibility of a Fe : Cr : Mn (60 : 25 : 15) alloy – normal and annealed —expressed as a loss in weight in grams per sq. dm., with 10 per cent. acids, is :

	HNO_3		H_2SO_4		HCl	
	N	A	N	A	N	A
24 hrs. cold .	0·02	0	0·28	0·82	0·34	0·15
1 hr. hot .	0·02	0	2·8	3·81	1·40	0·49

W. Guertler and T. Liepus also studied the corrodibility of the iron-manganese-molybdenum alloys. W. F. Rowden, and G. Burns studied the **manganese-molybdenum-iron alloys** ; and P. Berthier, and V. Ehmcke, **manganese-tungsten-iron alloys** ; A. Stavenhagen and E. Schuchard prepared **manganese-uranium-iron alloys** by the thermite process; and W. C. Hamilton examined some **manganese-vanadium-iron alloys.**

§ 28. Ferrous Oxide and its Hydrate

The supporters of the phlogiston theory knew that the calx of iron unites with different proportions of phlogiston. Thus, in 1777, C. W. Scheele[1] said :

> I dissolved 2 ounces of martial vitriol in 32 ounces of water, and precipitated the soln. with a caustic lye. The precipitate being settled, I decanted the clear liquor, and I put the deep green precipitate of iron, together with the remaining liquor, into a bottle and corked it well. After a fortnight (during all of which time I shook the bottle frequently), the green calx of iron had acquired the colour of *crocus martis*, and out of 40 parts of air, 12 were lost.

J. Priestley made some observations on the oxidation of iron based on the phlogiston theory.

At the end of the eighteenth century, A. L. Lavoisier recognised two stages in the oxidation of iron ; and, near the beginning of the nineteenth century,

C. L. Berthollet believed that a great many oxides of iron exist—indeed, he was inclined to believe that the iron and oxygen form a continuously progressing series of indefinite compounds; but J. L. Proust considered that the various oxides so-called were mixtures or combinations of ferrous and ferric oxide. C. F. Bucholz, and J. Dalton favoured J. L. Proust's hypothesis; J. F. d'Aubuisson, and L. J. Thénard, favoured C. L. Berthollet's. J. L. Gay Lussac recognized an intermediate variety between ferrous and ferric oxides; and J. J. Berzelius at first supposed that there are only two oxides, but later proved that there are three definite oxides, namely *iron monoxide*, or **ferrous oxide,** FeO; *ferrosic oxide*, Fe_3O_4; and *ferric oxide*, Fe_2O_3. The oxides with a composition between those of ferrous and ferrosic oxides are considered to be solid soln., and have been named *wüstite;* those with a composition between ferrous oxide and iron have been called *oxyferrites*, and if the iron is also associated with carbon and cooled rapidly, *oxyaustenites;* and likewise, also, with those oxides having a composition between those of ferrosic and ferric oxides—*vide infra*; they form solid soln. which have been called *martites* —*vide* ferric oxide. Salts of the unknown *iron dioxide*, FeO_2, and of the unknown *iron trioxide*, FeO_3, have also been prepared; the former are called *perferrites*, and the latter *ferrates;* whilst the salts of ferric oxide are called *ferrites*. There is also the supposed *iron tetroxide*, FeO_4, and the salts of the corresponding acid, namely, the *perferrates*.

A. Brun reported that volcanic lava passing from the vitreous to the crystalline state traverses a period in which ferrous oxide is deposited as a new mineral which he called **iozite.** The presence of iozite in the lava is taken to indicate that water was absent at the time of its formation. The ferrous oxide content of a lava is reduced by the oxidizing action of air or steam. Hence, the magma in the crater is probably less highly oxidized than the lava outside. The subject was discussed by G. Ponte. The individuality of iozite is not yet established as a definite mineral species.

According to R. F. Marchand, when iron is burnt in the oxyhydrogen flame, the product of combustion is not the scaly oxide obtained when the metal is burnt in oxygen gas, but a fused, malleable mass which dissolves in hydrochloric acid with the evolution of hydrogen to form ferrous chloride. R. F. Marchand found that the analysis agreed with the assumption that *eine Verbindungen des Eisenoxyduls mit metallischen Eisen*, $Fe_3(FeO)$, or *ferrous suboxide*, or *iron tetritoxide*, Fe_4O, is formed. This has not been confirmed; it is thought that the alleged suboxide is a mixture or solid soln. of iron and ferrous oxide, or, possibly, ferrosic oxide. R. Schenck obtained a product with the ultimate composition Fe_3O, *iron tritoxide*, by the action of a mixture of equal parts of carbon monoxide and dioxide on a mixture of magnesia and finely-divided iron at about 650° and atm. press., but the work of R. Schenck and co-workers, G. Lepetit, and J. Müller showed that the product is really a solid soln. of ferrous oxide and magnesia. I. L. Bell supposed that an *iron hemioxide*, Fe_2O, is formed by the action of carbon monoxide on ferric oxide, and L. Dusart, that a similar oxide is produced by the oxidation of the hemisulphide with steam at 60°; but R. Akermann and C. G. Särnström showed that the product obtained by the action of carbon monoxide is a mixture of iron, ferrous oxide, and ferrosic oxide. W. Galbraith, and F. R. Eichhoff assumed that a product approximating Fe_7O, occurs as an inclusion in iron. C. R. Wohrmann discussed the ferrous oxide inclusions in iron. W. G. Mixter obtained a product approximating Fe_5O_4 by the action of a current of nitrogen on ferrous oxalate at 900°, but it was considered to be a mixture of iron and ferrous oxide. J. B. Ferguson, in his study of the action of water vapour on heated iron, obtained no evidence of the formation of any oxide of iron lower than ferrous oxide.

The solubility of iron in ferrous oxide, observed by A. Matsubara, and E. D. Eastman, was found by H. Groebler and co-workers not to exist; the solubility of iron in solid ferrous oxide is inappreciable when examined by the X-radiogram process. F. S. Tritton and D. Hanson reported that molten ferrous oxide dissolves about 1 per cent. of iron. H. le Chatelier and B. Bogitsch noticed that oxygen can dissolve in solid iron; and the subject was examined by J. E. Stead, and J. H. Whiteley. E. D. Eastman found that ferrous oxide is unstable with respect to iron below 550°; but although iron is not appreciably soluble in ferrous oxide, ferrous oxide is soluble in iron to the extent of 20 to 25 molar per cent.—*i.e.* 6 to 8 per cent. of oxygen. F. S. Tritton and D. Hanson obtained an equilibrium diagram for iron containing from 0·1 per cent. oxygen up to approximately 22 per cent., represented by the compound FeO. There is a large range of immiscibility of the two components, which in the molten state separate into two liquid layers. C. H. Herty and J. M. Gaines found that arrest points for δ-, γ-, and β-iron are not affected by the presence of from 0·12 to 0·21 per cent. of oxygen. The solubility of ferrous oxide in γ-iron is rather greater than it is in α-iron, because the A_3-arrest is lowered by the presence of the oxide. The lowering of the A_3-arrest is accompanied by the raising of the A_4-arrest. K. Schönert gave for the solubility of oxygen as ferrous oxide in α-, β-, and γ-iron respectively 0·03, 0·13, and 0·15 to 0·19 per cent. The proportion dissolved in α-iron increases with a rising temp., so that in molten iron at the f.p. the solubility is 0·21 per cent., and the f.p. is depressed to 1509°. When more oxygen is present, two solid phases are formed, the phase rich in oxygen contains about 0·21 per cent. of oxygen, and it consists mainly of ferrous oxide, a little ferric oxide, and 0·99 per cent. of free iron. The m.p. is lowered from 1535° to 1530° with the dissolution of 0·21 per cent. of oxygen; beyond this conc. of oxygen two liquid layers are formed. The solubility of oxygen in solid iron is taken to approximate to 0·05 per cent. oxygen; and the solubility of iron in the oxide about 1 per cent. C. Benedicks and H. Löfquist represented the equilibrium diagram by Fig. 486. The diagram is based on the observations of R. Akermann and C. G. Särnström on the solid phases in the system; of L. Wöhler and co-workers on the reduction of iron oxide with carbon monoxide; of R. B. Sosman and J. C. Hostetter on the equilibrium conditions when steam acts on iron; and on the assumed existence of solid soln. between the phases Fe and FeO, FeO and Fe_3O_4, and Fe_3O_4 and Fe_2O_3, discussed by W. Mathesius, P. Goerens, H. Moissan, etc.—*vide infra.* In C. Benedicks and H. Löfquist's diagram the m.p. of iron is lowered to *B* by the presence of dissolved ferrous oxide, and *BD* represents the solubility curve of ferrous oxide in molten iron determined approximately by C. C. de Coussergues, and more exactly by C. H. Herty. In the higher ranges of temp., liquid ferrous oxide and iron are only partially miscible, and it is estimated that the two solubility lines meet near 2000°, when the two phases become completely soluble. The f.p. of ferrous oxide is considered to be near 1370°, so that the curve *CGM* extends at least to 1370°, and *M* falls to the right of the wüstite area. The eutectic *N* was observed by P. Oberhoffer and K. d'Huart to occur at about 1200°, with about 24 per cent. of oxygen. S. Hilpert and others examined the system FeO–Fe_2O_3, but the data are somewhat indefinite. Although R. B. Sosman and J. C. Hostetter consider that there is a continuous series of solid soln. between Fe_2O_3 and Fe_3O_4, C. Benedicks and H. Löfquist consider that the great difference in the crystal structure of the two oxides favours the view that the miscibility is partial. The polymorphic forms of

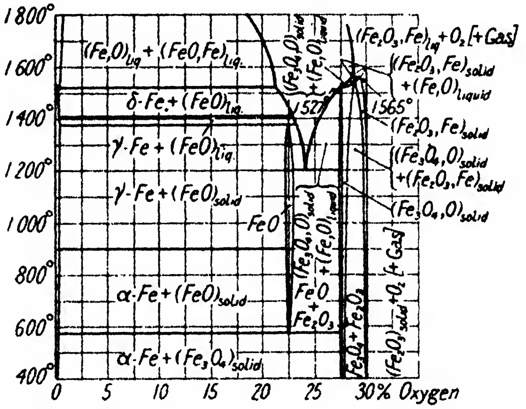

FIG. 486.—Equilibrium diagrams of the Iron-Oxygen System.

ferric and ferrosic oxides are not included in the diagram. The diagram was discussed by R. Schenck and T. Dingmann, P. Oberhoffer, E. Jänecke, R. Akerman, W. Austin, E. D. Eastman, E. W. Ehn, A. Matsubara, H. Monden, J. A. Picard, J. A. Picard and F. M. Potter, R. B. Sosman and J. C. Hostetter, J. E. Stead, A. E. White and J. S. Vanick, F. Sauerwald and W. Hummitzsch, and J. H. Whiteley.

The solubility of oxygen or ferrous oxide in molten iron was examined by A. Ledebur, P. Oberhoffer and K. d'Huart, F. Schmitz, A. Wimmer, and L. Romanoff. A. Ledebur found a maximum solubility of 0·24 per cent. of oxygen in liquid steel; F. S. Tritton and D. Hanson, K. Schönert, and C. H. Herty gave 0·21 per cent. at 1530°, and above that temp. the mixture separates into two layers; and A. Wimmer, 0·20 per cent. for iron at 40° or 50° above its m.p. C. H. Herty and J. M. Gaines gave for the solubility at 1535°, 0·94 per cent. of FeO, or 0·21 per cent. of oxygen; at 1600°, 1·36 per cent. of FeO, or 0·304 per cent. of oxygen; and at 1700°, 2·02 per cent. of FeO, or 0·452 per cent. of oxygen. H. le Chatelier observed that the dissociation press., p, of ferrous oxide dissolved in iron is $p\times10^{-8}=(1{\cdot}1C)^2$, where C denotes the conc. of the dissolved ferrous oxide. C. C. de Coussergues gave zero at 1400°, 1 per cent. at 1700°, and 3 per cent. at 1800°.

R. Schenck and T. Dingmann found a solubility of 2·8 per cent. ferrous oxide in solid iron at 1000°, and 2·05 per cent. at 700°. R. Schenck and co-workers later said that this result is only apparent, and is due to the formation of unstable wüstite; the solubility is 0·4 per cent. at 800° and 1000°; and they assumed a solubility of 0·8 per cent. at 700°. E. D. Eastman and R. M. Evans obtained a 5 per cent. solubility in iron at 772°; and A. Matsubara 6 to 7 per cent. For the solubility of oxygen in α-iron A. Wimmer gave 0·035 per cent., T. D. Yensen 0·4 per cent.; F. S. Tritton and D. Hanson gave 0·055 per cent. and P. Oberhoffer and co-workers 0·05 per cent. The solubility of oxygen in so-called β-iron was estimated by A. Wimmer to be 0·13 per cent., and a eutectic structure could be detected in iron with this proportion of oxygen. W. Dünwald and C. Wagner said that the solubility of oxygen in α- and γ-ferrites between 800° and 1000° is less than 0·01 per cent. The subject was discussed by H. Esser. The solubility of oxygen in γ-iron was measured by W. Austin, E. L. Reed, H. Monden, A. McCance, K. Schönert, P. Oberhoffer and co-workers, C. Benedicks and H. Löfquist, L. von Friesen, and J. C. W. Humfrey. The high values are based on equilibrium measurements, and the low values on the microstructure. Observations based on X-radiograms were made by H. Groebler and co-workers; and the magnetic measurements of J. Huggett and co-workers show no appreciable solubility of ferrous oxide in iron. W. Krings and J. Kempkens showed that the high values for the solubility of oxygen in iron are probably wrong, and they obtained 0·11±0·015 per cent. at 715°, and 0·095 ±0·010 per cent. at 800°. Even this is higher than the observed values for the quantity of oxygen in commercial iron, where the proportion is of the order 0·05 per cent. The results obtained by heating iron in mixtures of steam and hydrogen for 24 to 65 hrs. at 715°, when the estimated partial press. of the oxygen was p, were as follow:

Steam . . .	28·0	24·0	18·5	10·0	2·5	trace per cent.
$p\times10^{21}$ atm. .	0·87	0·57	0·305	0·0707	0·0038	—
Oxygen in iron .	0·0862	0·0832	0·0832	0·0832	0·0678	0·0185 per cent.

The limiting value is extrapolated to be 0·11 per cent. The results are in harmony with those obtained for the equilibrium: $FeO+H_2\rightleftharpoons Fe+H_2O$—*vide supra.*

R. Schenck studied the solid soln. of small quantities of ferrous oxide in iron, and he called them **oxyferrite,** or rather *oxoferrite;* if the ferrite be replaced by austenite, then the corresponding solid soln. is called **oxyaustenite.** Ferrous oxide does not occur as a solid phase, but it is part of a series of solid soln. of FeO and Fe_3O_4 called **wüstite.** Ferrous oxide is the dominant constituent of wüstite. At higher temp. the solid soln. wüstite approximates FeO. R. Schenck and co-workers found that in the reaction $FeO+CO \rightleftharpoons Fe+CO_2$, the proportions of stable oxyferrite, and wüstite formed are those indicated in Table LXXXVIII and Fig. 487. Wüstite can exist as a homogeneous solid soln. of variable composition only above 570° and all mixtures intermediate between oxyferrite and magnetite, below 570°, split into these components to form a heterogeneous mixture. Wüstite, however, may occur as a metastable phase down to about 420°. Oxyferrite also occurs as a homogeneous stable phase. Any mixture of intermediate composition cannot exist as a stable, homogeneous phase, but splits up into two solid soln., wüstite and oxyferrite. The mixture at the oxyferrite side will be oxyferrite saturated with wüstite, and that at the wüstite side will be wüstite saturated with oxyferrite or iron. There is a similar heterogeneous phase between wüstite and magnetite. There is a doubt whether R. Schenck has adopted the correct position for the wüstite area; E. D. Eastman and R. M. Evans placed their wüstite area astride the portion of the diagram corresponding with FeO. The subject was also studied by C. H. Mathewson and co-workers, U. Hofmann and E. Groll, and R. Schenck and E. Hengler. E. R. Jette and F. Foote studied the homogeneity of wüstite, and found that it decomposes between 565 and 570 ; they also showed that all samples had the space-lattice of FeO.

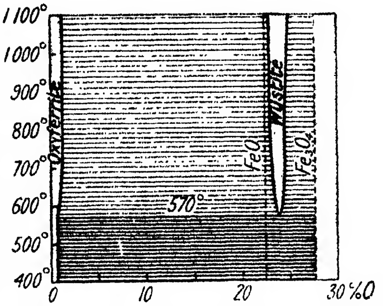

FIG. 487.—Iron–Oxygen System (Stable).

O. C. Ralston said that if R. Schenck's position for wüstite be accepted, no one could possibly prepare ferrous oxide by gas reduction or oxidation methods, and hence it is better to shift the position of the wüstite area to the left so that it includes ferrous oxide. R. Schenck's diagram does not show any difference between the solubility of wüstite in α-iron and in γ-iron. K. Schönert, and O. C. Ralston suggested that the lower slope of the oxyferrite boundary between 570° and 800° is associated with the properties of α-iron, and with those of γ-iron at a higher temp. By re-plotting R. Schenck's data, O. C. Ralston obtained the curves, Fig. 488, in which the lower one represents the solubility of ferrous oxide in α-iron, and the upper curve its solubility in γ-iron. The A_3-arrest is presumably lowered by the presence of ferrous oxide down to a eutectoid which had not been located but is somewhere in the range between 700° and 800°.

TABLE LXXXVIII.—THE IRON–OXYGEN SYSTEM.

O. C. Ralston plotted the pressure data of R. B. Sosman and J. C. Hostetter, and of L. Wöhler and R. Günther in the theoretical diagram of A. Smits and

J. M. Bijvoet, and obtained the diagram Fig. 489, which does not show the region occupied by the solid soln. oxyferrite and wüstite—*cf.* Figs. 487 and 488.

Ferrous oxide is metastable at ordinary temp. It is stable above approximately 570°, but below that temp. G. Chaudron and co-workers showed that it breaks up in accord with the equation $4FeO \rightleftharpoons Fe_3O_4 + Fe$. The invariant or triple point was given at 570° by G. Chaudron, A. Smits and J. M. Bijvoet, R. B. Sosman, W. Reinders, P. van Groningen, E. D. Eastman and R. M. Evans, and L. Wöhler and R. Günther; J. B. Ferguson gave 578°; and M. Tigerschiöld, 535°. Obviously, therefore, in preparing ferrous oxide by the reduction of a higher oxide with hydrogen or carbon monoxide, the temp. must exceed this invariant point, 570°, for below that temp. ferrous oxide is metastable with respect to $Fe + Fe_3O_4$, and instead of reducing ferrosic oxide to ferrous oxide, the tendency will be for ferrosic oxide to pass directly to iron without the intermediate stage, ferrous oxide, appearing at all. This brings under suspicion all the alleged preparations of ferrous oxide by the gaseous reduction of the higher oxides where these limitations have not been taken into consideration; and it shows a reason for the difficulty in preparing ferrous oxide free from magnetite and iron. Further, the equilibrium diagram, Fig. 486, shows that stable ferrous oxide cannot separate in a pure condition from a melt; it loses its identity at its m.p., 1370°, and it is metastable below 570°.

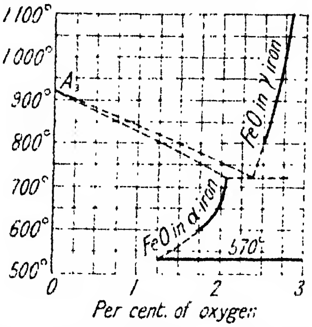

FIG. 488.—The Oxyferrite System.

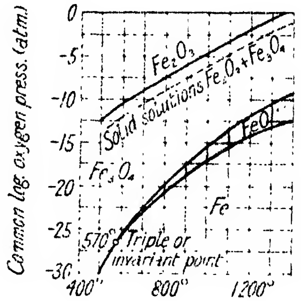

FIG. 489.—Pressure-Temperature Diagram for the System Fe–O.

According to J. B. Ferguson, and G. Chaudron and H. Forestier, the dissociation of ferrous oxide is reversible, for the reaction products—magnetite or ferrosic oxide, and iron—recombine to form ferrous oxide at temp. exceeding 570°. J. B. Ferguson kept a sample of ferrous oxide between 300° and 570° to allow complete decomposition to take place, and he then kept portions of the material at different temp. exceeding 570° for 5 hrs., and the results show that the iron and ferrosic oxide recombine to form ferrous oxide at temp. exceeding 570°; similarly, samples of ferrous oxide kept for 5 hrs. at different temp. below 570° slowly broke up at 536°, and the percentage decomposition increased as the temp. was lowered, until at 436° there was a 65 per cent. decomposition. This shows that the ferrous oxide must be super-cooled some distance below 570° before the rate of decomposition is appreciable during 5 hrs. G. Chaudron and H. Forestier found that about 78 per cent. ferrous oxide was decomposed in 8 hrs. at 445°. The rate of decomposition of ferrous oxide is a maximum at 480°, when about 80 per cent. decomposed in 24 hrs., and below 300° virtually no decomposition occurs during that period. Unlike J. B. Ferguson, G. Chaudron and H. Forestier obtained only a 50 per cent. recombination in 12 hrs. at 600°. The speed of decomposition is in accord with $dx/dt = k(100 - x)^4$, where x denotes the percentage decomposition in the time t, and k is a constant. The rate of decomposition is thus proportional to the 4th power of the concentration of the undecomposed ferrous oxide: $4FeO \rightleftharpoons Fe + Fe_3O_4$. The unit crystal cubic lattice contains four FeO molecules. According to

J. B. Ferguson, the invariant point 570° is lowered when ferrosic oxide is in solid soln. in the ferrous oxide, so that the new invariant point is between the solid soln., ferrosic oxide, iron, and gas.

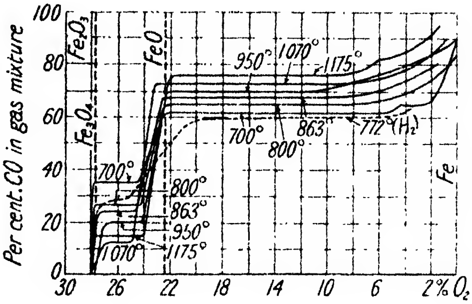

Fig. 490.—The Isothermal Reduction of Ferric Oxide.

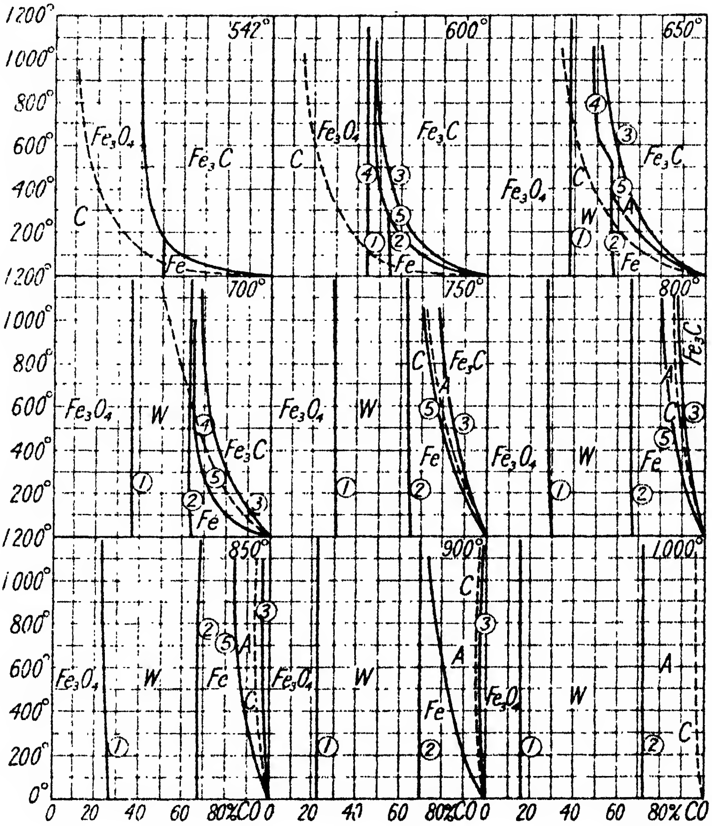
It follows from these observations that ferrous oxide prepared at high temp. can be safely cooled to room temp. without appreciable decomposition provided it be cooled rapidly through the range 570° to 300°; but if the product be slowly cooled, it will be contaminated with more or less ferrosic oxide and iron. At ordinary temp. the oxide is in a metastable state, and it can be preserved indefinitely provided it be protected from atm. oxidation. The preparation of ferrous oxide by the oxidation of iron or by the reduction of ferric or ferrosic oxide was discussed by S. Hilpert and J. Beyer, G. Chaudron and H. Forestier, J. B. Ferguson, L. Wöhler and R. Günther, L. E. Gruner, and G. Lepetit. The curves for the isothermal reduction of ferric oxide by carbon monoxide by R. Schenck at 700°, 800°, and 950°, and by A. Matsubara at 863°, 1070°, and 1175°, are shown in Fig. 490. The curves show the progress of the deoxidation at these temp. R. Schenck found that the mixture of ferrous and ferrosic oxides obtained at different temp. contained

p	$CO : CO_2$	650°	700°	720°
1 atm.	25 : 75	95·35	100	100 per cent. Fe_3O_4
	50 : 50	5·4	2·6	3·4 ,, ,,
atm.	75 : 25	—	91·87	91·23 ,, ,,

The curves show complications caused by the carburization of the iron when the proportion of oxygen in the solid has been reduced to about 8 per cent. R. Schenck's interpretation of the equilibria in the reaction between iron oxide and carbon monoxide, at one atm. press., is illustrated by Figs. 491 to 499. The dotted line refers to the producer gas equilibrium; *C* refers to the bivariant equilibrium: $2CO \rightleftharpoons C + CO_2$. The various fields of bivariant equilibria are numbered 1 to 5; (1) refers to Fe_3O_4, wüstite, and gas; (2) wüstite, oxyferrite, and gas; (3) Fe_3C, oxyaustenite, and gas; (4) wüstite, oxyaustenite, and gas; and (5) oxyferrite, oxyaustenite, and gas. *W* refers to the wüstite field; *Fe*, to the oxyferrite field; and *A* to the oxyaustenite field.

The increase in the proportion of carbon monoxide required for the reduction, that is, the lessened activity of the ferrous oxide near the iron-edge of the diagram, Fig. 490, is attributed to the disappearance of the pure ferrous oxide phase, and to the fact that the remaining ferrous oxide exists in solid soln. in the iron, and is then more difficult to reduce to metal. J. B. Ferguson suggested that two different forms of ferrous oxide may be concerned in the phenomenon. This is the region where R. Schenck's oxyferrite is formed. The subject was discussed by O. C. Ralston. H. Groebler and P. Oberhoffer obtained by the reduction process 97·8 per cent. ferrous oxide at 800°. They also attempted to remove iron from the product of the reduction by chemical agents, but the results were not good; a 95 per cent. ferrous oxide was so obtained. A. Smits and J. M. Bijvoet have discussed this subject from another aspect—*vide infra*, ferric oxide. The work of E. Baur and A. Glässner, L. Wöhler and O. Balz, P. P. Fedotéeff and T. N. Petrenko, R. Schenck and co-workers, M. Levin, H. Nippert, H. Kamura, J. B. Ferguson, H. J. van Royen, V. Falcke, E. Terres and A. Pongracz, A. Matsubara, and G. Chaudron on the equilibrium $K = [CO_2]/[CO]$, in the presence of iron and its oxides, at the absolute temp. *T*, summarized by E. D. Eastman, is indicated in

Fig. 502. According to O. C. Ralston, the horizontal lines represent equilibria between pairs of phases of approximately constant composition, whether pure compounds or solid soln. The portions curving away from the horizontal are obtained when the relative amount of one phase or another is small. Between Fe_3O_4 and FeO the isotherms show a horizontal portion which does not quite reach Fe_3O_4 or FeO, but is cut off by sloping portions of the curve. In this case, on the side next to FeO the change in direction is at the point where all of the free Fe_3O_4 is exhausted, and only a solid soln. of Fe_3O_4 in FeO is left in equilibrium with the gas; and then for every decrease in the amount of dissolved Fe_3O_4, gas of increased reducing power



FIGS. 491 to 499.—Space Model of the System: Fe–C–CO.

is necessary until all of the Fe_3O_4 is gone. Similarly, on the sloping branch of the curve next to the composition of Fe_3O_4, the FeO dissolves in the Fe_3O_4 in solid soln., as Fe_3O_4 is reduced to FeO, reducing the activity of the Fe_3O_4 and requiring gas of higher reducing power for the next step until enough FeO has been formed to saturate the Fe_3O_4. Afterwards the curve runs horizontally, excess FeO merely dissolving Fe_3O_4 to form a sat. soln. of Fe_3O_4 in FeO. The horizontal part of the curve is therefore actually one of equilibrium between two sat. soln., one mainly made up of magnetite and the other of FeO. The ends of the horizontal portions of the curves give directly the analyses of the sat. soln.

The dotted curve, Fig. 490, summarizes E. D. Eastman and R. M. Evans's results for the oxidation of iron by water vapour at 772°—when hydrogen is substituted for carbon monoxide as ordinate. The solid phase is here free from carbides, and again the phenomenon due to a decrease in the activity of the ferrous oxide, observed with carbon monoxide, occurs near the iron-edge of the diagram. The oxidation begins at about 750° with a gas mixture containing a less ratio than 0·54 of water vapour to hydrogen; below this temp., slightly oxidized specimens are reduced. The work of H. St. C. Deville, G. Preuner, G. Chaudron, P. P. Fedotéeff and T. N. Petrenko, P. H. Emmett and J. F. Shultz, L. Wöhler, and E. Schreiner and F. B. Grimnes on the equilibrium $K=[H_2O]/[H_2]$, in the presence of iron and its oxides, at the absolute temp. T, summarized by E. D. Eastman, is indicated in Fig. 501. These diagrams show the regions of stability of ferrous and ferrosic oxides at different temp., and in the presence of the respective gases. M. Tigerschiöld found that ferrous oxide is more readily reduced by hydrogen above 800°, and by carbon monoxide below that temp. W. Biltz and H. Müller gave values for the ratio $K=P_{H_2O}/P_{H_2}$; for Fe_3O_4/Fe, $K=0·2$ to 0·4 between 430° and 550°; for FeO/Fe, $K=0·5$ to 1·0 between 620° and 1000°; for Fe_3O_4/FeO, $K=0·6$ to 10 between 590° and 1050°; and for Fe_2O_3/Fe_3O_4, $K=7·5$ to 18 between 350° and 950°.

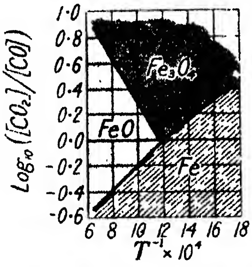


FIG. 500.—Equilibrium of the Solid Phases in the System with Iron, Iron Oxide, and Carbon Oxides.

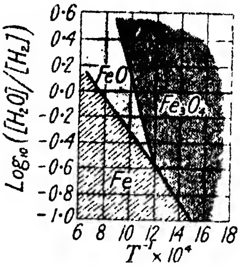

FIG. 501.—Equilibrium of the Solid Phases in the System with Iron, Iron Oxides, Hydrogen, and Steam.

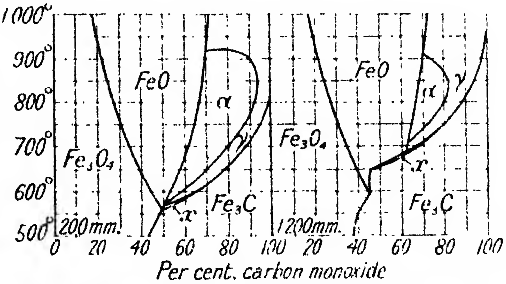
E. Scheil and E. H. Schulz developed a series of curves from R. Schenck's data showing the effect of press. on the equilibrium, and the isobars for 200 and 1200 mm. are shown in Figs. 502 and 503. x refers to another phase (solid soln.).



FIGS. 502 and 503.—Isobars for the System : C-Fe-O.

The preparation of ferrous oxide.—Ferrous oxide of a high degree of purity has not been prepared. R. B. Sosman and J. C. Hostetter always obtained a product containing iron or iron carbide, magnetite, or some oxide intermediate in composition between FeO and Fe_3O_4. S. Hilpert and J. Beyer obtained a product free from metallic iron but in which some magnetic oxide was present. As just indicated, the failure to prepare ferrous oxide free from ferrosic oxide is attributed to the formation of a solid soln. of the two oxides, and A. Smits and J. M. Bijvoet also suggested that over a particular range of temp. ferrous oxide has a higher dissociation press. than ferrosic oxide, so that the reaction: $4FeO=Fe_3O_4+Fe$ may occur as in the analogous case of iridous oxide: $2IrO=IrO_2+Ir$ observed by L. Wöhler and co-workers. On account of the instability of ferrous oxide if heated above or cooled below 570°, E. D. Eastman, R. W. G. Wyckoff and E. D. Crittenden, R. Schenck, and L. Wöhler and R. Günther consider that ferrous oxide cannot be deliberately prepared without some decomposition; whilst K. Hofmann held that ferric oxide reduced by hydrogen at 564° consists essentially of ferrous oxide. The subject was discussed by G. Chaudron, S. Hilpert and J. Beyer, and R. Schenck and T. Dingmann.

According to the analyses of A. L. Lavoisier, J. L. Proust, J. W. Döbereiner, J. J. Berzelius, L. J. Thénard, J. L. Gay Lussac, and C. F. Bucholz, the proportions of iron in samples prepared by the oxidation of iron or the reduction of ferric oxide have from 73 to 78 per cent. of iron when the theoretical value for FeO is 77·14 per cent. R. Schenck, and O. Pattenhausen said that commercial ferrous oxide is mainly ferrosic oxide, Fe_3O_4.

According to C. F. Bucholz, ferrous oxide is a product of the action of steam on red-hot iron, and G. Chaudron stated that the reaction $Fe+H_2O\rightleftharpoons FeO+H_2$ occurs at 570°. H. Nippert, and L. Wöhler and R. Günther studied the reaction—*vide supra*. J. A. N. Friend said that ferrous oxide is produced by heating iron in steam at 350°; and H. Debray, that ferric oxide is reduced to ferrous oxide by one vol. of water vapour mixed with one to three vols. of hydrogen. According to S. Hilpert and J. Beyer, the ferrous oxide is formed in an increasing proportion as the temp. is raised; thus, at 700°, the product contains 85 per cent. of FeO, and at 800°, 92 per cent., but pure ferrous oxide is not obtained even at 1100°; nor was it possible to obtain pure ferrous oxide by the oxidation of reduced iron in a mixture of steam and hydrogen. R. M. Bozorth also observed that when steam acted on iron at 700°, he found a 2×10^{-2} cm. inner layer of ferrous oxide, a 2×10^{-4} cm. layer of ferrosic oxide, and an outer 2×10^{-5} cm. layer of ferric oxide.

According to G. Tissandier, iron can be oxidized to ferrous oxide by heating it to bright redness in a current of carbon dioxide. I. L. Bell obtained a similar result by using a mixture of equal vols. of carbon monoxide and dioxide; A. Laurent said that the product is ferrosic oxide; and H. Nippert, that at 720° ferrous oxide is produced. The reaction has been previously discussed by G. Lepetit, R. Schenck and T. Dingmann, etc., in connection with the blast furnace.

G. Chaudron and co-workers observed that at a temp. exceeding 570°, iron reacts with ferrosic oxide to form ferrous oxide, so that at 592°, 24 per cent. was transformed in 24 hrs., and 51 per cent. at 600°. P. Oberhoffer and H. Schenck said that the reaction is nearly complete at 1600°. C. N. Schuette and C. G. Maier, and C. T. Anderson studied the reaction. L. Wöhler and R. Günther did not notice the reaction $Fe_3O_4+Fe=4FeO$, because their mixture was too coarse-grained. W. Mills obtained an impure product by heating ferric oxide with iron: $Fe+Fe_2O_3=3FeO$; and R. W. G. Wyckoff and E. D. Crittenden obtained impure ferrous oxide by fusing magnetite with iron—analysis: 0·54, Fe; 78·40, FeO; 20·32, Fe_3O_4. R. W. Millar tried unsuccessfully to purify the sample, but he did succeed in raising the ferrous oxide to 82·95 per cent. J. H. Whiteley, F. S. Tritton and D. Hanson, and C. H. Herty also obtained analogous products. G. Tammann and E. Kordes observed that the reaction $Fe+PbO=Pb+FeO$ begins at about 460°, and $Fe+CuO=FeO+Cu$ at 610°.

P. Sabatier and J. B. Senderens said that ferrous oxide is formed at 200° when nitrous oxide is passed over iron; and F. Emich added that ferric oxide is the end-product of this reaction. J. Férée stated that ferrous oxide is produced when iron amalgam is slowly oxidized by exposure to air, but this reaction is not to be regarded seriously as a method of preparation. W. Vaubel obtained ferrous oxide as a product of the action of ammonium nitrate on iron; F. Martin and P. Fuchs, as a product of the reduction of alkaline earth sulphates with iron; and A. de Méritens, by the anodic oxidation of iron.

According to F. Stromeyer, H. W. F. Wackenroder and F. Stromeyer, and G. Magnus, ferric oxide, at the softening temp. of glass, is reduced by hydrogen to ferrous oxide; and M. Siewert added that the reduction to ferrous oxide occurs at 280° to 300°—*vide infra,* the action of hydrogen on ferric oxide. The ferrous oxide produced at this low temp. is pyrophoric, but it loses this property if kept in hydrogen for about 12 hrs. The product is very liable to be contaminated with ferrosic oxide, but H. Moissan said that he obtained a product of a high degree of purity by heating ferric oxide at 500° in hydrogen for 20 mins. As indicated above, the reaction involves some complex equilibria, discussed previously in connection with the blast furnace. H. Debray obtained ferrous oxide by reducing ferric oxide with a mixture of one to three vols. of hydrogen, and one vol. of steam at a red-heat. The equilibrium conditions with water vapour were discussed by S. Hilpert and J. Beyer, J. Beyer, L. Wöhler and R. Günther, and G. Chaudron—*vide supra.*

H. Moissan obtained ferrous oxide by reducing ferric oxide in a current of dry carbon monoxide at 500°; and H. Debray, I. L. Bell, and F. Leplay and A. Laurent employed a mixture of equal vols. of carbon monoxide and dioxide; C. R. A. Wright and A. P. Luff said that the product at a bright red-heat has the composition $Fe_{16}O_{17}$. O. Pattenhausen said that with a mixture of equal vols. of carbon monoxide and dioxide, ferric oxide heated at first to 775° and then to 825° yields a product with 83 to 84 per cent. FeO; and at 850° to 870°, one with 84·5 per cent. FeO; G. Chaudron obtained ferrous oxide at 800° to 1000° after 3 hrs.' exposure to the mixture of equal vols. of carbon monoxide and dioxide. L. Wöhler and R. Günther said that the product is not to be regarded as pure ferrous oxide; but H. Groebler and P. Oberhoffer, and H. Groebler obtained a product with 99·3 per cent. FeO and only 0·7 Fe_3O_4. R. Schenck could not obtain ferrous oxide as an independent solid phase by reducing ferrosic oxide with carbon monoxide up to 1100°, although he did get a feebly magnetic sample with 0·1 per cent. of iron in excess of that required for ferrous oxide by reducing ferric oxide at 800° with the equilibrium mixture of 66·66 per cent. of carbon monoxide and 33·33 per cent. of carbon dioxide. The equilibrium conditions in the reaction were studied by R. Schenck and co-workers, J. Müller, G. Lepetit, etc.—*vide supra.* C. H. Herty and G. R. Fitterer heated ferric oxide in a graphite crucible in an electric furnace, removed the iron and iron carbide by a magnet, and found the remaining product contained 98·9 per cent. FeO. The preceding observations weaken confidence in the old methods which have been reported for preparing ferrous oxide. J. von Liebig said that ferrous oxide is formed when dry ferrous oxalate is heated to 150° or 160°, in the absence of air, and cooled in an atmosphere of carbon dioxide. A. Vogel, and G. Magnus obtained pyrophoric ferrous oxide by a similar process; and the products of this reaction were discussed by C. F. Rammelsberg, and J. W. B. Döbereiner. According to H. Moissan, and W. G. Mixter, in order to avoid the separation of carbon, or the formation of a carbide, it is an advantage to heat the ferrous oxalate gradually up to 520° in a current of nitrogen, and finish off at about 900°. The product contains a little iron. S. Birnie, M. Herschkowitz, V. Falcke, and H. Nippert were also of the opinion that the products of the reaction are iron, ferrous and ferrosic oxides, carbon, and possibly undecomposed oxalate. H. le Chatelier reported ferrous oxide to be formed when a mixture of ferrous carbonate and oxalate is heated in a current of equal vols. of hydrogen and carbon dioxide; but O. Ruff and E. Gersten always obtained a product contaminated with ferrosic oxide and carbon. H. Moissan said that ferrous oxide, along with some ferrosic oxide, is produced when ferrous carbonate is rapidly heated. R. Böttger said that ferrous oxide is formed when ferrous oxalate is added to a boiling soln. of potassium hydroxide; and J. Riban, when a 5 per cent. soln. of ferrous formate or acetate is heated in a sealed tube at 175°, but in both cases some ferrosic oxide is formed.

Ferrous oxide has been reported by F. Bode to be formed in J. Hollway's process of desulphurizing copper pyrites in the Bessemer converter; by L. Benedek, when pyrites is heated to 300° or 400° in water vapour; by A. Brun, when basic volcanic glasses are heated to 800° in vacuo; and by E. Diepschlag and H. Fliegenschmidt, when ferrous silicate is heated to 1200° in the presence of an excess of lime. It is common to find that the metal oxides produced at a low temp. are more chemically active than those which have been heated to a high temp. This, for instance, is the case with alumina, chromic oxide, ferric oxide, etc. In some cases there is an evolution of heat as the oxide is transformed into the insoluble form—*vide* **5**. 33, 10; and *vide infra*, the caloresence of ferric oxide. R. W. Millar's sp. ht. curve, Fig. **504**, has a peak at −170°. H. Moissan said that ferrous oxide can exist in two **allotropic forms** according as it has been produced at a high or at a low temp. He said that the variety produced below 600° is more chemically active, for on exposure to air it unites with oxygen so rapidly that the whole mass may become incandescent; it decomposes water slowly in the cold, but more rapidly at the b.p.; it is readily soluble even in dil. acids such as acetic acid; it easily displaces ammonia from its salts; and it begins to be reduced by hydrogen at about 280°. On the other hand, ferrous oxide which has been heated above 1000° is no longer pyrophoric on exposure to air; it does not decompose water; it is not soluble in dil. acetic acid; it is not reduced by hydrogen below 330°. F. Glaser gave 370° for the temp. of reduction of ferrous oxide by hydrogen. The two varieties when oxidized to ferrosic oxide give products which show some differences (*q.v.*). G. Chaudron suggested that two varieties are in the one case ferrous oxide stable above 570° and in the other case a mixture of ferrosic oxide and iron: $4FeO \rightleftharpoons Fe_3O_4 + Fe$, which has a transition temp. at about 570°—*vide infra*, magnetic properties of ferrous oxide.

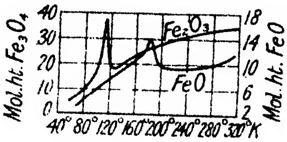


FIG. 504.—The Molecular Heats of Ferrous and Ferric Oxides.

The physical properties of ferrous oxide.—Ferrous oxide, when prepared by gaseous reduction, is a black powder, and when obtained by fusion processes, it is black and massive. Polished surfaces were found by H. E. Merwin to show the presence of magnetite by heat etching—the ferrous oxide at a red-heat assumes a matt appearance, whilst magnetite remains unaffected. The **crystals** are cubic. H. Groebler and P. Oberhoffer examined the **X-radiogram** of solid soln. with ferrosic oxide (*q.v.*). R. W. G. Wyckoff and E. D. Crittenden observed that the X-radiogram of ferrous oxide corresponds with a space-lattice of the sodium chloride type; the length of unit cube is $a=4{\cdot}2944$ A., V. M. Goldschmidt and co-workers found $a=4{\cdot}27$ A., and G. Natta, 4·28 A. D. W. Murphy and co-workers obtained $a=4{\cdot}289$ A. at temp. near the m.p. R. W. G. Wyckoff and E. D. Crittenden concluded that the unit cell contains 4 mols. of FeO. The unit cube of ferrous oxide containing some magnetite is slightly larger than is the case with ferrous oxide alone. The calculated **specific gravity** is 5·99, whereas the observed value making corrections for the ferrosic oxide impurity is 5·72. S. Hilpert and J. Beyer reported the sp.gr. of 97·83 per cent. ferrous oxide obtained by reducing ferric oxide in hydrogen to be 5·9, and if corrected for ferrosic oxide 5·92. W. Biltz studied the mol. vol.; and F. Sauerwald and G. Elsner, the adhesion of the compressed powder.

M. Mayer and B. Havas calculated values for the coeff. of **thermal expansion** from the addition rule for ferrous oxide in silicate glasses; and G. Chaudron and H. Forestier observed an anomaly in the thermal expansion corresponding with the change $4FeO \rightleftharpoons Fe_3O_4 + Fe$ below 570°. O. Kresta observed that the compressed powder, apparent sp. gr. 2·240, at about 49·8° has a **thermal conductivity** of 0·00133 cal. per cm. per second per degree. A. B. Lamb found the **specific heat** to be 0·1660 at 25° to 100°, or 0·1625 at 25°. If the temp. coeff. is the same as it is for iron, it would require 11,385 cals. to heat a gram of ferrous oxide from 25° to 727°. W. P. White gave for the true sp. ht. $c_p=0{\cdot}17508+0{\cdot}0000027\theta$, at temp. between 30° and 900°. M. Tigerschiöld calculated $C_p=10{\cdot}90$, at 17°, from the equilibrium relations $FeO+CO \rightleftharpoons Fe+CO_2$; and 10·64 from Kopp's rule. H. J. van Royen also made observations on this subject. R. W. Millar gave for the sp. ht., c_p, and the **molecular heat,** C_p, of a sample with 82·96 per cent. FeO, 14·54, Fe_3O_4, and 2·5, Fe:

	−202·3°	−182·8°	−160·0°	−122·4°	−105·0°
c_p . . .	0·04588	0·07020	0·09720	0·13970	0·16130
C_p . .	3·296	5·042	6·984	10·4	11·59
	−67·9°	−30·5°	−13·0°	1·6	28·8°
c_p . . .	0·16700	0·16280	0·16840	0·16730	0·17480
C_p . .	11·75	11·70	12·09	—	—

The results are plotted in Fig. 504. F. S. Tritton and D. Hanson gave 1370° for the **melting-point;** O. Ruff and O. Goecke, 1419°; C. H. Herty and G. R. Fitterer, 1355°; H. Groebler and P. Oberhoffer estimated 1377°; J. H. Andrew and co-workers, 1410°; B. Garre, 1530°; and F. Schönert, 1380°. As indicated above, G. Chaudron showed that ferrous oxide is unstable below 570°, decomposing in accord with $4FeO=Fe_3O_4+Fe$, and the thermal value of the reaction at 570° is $4\times66{\cdot}15$ Cals. L. Wöhler and R. Günther observed that the reaction is very slow at 550° in vacuo, for only 50 per cent. decomposed in 3 days. G. Chaudron and H. Forestier said that the reaction begins at 300° and attains a maximum speed at 480°. The **dissociation pressure** of ferrous oxide has not been measured directly. The values of the dissociation press. of the oxygen calculated indirectly are $8{\cdot}9\times10^{-22}$ atm. at 727° by H. J. van Royen; 4×10^{-21} to 5×10^{-21} atm. at 727° by O. Sackur; 10^{-21} atm. at 727° by G. Chaudron; and 10^{-8} atm. at 1327° by H. le Chatelier. H. Styri gave log $p=-7{\cdot}6$ for the dissociation press. of $2FeO=2Fe+O_2-131{,}400$ cals. L. Wöhler and R. Günther obtained:

	600°	800°	1000°	1200°	1400°
p . .	5×10^{-27}	3×10^{-21}	3×10^{-17}	3×10^{-14}	$6{\cdot}3\times10^{-12}$ atm.

H. von Jüptner calculated for the dissociation press. of the oxygen, in $2FeO=2Fe+O_2$, $\log[O_2]=-28752T^{-1}+1{\cdot}75\log T+2{\cdot}8$—*vide infra*; and values calculated from this equation are:

	600°	1000°	1400°	1800°	2200°	2400°
$\log[O_2]$.	$0{\cdot}0_{40}5151$	$0{\cdot}0_{20}1986$	$0{\cdot}0_{12}5869$	$0{\cdot}0_{7}3338$	$0{\cdot}0_{4}3803$	$0{\cdot}0_{3}5344$

A. Matsubara gave $\log p=-28{\cdot}752T^{-1}+1{\cdot}79\log T+13{\cdot}427$, and O. C. Ralston $\log p=2{\cdot}76-26750T^{-1}+0{\cdot}946\log T+0{\cdot}00072T^2-0{\cdot}0_81616T^3$. The dissociation press. approaches 1 atm. at about 4000°. No confidence can be given to extrapolation at such high temp. from equations derived from data collected at about 1000°. The dissociation press. of ferrous oxide at room temp. is of the order 10^{-42} atm. Observations on the subject were made by N. Parravano and G. Malquori, E. Baur and A. Glässner, L. Wöhler and O. Balz, K. Hofmann, E. Schreiner and F. B. Grimnes, A. McCance, G. Chaudron, F. Wüst and P. Rütten, and A. B. Lamb. C. H. Herty and co-workers estimated that the **melting-point** is not far above 1355°; P. Oberhoffer and O. von Keil gave 1390°; and D. W. Murphy and co-workers obtained 1360°±10°, and found that the oxide is stable above and below its m.p. when it has a constant lattice parameter of 4·289 A. The **heat of fusion** is 28 Cals. per grm., or 5 Cals. per mol.

J. Thomsen gave for the **heat of formation,** [Fe,O], 68·3 Cals.; H. le Chatelier, 64·6 Cals.; O. Ruff and E. Gersten, 60·4; G. H. Brodie and co-workers, 63·56 Cals.; M. Tigerschiöld, 66·3 Cals.; W. A. Roth and co-workers, 64·25 Cals.; J. Jermiloff, 66·713 Cals.; W. D. Treadwell, 66·6 Cals. at 1000°, or 68·6 Cals. at 25°; L. Wöhler and R. Günther, 63·35 Cals.; H. von Jüptner, 65·7 Cals.; W. G. Mixter, 64·3 Cals.; H. J. van Royen, 65·891 Cals.; E. D. Eastman, 63·73 Cals.; O. Doepke, 68·00 Cals.; and E. Baur and A. Glässner, 67·35 Cals. at 680° and at a constant press. P. A. Favre and J. T. Silbermann's value is too low. The results by W. D. Treadwell were calculated from the e.m.f., 0·040 volt, of the cell Fe,FeO: electrolyte: O_2,Ag with fused glass or borax as the electrolyte at 800° to 1193°; and those of M. Tigerschiöld, and L. Wöhler and R. Günther, from the equilibrium data of the system: $FeO+H_2\rightleftharpoons H_2O+Fe$. Observations were also made by M. Berthelot, and A. McCance, whilst E. Baur and A. Glässner said that there is a minimum value at 680°. The best representative value approximates 64 Cals. at 25°, per mol. FeO. W. A. Roth and co-workers gave $FeO+Fe_2O_3=Fe_3O_4+7{\cdot}0$ Cals.; and $2FeO+SiO_2$ (quartz)$=Fe_2SiO_4+8{\cdot}1$ Cals. J. Thomsen gave for the **heat of hydration** (Fe,O,Aq.) 68·9 Cals., or (Fe,O,H_2O), 68·28 Cals.; and for the **heat of neutralization** in acids 10·7 Cals. in N-HCl; 9·9 Cals. in N-$CH_3.COOH$; 12·5 Cals. in N-H_2SO_4; 5·0 Cals. in N-H_2CO_3; and 7·3 Cals. in N-H_2S. Observations were made by M. Berthelot. E. Petersen gave 13·265 Cals. for hydrofluoric acid. E. D. Eastman calculated for the **free energy** of ferrous oxide:

	600°	700°	800°	900°	1000°
Free energy .	−49,700	−48,075	−46,445	−44,840	−43,255 cals.

O. Sackur, G. Bodländer, H. J. van Royen, E. Baur and A. Glässner, and G. Beck studied the subject. F. Wüst and P. Rütten gave −49,000 cals. at about 600°; 43,000 cals. at about 900°; and 31,000 cals. at about 1500°. W. J. Sweeney gave −120·92 Cals. for the free energy of formation of $Fe(OH)_2$ from its elements; and W. G. Whitman and co-workers, −57,200 cals. G. N. Lewis and M. Randall, and O. C. Ralston gave: free energy $=-61{,}250+0\cdot94T\log T+0\cdot00165T-0\cdot0_637T^3+6\cdot82T^{-1}$, and this gives −57,472 cals. at room temp., and −42,083 cals. at 1000°. J. Chipman gave for the free energy, between 1550° and 1770°, of the reaction: $FeO+H_2=Fe+H_2O$, where $\log K=6200T^{-1}-3\cdot28$, $\delta F=-28400+15T$; and for the reaction: $Fe+\frac{1}{2}O_2=FeO$, $-31200-1\cdot0T$. The **entropy** of formation calculated for $Fe+\frac{1}{2}O_2=FeO$ is −21·3 Cals.; and for the absolute entropy of ferrous oxide 10·01 cals. per degree; R. W. Millar and J. D. Sullivan gave 12·7 cals. per degree at 25°. K. K. Kelley, and G. Beck studied the subject.

The effect of ferrous oxide on the **transmission of light** of short wave-length by glass is discussed in connection with ferric oxide. G. A. Dima said that the **photoelectric effect** with ferrous oxide is greater than it is with ferric oxide. W. A. Douglas-Rudge found that the powdered oxide acquires a negative charge when it is agitated in air. O. Kresta found that the compressed powder at 49·8° has an **electrical conductivity** of 0·00133 mho. G. Tammann and F. Westerhold made observations on the subject. A. B. Lamb calculated that an oxygen electrode and an iron electrode plunged in a sat. soln. of ferrous hydroxide would give zero **electromotive force** when the press. of the oxygen over the oxygen electrode is $4\cdot4\times10^{-90}$ atm. With the oxygen at atm. press., the e.m.f. of the cell would be $E=0\cdot01475\log 8\times10^{88}=1\cdot279$ volt; that of the cell $Fe|M\text{-}Fe^{\cdot\cdot}|1\cdot35\times10^{-5}M\text{-}Fe^{\cdot}|Fe$, −0·144 volt; and that of the cell $O_{2\text{atm.}}|M\text{-}OH'|2\cdot7\times10^{-5}M\text{-}OH|O_{2\text{atm.}}$, 0·269 volt. E. Baur and co-workers measured the e.m.f. of cells FeO,Fe (fused borax, glass or porcelain), CuO,Cu_2O at 700° to 1300°; and W. D. Treadwell, of the cell Fe,FeO(electrolyte of fused glass),O_2,Ag, and found 1·040 volts between 800° and 1193°. For W. D. Treadwell's cell, *vide supra*.

	800°	875°	940°	1000°	1100°	1180°
E.m.f. .	1·081	1·071	1·048	1·040	1·018	0·978 volts

and 1·06 volts was obtained for the potential Fe : FeO from the values obtained for the cell FeO,Fe | electrolyte | CuO,Cu_2O. Observations were also made by G. Chaudron, and E. Baur and A. Glässner. G. Schmidt, H. Debray, G. Lepetit, S. Hilpert and J. Beyer, S. Hilpert, S. Veil, and R. W. G. Wyckoff and E. D. Crittenden said that ferrous oxide is practically **non-magnetic.** H. Moissan obtained a magnetic variety at a temp. below 600°, and G. Chaudron observed that this is because the ferrous oxide decomposes: $4FeO=Fe_3O_4+Fe$ at a temp. between 550° and 580°, and this is evidenced by observations on the magnetic behaviour. J. B. Ferguson argued that since iron, ferric oxide, and ferrosic oxide undergo magnetic changes at 790°, 678°, and 530° respectively, ferrous oxide might be expected to behave similarly. Ferrous oxide containing ferrosic oxide was reduced to free iron and in the subsequent combination of the free iron the decrease in magnetic permeability did not correspond with the decrease in the free iron content of the sample. No evidence was obtained of the existence of a magnetic form of ferrous oxide. R. W. G. Wyckoff and E. D. Crittenden said the upper limit of the magnetic susceptibility is 0·00052 mass unit. Observations were made by S. Meyer, and E. F. Herroun and E. Wilson. A. Brun said that the mineral iozite is magnetic.

The chemical properties of ferrous oxide.—L. Wöhler and O. Balz observed only three equilibria in the reduction of ferric oxide with **hydrogen,** $K=[H_2O][H_2]$, for Fe_2O_3 to Fe_3O_4, 7·5 at 350° to 17·9 at 950°; for Fe_3O_4 to FeO, 1·3 at 640° to 5·07 at 950°; and for FeO to Fe, 0·62 at 750° and 0·92 at 990°. P. H. Emmett and J. F. Shultz found that the equilibrium constant, *K*, of the reaction $FeO+H_2 \rightleftharpoons Fe+H_2O$ is $K=p_{H_2O}/p_{H_2}$, and

	600°	700°	800°	900°	1000°
K . .	0·332	0·422	0·499	0·594	0·669

The subject was studied by J. Chipman, and by E. Schreiner and F. B. Grimnes—*vide* the blast-furnace reactions. For the temp. at which the reaction begins, *vide supra*. H. Moissan observed that in **oxygen** pyrophoric ferrous oxide burns to ferric oxide, but in consequence of the large evolution of heat, the temp. of combustion is high, and ferrosic oxide is formed. W. Eitel discussed the reaction $2FeO+\frac{1}{2}O_2 \rightleftharpoons Fe_2O_3$. According to L. Wöhler and R. Günther, finely-divided ferrous oxide readily oxidizes at room temp., and when heated to 200° or 250°, it readily burns in atm. **air,** as indicated above, to form ferrosic oxide. Observations were also made by M. Siewert, S. Birnie, H. Moissan, F. Glaser, and S. Hilpert and J. Beyer. A. G. Doroschevsky and A. Bardt observed that dry ferrous oxide does not oxidize in dry air at ordinary temp., but it is slowly oxidized in moist air below 100°. J. Férée found that the pyrophoric oxide oxidizes in air at 350° to form ferrosic oxide; H. Debray, and G. Tissandier also observed the formation of ferrosic oxide when ferrous oxide is heated in air. G. Schikorr studied the action of hydrated ferrous oxide on **water**—*vide infra*, the corrosion of iron. H. Moissan, and W. Eitel observed that the reaction with steam can be symbolized: $3FeO+H_2O \rightleftharpoons H_2+Fe_3O_4+15{,}400$ cals. J. Férée found that the pyrophoric oxide reacts with aerated water to form ferrosic oxide; and H. Moissan, that the pyrophoric oxide decomposes water slowly at ordinary temp., and rapidly at 100°. J. Riban found that when ferrous oxide and water are heated in a sealed tube, ferrosic oxide is formed. L. J. Thénard found that **hydrogen dioxide** oxidizes it to ferric oxide. A. V. Pamfiloff and N. N. Petin studied the influence of ferrous oxide on the liberation of iodine from an iodide by the action of hydrogen dioxide; and as a result they concluded that the mechanism of the action of ferrous oxide, typical of inductors in general, is probably based on its spontaneous oxidation, and the retarding influence exerted on the reaction by acidity is related to the great stability of ferrous ions in an acid soln.

Ferrous oxide dissolves in **acids** to form a well-defined series of ferrous salts. H. Moissan observed that the pyrophoric oxide dissolves readily in dil. acids. H. Moissan observed that **fluorine** does not act in the cold on ferrous oxide, but when gently warmed a reaction sets in with incandescence, and a skin of white fluoride is formed. A. Michael and A. Murphy found that ferrous oxide reacts at −18° with **chlorine** dissolved in carbon tetrachloride: $6FeO+3Cl_2=2Fe_2O_3+2FeCl_3$. R. Weber observed that chlorine acts on ferrous oxide to form ferric chloride, and, according to H. Schulze, a higher oxide is also produced. R. Wasmuht found that ferrous oxide alone reacts with chlorine at 150°. L. Mathesius found that ferrous oxide, prepared at 600°, is not attacked by an aq. soln. of **bromine**; and I. L. Bell, that the oxide prepared at a red-heat is not attacked by a cold aq. soln. of **iodine.** H. St. C. Deville found that ferrous oxide reacts slowly with **hydrogen chloride,** forming ferrous chloride and ferrosic oxide. L. Wöhler and R. Günther said that the oxide prepared at 700° or 800° is easily dissolved by dil. **hydrochloric acid**; G. Tissandier, that the oxide prepared at a red-heat dissolves easily in hydrochloric acid; R. W. G. Wyckoff and E. D. Crittenden, that the oxide prepared by a fusion process dissolves very slowly in boiling hydrochloric acid.

According to D. L. Hammick, when ferrous oxide, prepared at 300°, is heated in **sulphur dioxide,** the mass becomes incandescent, and clouds of sulphur and sulphur trioxide are formed, and the solid contains sulphide, ferric oxide, and ferrous and ferric sulphates. A. C. Halferdahl calculated for the reaction $6FeO+SO_2=2Fe_3O_4+\frac{1}{2}S_2$, the free energy −30,000 cals. at 600°, and +4300 cals. at 1400°;

for $4FeO+SO_2=2Fe_2O_3+\frac{1}{2}S_2$, −14,700 cals. at 600°, and +20,400 cals. at 1400°; and for $7FeO+SO_2=3Fe_2O_3+FeS$, −29,300 cals. at 600°, and +29,400 cals. at 1400°. R. W. G. Wyckoff and E. D. Crittenden found that the oxide prepared by the fusion process is almost insoluble in **sulphuric acid**; and N. J. Harrar observed that in 40 and 60 days, at 25°, sulphuric acid dissolved respectively 67·205 and 95·045 mgrms. of iron from ferrous oxide per 100 c.c. of soln.

S. Hauser studied the reduction of ferrous oxide by **ammonia.** F. Haber observed that the oxidizing and reducing action of **hydroxylamine** may be illustrated by adding hydroxylamine hydrochloride to a hot emulsion of ferrous hydroxide precipitated by means of sodium hydroxide. The greenish mass rapidly becomes reddish-brown, owing to the oxidation of the hydroxide. If now the liquid be acidified and a fresh quantity of hydroxylamine hydrochloride added, the latter acts as a reducing agent, and rapidly converts the ferric into ferrous salt, the change being rendered evident by the disappearance of the yellow colour. A. Smits found that **magnesium nitride** reacts vigorously with ferrous oxide; and O. Meyer likewise found that **titanium nitride** is vigorously attacked by ferrous oxide at a high temp. L. Santi said that a soln. of **ammonium chloride** converts ferrous oxide into chloride with the evolution of ammonia; and H. Moissan also observed that ferrous oxide liberates ammonia from the ammonium salts, but S. Hilpert and J. Beyer did not agree. H. Moissan found that when the pyrophoric oxide is gently warmed with **nitric oxide,** ferric oxide is produced, and similarly with **nitrogen dioxide**; whilst with **nitric acid** the pyrophoric oxide becomes incandescent. H. Debray found that ferrous oxide prepared at a red-heat dissolves in nitric acid with the evolution of nitrous fumes, and G. Tissandier also observed that the oxide prepared at a red-heat dissolves in nitric acid. H. Schackmann and W. Krings represented the action of **phosphorus** by $5FeO+2P\rightleftharpoons P_2O_5+5Fe$; and by $8FeO+2P\rightleftharpoons(FeO)_3P_2O_5+5Fe$; and W. Krings and H. Schackmann, the action of **iron phosphide,** by $8FeO+2Fe_3P\rightleftharpoons(FeO)_3P_2O_5+11Fe$.

V. Falcke and co-workers observed that when ferrous oxide is heated with purified **carbon,** no reaction occurs below 650°, but above this temp., reduction occurs. The speed of the reaction depends upon the form of carbon employed; thus, sugar-charcoal is relatively inert, for it does not begin to react until about 800°, whereas carbon obtained by burning acetylene in chlorine begins to react at 650°. W. Baukloh and R. Durrer observed that ferrous oxide is reduced by carbon only above 700°, and the rate of the reaction is the same as that at which carbon diffuses through iron, showing that the reaction proceeds from the surface inwards. N. Parravano and G. Malquori gave for the gas reaction: $2FeO+C=2Fe+CO_2$, $\log p_{CO_2}=4{\cdot}95$. Observations were made by J. R. Cain and L. Alder, H. Nippert, and R. Schenck and co-workers—*vide supra*, and also *infra*, magnetite. A. L. Feild assumed that the equilibrium constant K of the reaction $FeO+C\rightleftharpoons Fe+CO$ in molten steel is of the order $K=0{\cdot}010$, where $K=xy$, when x denotes the percentage weight of carbon and y that of iron oxide. It is assumed that the mass of the iron is constant, and that the press. of the carbon monoxide is a constant and equal to one atmosphere. C. H. Herty at first gave 0·040, but later 0·016. A. B. Kinzel and J. J. Egan obtained $K=0{\cdot}0005$ at 1550°. O. Meyer observed that ferrous oxide is attacked by **carbides**—*e.g.* silicon, chromium, and molybdenum—at 1500°. O. Houghton said that the reaction with silicon carbide begins at 1300°. The reaction was studied by E. H. Schulz and A. Kanz. R. Akermann and C. G. Särnström observed that a mixture of **carbon monoxide** and dioxide (10 : 4) reduces ferrous oxide at 850°—*vide supra* for the reducing action of carbon monoxide. The mean of A. C. Halferdahl's values for the free energy of the reaction $FeO+CO=Fe+CO_2$, can be represented by $-63{\cdot}265+16{\cdot}279T$, and the value at 25°, is −58,410 cals. H. Moissan, and W. Eitel discussed the reaction between **carbon dioxide** and pyrophoric ferrous oxide: $3FeO+CO_2\rightleftharpoons Fe_3O_4+CO$; or $2FeO+CO_2\rightleftharpoons Fe_2O_3+CO$. N. J. Harrar found the amounts of ferrous oxide, expressed in milligrams Fe per 100 c.c. of soln., at 25°, dissolved in 40 and 60 days by **formic acid** to be respectively 5·792 and 6·337 ; **acetic acid,** 0·520 and 0·491 ; **propionic acid,** 0·449 and 0·456 ; **oxalic acid,** 42·525 and 42·995 ; **malonic acid,** 31·734 and 47·451 ; **succinic acid,** 0·794 and 0·973 ; **lactic acid,** 12·398 and 13·871 ; **tartaric acid,** 14·022 and 28·084 ; **citric acid,** 31·122 and 42·226 ; **benzoic acid,** 2·022 and 2·148 ; and **salicylic acid,** 14·627 and 14·953. H. Moissan observed that ferrous oxide which has been heated to 1000° does not dissolve in dil. acetic acid. M. Juschkewitsch found that ferrous oxide dissolves very slowly in a 7 per cent. soln. of **potassium cyanide** at ordinary temp. A. G. Doroschevsky and A. Bardt found that **alcohol** vapour is oxidized to aldehyde in the presence of ferrous oxide ; and P. Sabatier discussed ferrous oxide as a catalytic agent in organic chemistry. C. H. Herty found that the deoxidation of iron by **silicon** proceeds $Si+2FeO \rightleftharpoons SiO_2+2Fe$, and when the metal is saturated with silica, $K=[Si][FeO]^2$, or $K=1{\cdot}49\times10^{-4}$. G. Tammann and G. Bätz observed that ferrous oxide reacts exothermally with quartz at about 700° or 800°, and with precipitated and calcined **silica,** at 800°. M. Rüger observed no combination with silica between 900° and 1200°. N. L. Bowen and J. F. Schairer, and F. Sauerwald and W. Hummitzsch studied the $FeO-SiO_2$ system. R. Sachsse and A. Becker found that ferrous oxide opens up the **silicates** by rendering them susceptible to attack by analytical reagents. G. Rauter observed that when ferrous oxide is heated with **silicon tetrachloride** in a sealed tube, ferrous chloride and ferric oxide are formed. P. Ramdohr studied the system with **titanic oxide:** $FeO-Fe_2O_3-TiO_2$. F. Halla noted the formation of the spinel **ferrous titanite,** $FeO.Ti_2O_3$, at 1000° ; the lattice parameter of this salt is $a=8{\cdot}47$ A., and the sp. gr. 4·68.

P. Oberhoffer represented equilibrium conditions of the reaction with **manganese,** $FeO+Mn \rightleftharpoons Fe+MnO$, by the curve Fig. 505. Observations on the subject were made by H. le Chatelier, R. Schenck, H. Styri, A. McCance, W. Krings and H. Schackmann, H. Giersch, and C. H. Herty. W. Krings and H. Schackmann found that the equilibrium constant $K=[Mn][FeO]/[Fe][MnO]$ is 0·0032 at 1550° to 1560°. B. Garre found that the reaction with **magnesium** begins at 575°, and 78·2 Cals. of heat are evolved. G. L. Clark and co-workers found **ferrous aluminate** is of the special type with unit cell having the parameter $a=8{\cdot}119$ A., and **ferrous chromite,** with $a=8{\cdot}344$ A.—*vide* aluminates and chromites. H. zur Strassen gave for the action of **nickel** $Fe+NiO=FeO+Ni+6{\cdot}4$ to 14·2 Cals. W. Jander and H. Senf studied the reaction. F. Sauerwald and W. Hummitzsch studied the system with **calcium oxide.** F. de Carlo found that **lead dioxide** converts ferrous oxide at 250° to 300° into a higher oxide. The miscibility of ferrous oxide with **iron** has been previously discussed ; and its miscibility with **ferrosic oxide** is discussed in connection with the last-named oxide. P. Oberhoffer and O. von Keil determined the m.p. of some mixtures of **manganous oxide** and ferrous oxide. They found :

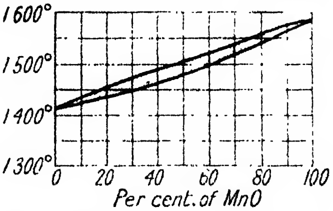

FIG. 505.—Equilibrium Diagram of the System : FeO–MnO.

FeO . . .	100	75	50	25	0 per cent.
Melting-points .	1390°	1470°	1513°	1650°	(1700°)

C. Benedicks and H. Löfquist have constructed a provisional equilibrium diagram on the basis of these meagre data ; and from the work of M. Matwéeff, and P. Oberhoffer and K. d'Huart, it is assumed that complete miscibility occurs in the liquid state. F. Sauerwald and W. Hummitzsch studied the reaction. C. Benedicks and H. Löfquist also constructed a provisional equilibrium diagram of the ternary system : Mn–Fe–O. According to G. Tammann and F. Westerhold, ferrous oxide reacts when heated with **molybdenum trioxide** to form ferrous molybdate ; and with **tungsten trioxide** to form ferrous tungstate. G. Tammann and W. Rosenthal studied the action of ferrous oxide on **uranium trioxide ;**

V. Lepiarczyk, its action on **calcium sulphide,** and on **calcium sulphate**; and C. Montemartini and A. Vernazza, its action on soln. of **chromic sulphate.**

Ferrous hydroxide, or **hydrated ferrous oxide.**—A. F. de Fourcroy observed that green *précipités martiaux* is formed when caustic alkalies are added to soln. of iron in acids. The precipitate was examined by G. F. Rouelle, C. W. Scheele, J. L. Proust, J. L. Gay Lussac, M. Darso, C. F. Bucholz, and J. J. Berzelius. L. J. Thénard obtained a white precipitate under similar conditions, and for a time it came to be called *Thénard's white oxide.* L. J. Thénard's idea that the precipitate obtained by the addition of alkali-lye to a soln. of a ferrous salt is a peculiar oxide was shown to be wrong by J. L. Proust, C. F. Bucholz, and J. J. Berzelius; M. Darso, C. F. Bucholz, and T. Thomson regarded it as a basic sulphate. J. L. Proust, H. Davy, and J. J. Berzelius at first considered the white or green precipitate to be a hydrate of ferrosic oxide, but later, J. J. Berzelius showed that it is a *monohydrate* of ferrous oxide, $FeO.H_2O$, or **ferrous hydroxide,** $Fe(OH)_2$. According to F. Hart, an impure *dihydrate,* $FeO.2H_2O$, occurs in the clay near Cuxhaven, in hard, yellowish-brown lumps which crumble on exposure to air.

The formation and preparation of ferrous hydroxide.—According to A. Ackermann, A. Bineau, H. Wölbling, R. Stumper, W. R. Dunstan and J. R. Hill, J. A. N. Friend, F. W. Durkee, W. G. Whitman and co-workers, and W. A. Tilden, ferrous hydroxide is formed as an intermediate stage in the rusting of iron; and when iron is in contact with aerated waters, or waters containing carbonic or sulphuric acid. A. Kaufmann observed that it is formed in green flecks when iron or solid ferrous salts are kept in contact with a sat. soln. of ammonium nitrate. P. de Clérmont and J. Frommel showed that ferrous hydroxide is produced by the action of boiling water on ferrous sulphide. O. Baudisch and co-workers found that the hydroxide is produced in the hydrolysis of ferrous hydrocarbonate; R. Fink, by treating a soln. of ferrous sulphate with basic copper sulphate; D. Vitali, by the action of silver oxide on a soln. of ferrous nitrate; and G. Kassner, by the action of potassium hydroxide on a soln. of ferrous cyanide, or, according to S. U. Pickering, on ferrous tartrate. O. Baudisch and L. W. Bass found that white, glistening crystals are formed when an alkaline normal soln. of potassium ferrocyanide, free from oxygen, is exposed for some hours to sunlight; and M. Volmar found that ferrous hydroxide and tartrate are produced when a soln. of potassium ferrous tartrate is exposed to ultra-violet rays.

H. E. Patten and G. H. Mains found that hydrated ferrous oxide is precipitated by ammonia or sodium hydroxide when the H˙-ion conc. is $p_H=5{\cdot}5$ to $6{\cdot}0$. Observations were also made by J. H. Hildebrand. H. T. S. Britton found that in the electrometric titration of 100 c.c. of $0{\cdot}025M$-$FeSO_4$, with $0{\cdot}0990N$-NaOH, the results shown in Fig. 506 were obtained. Precipitation began when 0·8 c.c. of the alkali soln. had been added, and when the H˙-ion conc. was $p_H=5{\cdot}49$; and it was complete when 1·71 eq. of alkali had been added. S. U. Pickering observed that complete precipitation had taken place from ferrous sulphate soln. at the point where they became alkaline to phenolphthalein, and this was when sodium hydroxide had been added in amounts which varied from 1·77 to 1·86 eq. He considered this sufficient justification for the assertion that the precipitate was a definite basic salt, $10FeO.SO_3$. H. T. S. Britton found that precipitation usually occurs somewhere near the point of the first inflexion, although often at a p_H which was a little less than that at which the main precipitation took place. This was probably due to the precipitate having been formed at a point in the liquid where the precipitation value of p_H had been temporarily exceeded, and time not having been allowed for its re-solution. If, therefore, the two straight portions of the curve be produced, it is probable that the point of intersection corresponds more nearly

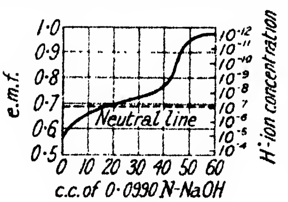

FIG. 506.—Electrometric Titration of Solutions of Ferrous Sulphate.

to the amount of alkali which had to be added to produce incipient precipitation, and also to the actual hydrion concentration at which precipitation under ideal conditions would commence. This point represents the limiting conditions necessary to form a precipitate. The conc. of the metal ions is then $p_{H^{\cdot}}=5{\cdot}77$, $p_{OH'}=8{\cdot}37$; and 0·6 c.c. 0·0990*N*-NaOH are required and $C_{Fe^{\cdot\cdot}}=3{\cdot}0\times10^{-4}$, so that $[Fe^{\cdot\cdot}][OH']^2=4{\cdot}5\times10^{-21}$—*vide infra*, solubility product.

G. Schmidt prepared ferrous hydroxide by mixing a soln. of a ferrous salt, free from ferric salt, with soda-lye or potash-lye freed from air by boiling, and performing the operation in a vessel from which air is excluded. The vessel is filled with boiling water and closed. The white flakes must be preserved from contact with air during washing and drying. The precipitate is allowed to settle, and the liquid decanted with a syphon; the vessel is again filled with boiling water, poured in slowly so as not to disturb the precipitate, and afterwards shaken and closed. This purification by alternate subsidence and decantation must be performed as quickly as possible, since hydrated ferrous hydroxide is decomposed by prolonged contact with water. The pale green precipitate is then placed in a retort with ether vapour, and the beak of the retort dipped under mercury. Air is expelled by the ether as the retort is warmed, and the water is afterwards driven off. The product can be preserved in hydrogen out of contact with air. If aq. ammonia is employed in place of potash-lye, the precipitate after long standing gives off hydrogen and is converted into black ferrosic oxide containing adsorbed ammonia. As commonly prepared, ferrous hydroxide is a bulky, greenish-grey substance, very liable to oxidation to greenish-black hydrated ferrosic oxide and finally to red ferric hydroxide. According to E. Divers and T. Haga, if, after the precipitation, the supernatant mother-liquor is poured off and solid potassium hydroxide dissolved in the remaining mother-liquor, the ferrous hydroxide diffused through it undergoes in the course of a few hours a very considerable diminution in vol., and then forms a pale greenish-grey pulverulent precipitate, although the gelatinous precipitate may have been of a much darker colour. This dense hydroxide is much more stable, and in oxidizing does not form the black hydroxide before becoming ferric hydroxide. According to E. Deiss and G. Schikorr, when gaseous ammonia is passed into a soln. of ferrous chloride, completely protected from oxygen, a pure white pulverulent precipitate is obtained, resembling in appearance calcium hydroxide. If the precipitate stands in contact with the mother-liquor for a long time, it may be partly peptized. The precipitate is washed with air-free water. O. Baudisch and P. Mayer, and O. Baudisch and L. A. Welo described a special apparatus for washing the precipitate while it is protected from air. The precipitate was found by W. R. Dunstan and T. S. Dymond to retain ammonia very tenaciously, and they added that the precipitation is incomplete (peptization). The hydroxide was obtained by the ammonia precipitation by A. Quartaroli, and K. Endell and R. Rieke; the alkali-lye precipitation, by W. R. Dunstan and T. S. Dymond, O. Baudisch and co-workers, J. Woost, S. Hilpert, A. Krause, M. Kuhara, G. Schmidt, and E. Deiss and G. Schikorr; and milk-of-lime, by W. von Zorn, and W. R. Dunstan and T. S. Dymond. A. B. de Schulten treated a soln. of ferrous chloride with an excess of potassium hydroxide and heated the mixture for a long time in a current of coal gas; and on cooling the green soln., obtained the hydroxide in green hexagonal prisms.

L. Brugnatelli, and R. Saxon obtained the hydroxide electrolytically using iron as an anode. R. Lorenz used a platinum cathode, an iron plate as anode, and an aq. soln. of sodium chloride, sulphate, or nitrate as electrolyte. The liquid was kept stirred during the electrolysis. H. Buff, F. Förster and co-workers, B. la Croix von Langenheim, P. Krassa, J. Woost, C. Monnet, R. Kremann and J. Lorber, M. Tichwinsky, O. Faust, O. Pattenhausen, and M. Roloff also obtained the hydroxide in an analogous manner. H. J. M. Creighton produced the *rhythmic precipitation* of ferrous hydroxide by passing an electric current, of potential gradient 0·0093 volt, through a 2-in. U-tube containing in the horizontal part 10 per cent. agar-agar mixed with small quantities of phenolphthalein and sodium chloride. The ends were filled with a dil. soln. of sodium chloride, with iron nails as electrodes. In a few days' time green discs of ferrous hydroxide appeared separated from one another by a pink jelly.

E. Deiss and G. Schikorr precipitated white ferrous hydroxide from a soln. of ferrous chloride by means of ammonia gas, and then by repeated centrifugal separation washed the precipitate with air-free water until it formed a **hydrosol of ferrous hydroxide.** A. Schmauss also obtained the hydrosol by electrical spluttering of iron wires under water containing a little gelatin in soln. E. Deiss and G. Schikorr found that the soln. is colourless by reflected light and red by transmitted light. The concentration is about 4 grms. per litre, and it cannot be kept longer than 6 days without flocculation. The particles are positively charged, and are flocculated by electrolytes. A. Schmauss's sol is green and unstable; it becomes yellow, by oxidation, on exposure to air. The hydrosol is cataphoretic, and it is flocculated by the positively charged hydrosol of ferric hydroxide. The absorption spectrum shows bands from $496\mu\mu$ to $662\mu\mu$.

The properties of ferrous hydroxide.—The dried, amorphous ferrous hydroxide is brittle, friable, and green. J. von Liebig and F. Wöhler said that the green colour is probably due to incipient oxidation. A. B. de Schulten obtained the hydroxide in green hexagonal prisms by crystallization from a conc. soln. of sodium hydroxide—*vide supra.* O. Baudisch and co-workers, E. Deiss and G. Schikorr, and M. Kuhara obtained the white hydroxide by carefully excluding oxygen during its preparation. According to G. Natta and E. Casazza, the **crystals** of ferrous hydroxide belong to the holohedral class of the rhombohedral system; and X-radiograms show that the crystals have a lattice structure like brucite. The elementary cell has one molecule, and the dimensions a=3·24 A., and c=4·47 A., so that the axial ratio $a:c$=1 : 1·38; and the calculated density is 3·40. H. Seifert studied the subject. G. Natta discussed the isomorphism of the bivalent hydroxides from the point of view of the space-lattice, and the atomic radii. J. Thomsen gave for the **heat of formation** of the hydroxide (Fe,O,H_2O)=68·28 Cals.; and M. Berthelot, 69·00 Cals. J. Thomsen gave for the **heat of neutralization** of the hydroxide with sulphuric acid, 24·92 Cals., and with hydrochloric acid, 21·39 Cals.; and M. Berthelot gave 21·4 Cals. with dil. hydrochloric acid. J. Thomsen found the **heat of oxidation,** $Fe(OH)_2 \rightarrow Fe(OH)_3$, to be 27·29 Cals. R. Dallwitz-Wegener discussed the **free energy** of the compound. M. Randall and M. Frandsen gave −115·4 Cals. for the free energy of formation of the hydroxide, and for $Fe+2H_2O=Fe(OH)_2+H_2$, −2·28 Cals.

F. Allison and E. J. Murphy studied the magneto-optic properties. F. Förster and V. Herold gave −0·740 volt for the **electrode potential** of ferrous hydroxide against a hydrogen electrode at 20°; O. Faust, −0·75 volt; and J. Woost for the electrode potential with 2·85N-KOH, hydrogen electrode unity, −0·835 to −0·845 volt at 0°; −0·825 to −0·840 volt at 20°; −0·820 to −0·835 volt at 50°; and −0·80 volt at 75°. O. Pattenhausen said that ferrous hydroxide shows two potentials—namely, −0·66 volt, and −0·55 to −0·53 volt—corresponding with two different stages in the hydration of ferrous oxide at ordinary temp. and with a current of 0·07 ampère. S. Miyamoto found the electric potentials of cells with N-, 2N-, 4N-, and 5N-NaOH soln. at 25° using platinized platinum. In the case of $Pt \mid NaOH,Fe(OH)_2,Fe_3O_4.nH_2O \mid NaOH \mid HgO,NaOH \mid Hg$, the potential $E=0{\cdot}8030-0{\cdot}0015 \log C'_{NaOH}$; with the cell $Pt,H_2 \mid NaOH \mid HgO,NaOH \mid Hg$, $E=0{\cdot}9270-0{\cdot}00332 \log C_{NaOH}$; and with the cell $Pt \mid NaOH,Fe(OH)_2,Fe_3O_4.nH_2O \mid NaOH \mid H_2,Pt$, $E=0{\cdot}1240+0{\cdot}00332 \log C_{NaOH}-0{\cdot}0015 \log C'_{NaOH}$. S. Hilpert, and J. von Liebig and F. Wöhler said that ferrous hydroxide is non-magnetic. A. Quartaroli gave $\chi=30\times10^{-6}$ to 60×10^{-6} for the **magnetic susceptibility** of the hydroxide precipitated by aq. ammonia; and $\chi=20\times10^{-6}$ to 30×10^{-6} mass unit. Observations were also made by G. Wiedemann.

A. Bineau prepared a soln. of ferrous hydroxide by means of iron and purified water, slightly aerated, and found that the **solubility** is such that one part of ferrous hydroxide dissolves in 150,000 parts of water, or $7{\cdot}5\times10^{-5}$ mol per litre; W. G. Whitman and co-workers gave $6{\cdot}7\times10^{-5}$ mol per litre, a value higher than that for ferric hydroxide. E. Müller and F. Kapeller calculated from the ferric-ferrous potential the **solubility product** $[\mathrm{Fe}^{\cdot\cdot}][\mathrm{OH}']^2=1{\cdot}69\times10^{-14}$, and the solubility was calculated to be $1{\cdot}6\times10^{-5}$; H. T. S. Britton obtained $4{\cdot}5\times10^{-21}$ for the solubility product—*vide supra*. B. Schrager calculated for $[\mathrm{Fe}^{\cdot\cdot}][\mathrm{OH}']^2$, 7×10^{-13}. Ferrous hydroxide shows amphoteric qualities, for it dissolves slightly as an acid in aq. soln. of sodium hydroxide owing to the reaction $\mathrm{Fe(OH)_2}+\mathrm{OH}'\rightarrow\mathrm{Fe(OH)'_3}$, where $K=[\mathrm{Fe(OH)'_3}]/[\mathrm{OH}']=5\times10^{-5}$. P. Krassa calculated, from the ferrous ion concentration in 20 per cent. potash-lye, the solubility product $8{\cdot}7\times10^{-14}$, and the solubility was calculated to be $2{\cdot}8\times10^{-5}$; J. W. Shipley and I. R. McHaffie calculated from the rate of corrosion of iron $3{\cdot}9\times10^{-15}$, and the solubility was calculated to be 1×10^{-5} mol per litre; and A. B. Lamb found, by conductivity methods, the conc. of the ferrous ion in a sat. soln. of ferrous hydroxide to be $1{\cdot}35\times10^{-5}$. G. Bodländer's values $2{\cdot}5\times10^{-21}$ for the solubility product, and $1{\cdot}7\times10^{-7}$ for the solubility in gram-equivalents per litre are not in good agreement with the others. W. G. Whitman and co-workers found 3·75 parts of iron per million, or $6{\cdot}7\times10^{-5}$ mols of ferrous hydroxide per litre for the solubility. The $\mathrm{H}^{\cdot}$-ion concentration of the soln. is represented by $p_{\mathrm{H}}=9{\cdot}6$, or $[\mathrm{OH}']=4\times10^{-5}$ and $[\mathrm{Fe}^{\cdot\cdot}]=2\times10^{-5}$. The **degree of ionization** in a sat. soln. where $p_{\mathrm{H}}=9{\cdot}6$ at 25° $\mathrm{Fe}^{\cdot\cdot}/\mathrm{Fe(OH)_2}$ is 30 per cent.; when $p_{\mathrm{H}}=9{\cdot}2$, 29 per cent.; and $p_{\mathrm{H}}=8{\cdot}2$, 24 per cent. The **ionization constant** $[\mathrm{Fe}^{\cdot\cdot}][\mathrm{OH}']^2/[\mathrm{Fe(OH)_2}]$ is $6{\cdot}8\times10^{-6}$ for the sat. soln. at 25°; and for soln. with $p_{\mathrm{H}}=9{\cdot}2$, $6{\cdot}0\times10^{-10}$; and for $p_{\mathrm{H}}=8{\cdot}2$, $1{\cdot}15\times10^{-10}$. S. Veil, and O. Baudisch and L. A. Welo studied the **magnetic properties** of the hydroxide.

The white hydroxide rapidly becomes green on exposure to air, then black owing to the formation of hydrated ferrosic oxide, and finally reddish-brown owing to the production of hydrated ferric oxide. These changes were discussed by L. J. Thénard, O. Baudisch and co-workers, J. J. Berzelius, C. F. Bucholz, M. Darso, H. Davy, E. Divers and T. Haga, O. Faust, P. Fireman, and J. von Liebig and F. Wöhler. A. B. de Schulten observed that even after the crystals have been washed with alcohol, and ether, and dried out of contact with air, they oxidize immediately on exposure to oxygen, developing much heat, and yielding ferric oxide. According to G. Schmidt, if the moist hydroxide be exposed to air, it quickly forms dingy green hydrated ferrosic oxide, and then yellowish-brown hydrated ferric oxide; but if the dried amorphous hydroxide be exposed to air, it is instantly converted into ferric oxide, and the change is attended by an evolution of heat, which often makes the mass red-hot. If the liquid in which the white flakes of hydroxide have been precipitated is boiled, the colour becomes black, due, said J. von Liebig and F. Wöhler, to the formation of ferrosic oxide by the action of the air. R. G. Knowland recommended ferrous hydroxide as an agent for removing dissolved oxygen from water. A. A. Bonnema showed that ferrous oxide or hydroxide form nitrite on exposure to air.

As just indicated, ferrous hydroxide readily **oxidizes** when exposed to air, but only under certain conditions does the end-product correspond with ferric hydroxide. P. Fireman observed that the colour of the product varies from yellow to brown to black according to the proportion of ferric hydroxide produced, and A. Krause showed that the colour of the oxidation product is darker the greater the proportion of contained ferrous hydroxide. S. Miyamoto found that the rate of oxidation is reduced by the presence of alkalies; and that the coeff., k, of the rate of oxidation of ferrous hydroxide suspended in soda-lye is independent of the quantity of ferrous hydroxide present, and its value is identical with that for the oxidation of sodium sulphite and stannous hydroxide in alkaline soln. The value of k is only slightly affected by temp., but decreases with increasing concentration of sodium hydroxide, since the velocity is probably determined by the speed of dissolution of oxygen, which is decreased by the sodium hydroxide. On the other hand, A. Krause found that the speed of oxidation is greatly favoured by a rise of temp. W. Gluud and W. Riese observed the rate of oxidation of suspensions of ferrous hydroxide in various solutions by a current of air. In soln. of sodium or ammonium hydrogen carbonate increase of alkalinity favours oxidation of ferrous hydroxide. With the former, however, increase of salt concentration reduces the oxidation rate. The addition of sodium sulphate or other neutral salt renders it more difficult to remove the carbon dioxide by air-blowing the sodium hydrogen carbonate soln. Ammonium sulphate facilitates the removal of both carbon dioxide and ammonia.

S. Miyamoto also showed that sodium hydroxide retards the oxidation, even though the reducing power of ferrous hydroxide increases with the conc. of HO′-ions; and A. Krause observed that ferrous hydroxide is oxidized to ferric hydroxide only when the alkali present does not exceed the mol. ratio $NaOH : FeSO_4 = 1 : 1$; if more alkali be present, the oxidation of the ferrous hydroxide by air is incomplete; and this the more the higher the proportion of alkali, but the mol. ratio of ferrous to ferric hydroxide does not exceed $FeO : Fe_2O_3 = 0{\cdot}3 : 1$. The water-content of the dried product decreases with increasing proportions of ferrous hydroxide. The oxidation of ferrous hydroxide by air is dependent on the H˙-ion conc. of the liquor from which it is precipitated. Reddish-yellow metaferric hydroxide or ferroferrite may be formed. The iso-electric point of hydrated metaferric oxide, corresponding with an air-dried product $Fe_2O_3.2H_2O$, is $p_H = 5{\cdot}2$. If the p_H is greater than 5·2, $(Fe_2O_3.aq.)'$ is formed; with p_H less than 5·2, $(Fe_2O_3.aq.)^{\cdot}$ is formed; and with p_H less than 0·3, the ferrous salt is stable in air. The oxidation of ferrous hydroxide to a ferrous ferrite, when the p_H is greater than 5·2, is shown by oxidizing ferrous hydroxide in the presence of magnesium hydroxide, for then the oxidation to magnesium ferrite is complete. Hydrated metaferric hydroxide differs in chemical and physical properties from orthoferric oxide with an isotectic point of $p_H = 7{\cdot}7$. E. Deiss and G. Schikorr also considered that a ferrous ferrite is formed as an intermediate stage in the reaction. The production of an intermediate peroxide of the type $FeO_2(OH)_2$ was discussed by W. Manchot and H. Schmid, G. Just, C. Sandonnini, and O. Baudisch and co-workers. According to C. Sandonnini, black ferrite is formed when a dil. suspension of the ferrous hydroxide is boiled in presence of air, or at the ordinary temp. when the hydroxide is protected by a deep layer of water. In the presence of chromic or aluminium hydroxides, however, no ferrite is formed even under these conditions. In an atmosphere of pure oxygen ferrous hydroxide is oxidized practically quantitatively to ferric hydroxide. A suspension of ferrous hydroxide in water which has been boiled for a long time in an atmosphere of hydrogen is oxidized directly to ferric hydroxide when subjected to the conditions which normally would give the black ferrite. W. Manchot, and W. Manchot and F. Glaser said that during the oxidation of ferrous hydroxide some oxygen is activated, and is taken up by an acceptor—say arsenious acid. N. R. Dhar found that the oxidation of ferrous hydroxide can be induced by the presence of a number of organic and inorganic substances. Ferrous hydroxide, precipitated by hydrolysis or by the action of hydroxyl ions from a soln. of ferrous hydrogen carbonate reacts in the nascent state with molecular oxygen to form a compound exhibiting a very high oxidation and reduction potential. With the oxidation process as a primary reaction, there are the oxidation of potassium oxalate and of nickel hydroxide as secondary reactions.

For the chemical action of ferrous hydroxide on **water**, *vide infra*, ferrous chloride. A. Bineau said that the aq. soln. of ferrous hydroxide rapidly becomes turbid on exposure to air; and, according to J. von Liebig and F. Wöhler, and G. Schmidt, ferrous hydroxide can decompose water, slowly in the cold, and rapidly when heated. O. Baudisch and L. A. Welo, E. Deiss and G. Schikorr, and W. Traube and W. Lange said that ferrous hydroxide remains unchanged when kept in contact with air-free water, and E. Deiss and G. Schikorr added that the oxidizing action reported by G. Schmidt is due to the action of dissolved oxygen from the air. If reducing agents be present, W. R. Dunstan and T. S. Dymond, and W. Manchot found that the water may be decomposed by the hydroxide; for example, W. Traube and W. Lange observed that in the presence of a trace of palladious chloride, there is a slow development of hydrogen, and black ferrosic oxide is formed. E. Berl and F. van Taack observed that when heated with water in a bomb, under press., black ferrosic oxide is formed and hydrogen is evolved.

The dehydration curve obtained by G. F. Hüttig and H. Möldner for white hydrated ferrous oxide is derived from the data for $FeO.nH_2O$:

	114°	220°	228°	230°	234°	261°	270°	277°	336°
n .	1·018	0·933	0·858	0·773	0·697	0·621	0·536	0·463	0·382

As the reaction $FeO.H_2O \rightarrow FeO + H_2O$ proceeds, the colour becomes black. There is also a side reaction $3(FeO.H_2O) \rightarrow Fe_3O_4 + 2H_2O + H_2$. The X-radiograms are indicated in Fig. 507.

A. B. de Schulten said that ferrous hydroxide is readily soluble in soln. of the **alkali hydroxides,** and also in aq. ammonia, so that ferrous hydroxide is not completely precipitated from soln. of ferrous salts by ammonium hydroxide, even in the presence of ammonium chloride. If the soln. of ferrous hydroxide in these menstrua be exposed to air or oxygen, the ferrous hydroxide is rapidly converted into hydrated ferric oxide. On the other hand, E. Deiss and G. Schikorr, and O. Baudisch said that the hydroxide is insoluble in sodium and potassium hydroxides; so that the alleged solubility is a case of peptization to form a hydrosol. S. H. Carsley found that ferrous hydroxide is partially peptized by boiling it with conc. alkali-lye. The rate of settling of hydrated ferrous oxide in neutral and dil. alkali soln. is greatly increased by boiling, owing, it is supposed, to the partial dehydration and coagulation of the particles. According to W. G. Whitman and co-workers, the solubilities of ferrous hydroxide in various **salt solutions**—calcium, sodium, ammonium, and magnesium chlorides, and in sodium sulphate, chromate,

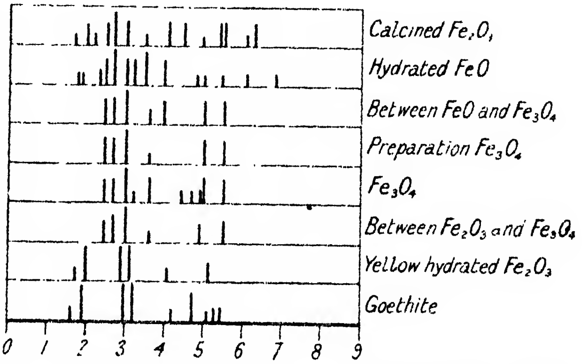

FIG. 507.—X-radiograms of some Hydrated Iron Oxides.

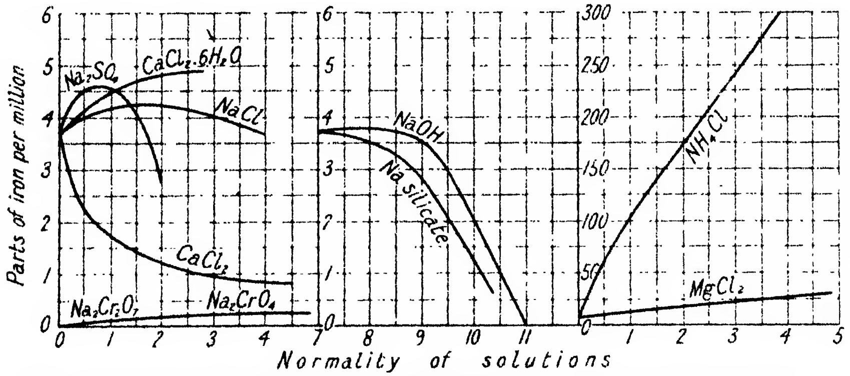

FIGS. 508 to 510.—The Solubility of Ferrous Hydroxide in Various Solutions.

dichromate, silicate, and hydroxide—are indicated in Figs. 508 to 510. The difference in the results for anhydrous calcium chloride and its hexahydrate is attributed to the presence of a small amount of calcium oxide in the former. It was found that the rates of corrosion of iron by these salt soln. are parallel with the solubilities of ferrous hydroxide in these soln., and this is taken to be in agreement with the colloidal theory of corrosion discussed by J. A. N. Friend. According to G. Pellini and D. Meneghini, ferrous hydroxide suspended in alcohol and treated at a low temp. with **hydrogen dioxide** furnishes a mixture of ferric hydroxide, and iron peroxide. A. S. Loevenhart and J. H. Kastle discussed the effect of inhibitors on the catalytic decomposition of hydrogen dioxide by ferrous hydroxide. G. Kassner observed that ferrous hydroxide is oxidized by **sodium dioxide.**

Ferrous hydroxide readily dissolves in **acids,** forming the respective ferrous salts ; and, according to G. Schmidt, much heat is evolved. E. Petersen observed that ferrous hydroxide is soluble in **hydrochloric acid;** and J. Lefort, that it is soluble in hydrochloric acid. W. van Wüllen Scholten found that ferrous hydroxide is oxidized by **alkali hypochlorites;** C. W. Hempel, that **iodic acid** is reduced ; and B. Sjollema, and E. Weitz and H. Müller, that in boiling soln. in the absence of free alkali, **potassium perchlorate** is reduced quantitatively by ferrous hydroxide to form potassium chloride. W. Feld observed that ferrous hydroxide suspended in water is converted to ferrous sulphide by **hydrogen sulphide.** J. Lefort observed that the hydroxide is soluble in conc. **sulphuric acid.**

M. Darso, J. L. Gay Lussac, and G. Schmidt considered that ferrous hydroxide is slightly soluble in aq. **ammonia,** but this is probably a case of peptization to form the hydrosol. H. Becquerel said that the hydroxide is soluble in aq. ammonia in the presence of ammonium salts, and this is attributed to the formation of complex ammines. The action was studied by O. Faust, E. Deiss and G. Schikorr, and V. Paissakowitsch. Ferrous hydroxide generally acts as a reducing agent. W. R. Dunstan and T. S. Dymond found that feebly alkaline soln. of **hydroxylamine** are decomposed by ferrous hydroxide to form ammonia and a little nitrogen ; and F. Haber, C. Kjellin, and A. Kurtenacker and R. Neusser showed that if an alkali-lye or ammonia emulsion of ferrous hydroxide is employed, the yield of ammonia is almost quantitative. On the other hand, E. Ebler and E. Schott found that with a conc. soln. of hydroxylamine, nitrogen and nitrous oxide are at first turbulently evolved, and only towards the end of the reaction is ammonia formed. C. Kjellin found that β-methyl hydroxylamine, β-ethyl hydroxylamine, and β-*iso*-propylhydroxylamine are reduced by ferrous hydroxide to the primary amines. F. Haber said that **hydrazine** is not attacked by ferrous hydroxide. W. R. Dunstan and T. S. Dymond found that **hyponitrous acid** is slowly decomposed by ferrous hydroxide with the formation of nitrogen, but neither ammonia nor hydroxylamine is produced. According to E. Divers and T. Haga, if **nitric oxide** be passed into a soln. of potassium hydroxide mixed with some ferrous hydroxide, ferric oxide is formed, and the nitric oxide is largely converted into ammonia, but neither hydroxylamine nor alkali hyponitrite could be detected among the products of the reaction. On the other hand, W. R. Dunstan and T. S. Dymond observed that in this reaction a little ammonia and no hydroxylamine are formed, but some hyponitrite, nitrogen, and a little nitrous oxide are produced. In the absence of alkali, hyponitrite, ammonia, and hydroxylamine are not formed, but nitrogen and nitrous oxide appear. In the presence of a conc. soln. of potassium hydroxide, ammonia, nitrogen, and nitrous oxide are formed, but no hyponitrite. A. Klemenc, H. Reihlen and A. von Friedolsheim, and O. Baudisch and L. A. Welo also studied the reduction of nitric oxide by ferrous hydroxide, and the formation of hydrated ferrosic oxide. J. Gay, and E. Péligot found that **nitrogen peroxide** is reduced to nitrogen and nitrous oxide by ferrous hydroxide. W. von Zorn showed that freshly precipitated ferrous hydroxide energetically reduces **sodium nitrite** in aq. soln. ; heat is evolved, and hyponitrite, ammonia, nitrogen, and nitrous oxide are formed. E. Divers and T. Haga observed no hyponitrites in the products of the reaction ;

but W. R. Dunstan and T. S. Dymond said that the gas which is evolved is a mixture of nitrogen and nitrous oxide, and in the soln. hyponitrites, but not hydroxylamine, are formed ; if an excess of ferrous oxide is employed, nitrogen and ammonia are produced. O. Baudisch and co-workers found that alkali nitrites are quantitatively reduced in the presence of an excess of ferrous hydroxide, *in statu nascendi*, in neutral or alkaline soln., and in the absence of oxygen. With boiling soln. of alkali hydroxide, ammonia is the sole product ; and with boiling soln. of alkali carbonate, ammonia and nitrous oxide are formed. According to E. Divers and T. Haga, alkali nitrites yield much ammonia when treated with ferrous hydroxide in the presence of a soln. of potassium hydroxide—but no hydroxylamine, or hyponitrite, or any gaseous product is formed. The reducing action was also studied by W. von Zorn, and G. Schikorr. By this reaction S. Miyamoto determined the nitrites in soln. as ammonia. The velocity of reaction between potassium nitrite and ferrous hydroxide in alkaline soln. was measured at 25°, 35°, and 45°. When the initial concentration of the nitrite is very small compared with that of the alkali hydroxide, the velocity curve is linear. The velocity constant increases with the concentration of the alkali hydroxide, and is expressed by the formula : $k=e^{20\cdot609\quad 8098\cdot2/}p(1+0\cdot79C_{\mathrm{KOH}})$. The velocity constant is increased 2·35 times for each rise in temp. of 10°. The presence of potassium sulphate in the system has no effect on the reaction velocity. The speed of the reaction is too great for measurement at the b.p., 108°. A. Thum said that the ferrous hydroxide is rapidly converted to hydrated ferrosic oxide, and then slowly to hydrated ferric oxide. F. Kuhlmann, and W. von Zorn observed that a warm, dil. soln. of **potassium nitrate** is reduced by ferrous hydroxide and ammonia is formed—*vide supra*. S. H. Carsley observed that the reduction of the nitrate to ammonia is quantitative and the hydroxide forms the black magnetic ferrosic oxide ; and instead of $8\mathrm{Fe(OH)_2}+\mathrm{NaNO_3}=4\mathrm{Fe_2O_3}+6\mathrm{H_2O}+\mathrm{NaOH}+\mathrm{NH_3}$, with the intermediate formation of $\mathrm{Na[Fe(OH)_3]}$, S. H. Carsley, and C. Sandonnini and S. Bezzi prefer the equation : $12\mathrm{Fe(OH)_2}+\mathrm{NaNO_3}=4\mathrm{Fe_3O_4}+10\mathrm{H_2O}+\mathrm{NaOH}+\mathrm{NH_3}$. In dil., neutral soln., previously boiled ferrous hydroxide reduces the nitrate more slowly than does the freshly precipitated oxide owing to the dehydration and agglomeration of the hydrated ferrous oxide. E. Divers and T. Haga found that alkali nitrates were not reduced ; but W. R. Dunstan and T. S. Dymond said that a little ammonia, and a small quantity of a gas are produced ; and with small proportions of potassium nitrate, the conversion to ammonia is complete. The reaction was also studied by E. Deiss and G. Schikorr. S. Miyamoto found that the reduction of the nitrates does not proceed so easily as is the case with the nitrites, but that the reduction does occur in boiling soln., and it is quantitative, so that it can be employed for the determination of nitrates in soln. The velocity of reaction between potassium nitrate and ferrous hydroxide in alkaline soln. was measured at 108° and 112·2°, the velocity constant being approximately $7\cdot577\times10^{-3}$ (calc. $7\cdot726\times10^{-3}$; C_{KOH} : 5·5394 mol. per litre) and $2\cdot331\times10^{-2}$ (calc. $2\cdot326\times10^{-2}$; C_{KOH} : 6·9541 mol. per litre respectively). According to O. Baudisch and co-workers, ferrous hydroxide in neutral or faintly alkaline soln. is unable to reduce nitrates to nitrites ; but the reduction takes place with the co-operation of atm. oxygen. Nascent ferrous hydroxide is far more powerful as a reducing agent than the freshly precipitated ferrous hydroxide towards nitrites. It is assumed that ferrous hydroxide absorbs oxygen, forming *ferrous peroxyhydroxide* : $[\mathrm{Fe(H_2O)_6}](\mathrm{OH})_2+\mathrm{O_2}=[\mathrm{FeO_2(H_2O)_5}](\mathrm{OH})_2+\mathrm{H_2O}$, otherwise expressed :  $\mathrm{Fe(OH)_2}+\mathrm{O_2}=\begin{matrix}\mathrm{O}\\\mathrm{O}\end{matrix}\!>\!\mathrm{Fe(OH)_2}$. The peroxide so formed, in virtue of its iron nucleus, has the power of activating the oxygen subsidiary valencies of other substances and forming unstable compounds with them. S. H. Carsley said that O. Baudisch and co-workers prepared their hydrated ferrous oxide at different temp., so that their results are complicated by differences in the degrees of agglomeration of the hydrated oxide. The effect of oxygen on hyrdated ferrous oxide is to form an unstable higher oxide—$\mathrm{Fe_2O_4}$ or $\mathrm{FeO_3}$—as O. Baudisch assumed.

O. Baudisch and co-workers showed that ferrous peroxyhydroxide can act as an oxidizing agent, as is shown by the conversion of alcohol to aldehyde and by its behaviour towards starch and sugar. It acts in this respect in the same manner as light energy alone or in the presence of traces of iron. It can effect the reduction of alkali nitrate to ammonia. The first action is supposed to involve a reaction with the peroxyhydroxide and the nitrate: $FeO_2(OH)_2+2NaNO_3=Fe(OH)_2+2NaNO_2+2O_2$, and the nitrite is then reduced by the hydrated ferrous oxide to ammonia. Both types of reaction can take place in one and the same soln. Formaldoxime and traces of nitromethane are formed when a methyl alcohol soln. of nitrite is treated with ferrous sulphate and an excess of sodium hydrocarbonate and shaken with air. The nitric acid is reduced to hyponitrous acid, which reacts with the formaldehyde produced by the oxidation of methyl alcohol, yielding formhydroxamic acid, which is in part converted into formaldoxime. Both iron and ferrous peroxyhydroxide are ferromagnetic, but ferrous hydroxide is not so. According to O. Baudisch and L. A. Welo, when the precipitate of hydrated ferrous oxide is stored in the absence of air—although apparently stable even when boiled—it gradually loses its power of reducing nitrates to nitrites, and of catalysing the oxidation of organic compounds such as uracil and lactic acid, although on exposure to air they still absorb oxygen. The loss of therapeutic efficacy undergone by certain mineral waters through keeping has been correlated with a precipitation and consequent inactivation of ferrous salts analogous to the ageing process described above; it was found that the ageing of the mineral water was accelerated by exposure to light. The ageing process is attributed to the gradual passage of the hydrate from the amorphous to the crystalline state.

G. Schmidt found that dried ferrous hydroxide rapidly absorbs **carbon dioxide,** becoming at the same time hot and black. According to E. Deiss and G. Schikorr, the oxidizing action attributed to carbon dioxide is really due to the oxygen dissolved in the water. P. N. Raikow found that ferrous hydroxide reacts with carbon dioxide to form ferrous carbonate and hydrocarbonate. F. K. Cameron and W. O. Robinson also studied this reaction. H. C. Allen, and S. Miyamoto observed that ferrous hydroxide in a soln. of alkali hydroxide also reduces **nitrobenzene** to aniline at ordinary temp. E. J. Morgan and J. H. Quastel found that **methylene blue** is decolorized; and F. Feigl, that **benzidine** is not coloured blue by ferrous hydroxide. L. Cramer noted that **gelatin** is coagulated by ferrous hydroxide. C. C. Palit and N. R. Dhar studied the action of the hydroxide as a catalyst in the oxidation of **glycerol;** and N. R. Dhar, in the induced oxidation of fats, proteins, sugar, starch, formic acid, etc. C. H. Herty and co-workers studied the reaction between **silicon** and ferrous oxide, and found for the equilibrium constant, K, in the reaction $Si+2FeO\rightleftharpoons 2Fe+SiO_2$, $K=0{\cdot}000165$. W. A. Roth and co-workers determined thermochemically that in the reaction with **silica,** $2FeO+SiO_{2\,quartz}=Fe_2SiO_4+8{\cdot}1$ Cals. O. von Keil and A. Dammann, J. H. Whiteley and A. F. Hallimond studied the reaction with **silica.**

G. Grube and H. Gmelin found that by anodically polarizing iron in a 40 per cent. soln. of **sodium hydroxide,** and a low current density, in the absence of air, the iron goes into soln. as **sodium hypoferrite,** Na_2FeO_2. At higher temp. this forms ferrites and ferrate—*vide infra.* W. Biltz and co-workers prepared spinels with ferrous oxide and **alumina, ferric oxide,** or **chromic oxide.** J. H. Andrew and co-workers found that mixtures of **manganese oxide** and ferrous oxide form a complete series of solid soln. with a m.p. rising almost linearly from that of ferrous oxide at 1410° to that of manganese oxide at 1585°. The liquidus is within 20° of the solidus throughout the whole range.

According to A. Levol, **cupric hydroxide** and **cupric salts** are reduced by ferrous hydroxide. The reaction was studied by H. R. Ellis and W. H. Collier, F. Förster and V. Herold, H. Frischer, F. Herrmann, and T. S. Hunt. According to E. Müller and F. Kapeller, the reducing power of a soln. containing ferrous and ferric ions increases with the ratio $Fe^{\cdot\cdot}/Fe^{\cdot\cdot\cdot}$. For example, (i) Atmospheric oxygen does not oxidize an acid soln. of ferrous sulphate, but is quickly absorbed if an alkali is added. In the former, the ratio cannot much exceed 10^3, whereas in presence of normal alkali it is $1{\cdot}5\times10^{22}$, owing to the greater solubility of ferrous hydroxide. (ii) Soln. of ferrous sulphate and **cupric sulphate** do not react, but cuprous oxide is precipitated if potassium fluoride is added to the neutral mixture, and metallic copper if it is added to the acidic soln. In this case, the ratio is increased by the conversion of ferric ions into complex ions containing iron and fluorine. In neutral soln. the cuprous ions produced by the reduction separate as hydroxide, whilst in acidic soln., owing to the higher conc. reached, they yield metallic copper and cupric ions. (iii) The oxidation of hydriodic acid to iodine by ferric ions, $2\mathrm{I}'+2\mathrm{Fe}^{\cdot\cdot\cdot}=\mathrm{I}_2+2\mathrm{Fe}^{\cdot\cdot}$, is also reversed by the addition of potassium fluoride. R. C. Wells represented the main reaction between ferrous hydroxide and **cuprous salts** by $3\mathrm{FeO}+2\mathrm{CuCl}=2\mathrm{Cu}+\mathrm{Fe}_2\mathrm{O}_3+\mathrm{FeCl}_2$, especially when the cuprous salt is in excess; with a decrease in the latter, the reaction is $4\mathrm{FeO}+2\mathrm{CuCl}=2\mathrm{Cu}+\mathrm{Fe}_3\mathrm{O}_4+\mathrm{FeCl}_2$. The reaction $\mathrm{Cu}^{\cdot}+\mathrm{Fe}^{\cdot\cdot}\rightleftharpoons\mathrm{Cu}+\mathrm{Fe}^{\cdot\cdot\cdot}$ results in the separation of copper when the $\mathrm{H}^{\cdot}$-ion concentration $p_{\mathrm{H}}>5{\cdot}0$. H. Ost observed that ferrous hydroxide reacts with **magnesium chloride** to form ferrous chloride and magnesium hydroxide; and similarly with **magnesium sulphate;** but E. Deiss and G. Schikorr observed no reaction with magnesium sulphate. C. A. Graumann observed that a mixture of **zinc sulphide** and ferrous oxide, when heated, does not give off zinc vapour. C. W. Hempel found that ferrous hydroxide reduced **mercuric chloride** to mercurous chloride; H. Ost, that it forms aluminium hydroxide when added to neutral soln. of **alum**; E. Deiss and G. Schikorr, that **chromic hydroxide** is not reduced by ferrous hydroxide; and C. W. Hempel, that **platinum tetrachloride** is reduced to the metal.

§ 29. Ferrosic Oxide ; or Magnetic Oxide of Iron

The Chinese have been credited with knowing something about the magnetic needle so far back as 1100 B.C. In his *Περί λίθων*, written about 325 B.C., Theophrastus referred to the power of attraction which some stones—*e.g.* the *λίθος σιδηροναγοῦσα*—have for iron—*vide* the history of manganese ; and the subject was discussed by O. Lenz.[1] At the beginning of our era, Pliny, in his *Historia naturalis* (**36**. 25), discusses the mineral *magnes* which has the power of attracting iron ; and added that in Æthiopia, there is a mountain in which the stone *theamedes* is found ; this mineral repels and rejects iron. This report may be founded on the repulsive action of the like poles of two magnets. The property of polarity which distinguishes the *lodestone* (or *lòadstone*) is exceptional. Pliny also mentions the magnetic properties of the *siderites* or *herachion*. This mineral is also the *μαγνῆς λίθος*, mentioned by Dioscorides in his first-century work *Περί ὕλης ἰατρικῆς*. According to E. Wiedemann, the Arabian Abû Mûsa Gâbir ben Hajjan mentioned that a sample of magnetic iron ore lifted 100 dirhems of iron, but after it had stood for some time it could not lift 80 dirhems of iron. The Arabian, Al Dimaschque, also wrote on the subject about 1320. Magnetic iron ore was described by A. Aphrodisiensis, and the subject was discussed by M. Steinschneider, and V. Rose. It was called *Siegelstein* by G. Agricola ; the *minera ferri nigricans magneti amica*, or *magnet* of J. G. Wallerius ; the *minera ferri attractoria* of A. Cronstedt ; the *magnetischer Eisenstein* of A. G. Werner ; and the **magnetite** of W. Haidinger.

Analyses were reported by H. Arsandaux,[2] J. J. Berzelius, W. Bornhardt, A. Breithaupt, A. Cathrein, A. H. Chester, F. W. Clarke, E. Classen, C. Despretz, E. Dittler and H. Hueber, J. N. von Fuchs, J. L. Gay-Lussac, F. F. Grout and T. M. Broderick, B. J. Harrington, M. F. Heddle, T. H. Holland, E. Hugel, C. J. B. Karsten, A. Knop, F. von Kobell, G. A. Koenig, A. Lacroix, S. M. Losanitsch, D. Lovisato, G. W. Maynard, J. A. Michaelson, W. G. Miller, T. Nordström, G. Nyiredy, T. Petersen, W. B. Phillips, F. J. Pope, C. F. Rammelsberg, L. Ricciardi, F. Scafile, B. Schwalbe, E. Sochting, J. del Pan, A. Stanojevic, J. Thiel, G. P. Tschernik, J. H. L. Vogt, T. L. Walker and A. L. Parsons, C. H. Warren, M. Weibull, and F. Zambonini. The results are, in the main, in agreement with the formula of *iron tritatetroxide*, or **ferrosic oxide,** Fe_3O_4, or $FeO.Fe_2O_3$, for the idealized mineral. The *ferropicotite* of A. Lacroix, found in Madagascar, has the composition $(Fe,Mg)O.(Al,Fe)_2O_3$. F. von Sandberger reported either stannous or stannic oxide in the magnetites of Hirschberg. Manganous oxide may be present, and M. Weibull writes the formula $(Fe,Mn)O.Fe_2O_3$; some magnesia and alumina were found by A. Knop to be associated with the mineral thus making the formula $(Fe,Mg)O.(Al,Fe)_2O_3$; and for the chromiferous varieties described by A. Cathrein, $FeO.(Fe,Cr)_2O_3$; while the titaniferous varieties may have $FeTiO_3$ or $MgTiO_3$ in solid soln. with Fe_2O_3; but, as shown by W. B. Phillips, magnetite exhibits a wide variation in composition, for the extremes in 30 analyses were:

	Fe as FeO	Fe as Fe_2O_3	$FeO : Fe_2O_3$
Magnetite (ideal) . . .	24·11	48·29	1 : 2·00
Octahedra from Vogelsberg . .	39·85	15·22	1 : 0·38
Sheperd Mt., Missouri . . .	1·36	63·95	1 : 47·02

T. L. Walker found the dominant mineral in loadstone from Bon Accord, Transvaal, to be $(Fe,Ti)_2O_3$. J. D. Dana classed the magnetites as (1) ordinary massive, crystalline or sandy magnetites; (2) magnesian magnetites; (3) niccoliferous magnetites; (4) titaniferous magnetites; (5) manganesian magnetites; and (6) ochreous magnetites. W. N. Hartley and H. Ramage observed the presence of sodium, potassium, rubidium, silver, copper, gallium, manganese, lead, and nickel.

The existence of ferrosic oxide as a chemical individual was demonstrated by J. L. Gay Lussac, and J. J. Berzelius. J. L. Gay Lussac regarded it as a particular stage in the oxidation of iron, but J. Dalton, and J. J. Berzelius considered it to be a compound of ferrous and ferric oxides. The graphic formula is usually based on the assumption that the oxide contains both ferric and ferrous iron, as is exemplified by the presence of both salts of iron when ferrosic oxide is dissolved in acids. The graphic formula is $O{=}Fe{-}O{-}Fe{-}O{-}Fe{=}O$, or $Fe(FeO_2)_2$. S. H. Emmens, and W. G. Brown preferred formulæ in which the iron atoms were supposed to be quadrivalent. The formula $Fe(FeO_2)_2$ agrees with the spinel structure deduced by M. L. Huggins from the space-lattice.

According to S. Hilpert, the formation of the magnetic ferrosic oxide from non-magnetic, hydrated ferrous and ferric oxides shows that the magnetic property lies primarily in the combination of the two—where ferric oxide acts as an acid anhydride, and ferrous oxide as a base. This makes magnetic ferrosic oxide a **ferrous ferrite,** $Fe(FeO_2)_2$, *i.e.* a member of the family of spinels. That the magnetic property depends on the acidic property of the ferric oxide is shown by the fact that the ferrous oxide can be replaced by cupric, cobaltous, calcium, barium, and potassium oxide to form magnetic ferrites—*vide infra.* Indeed, cupric ferrite, $(CuO)^+(Fe_2O_3)^-$, is as strongly magnetic as $(FeO)^+(Fe_2O_3)^-$. It is possible to oxidize magnetite to magnetic ferric oxide; but in the compound $FeO.Fe_2O_3$, only the ferrous iron can be oxidized to furnish $(Fe_2O_3)^+(2Fe_2O_3)^-$, or *ferric orthoferrite,* $Fe^{\cdots}(FeO_3)^{\cdots}$, and this red powder is the true magnetic ferric oxide (*q.v.*). The cobalt ferrite, $(CoO)^+(Fe_2O_3)^-$, can be similarly oxidized to $(Co_2O_3)^+(2Fe_2O_3)^-$. O. Mügge's study of the reduction products of hæmatite and the oxidation products of magnetite led him to suggest that magnetite is a solid soln. of ferric oxide in the cubic form of ferrous oxide; and this view is favoured by A. Gawalowsky, and K. Hofmann. A. Krause and J. Tulecki obtained magnetic ferrous ferrite, at 18°, (i) by adding ammonia to an acid soln. of ferrous chloride containing meta ferric hydroxide in suspension; and (ii) by adding ammonia to a mixed soln. of ferrous and ferric chlorides. The latter varied in composition owing to oxidation, and contained more water than the former; the former approximated closely to $Fe(FeO_2)_2-\frac{1}{2}H_2O$.

S. Breislak,[3] J. J. Ferber, C. W. C. Fuchs, F. Galiani, G. Gioeni, P. Groth, A. Johnsen, A. Lacroix, T. Monticelli and N. Covelli, L. Pilla, S. C. Ponte, J. S. Presl, C. F. Rammelsberg, A. Scacchi, G. Strüver, D. F. Wiser, and F. Zambonini found that magnetite occurs as a sublimation product in the lava of Vesuvius and Etna. J. H. L. Vogt regarded magnetite as a product of magmatic differentiation; thus, J. Morozewicz observed that in artificial magmas, magnetite is easily formed when the proportion of silica is low, for any iron in excess of that needed to combine with silica is liable to be deposited as magnetite. The order of its separation with respect to other minerals is not invariable. Magnetite, like other spinels, may be formed by the breaking down of other minerals, or by reactions between them; *i.e.* magnetite may be a product of contact metamorphism. Thus, C. Doelter obtained it by fusing various rocks with limestone; the fusion of acmite furnishes magnetite and a glass; and glaucophane gave a mixture in which magnetite occurred. The fusion of biotite, and microcline gave F. Fouqué and A. Michel-Lévy magnetite, leucite, and olivine; J. Lenarcic found magnetite in the mass produced by fusing a mixture of leucite and augite, but when magnetite is dissolved by fused labradorite, augite is formed. C. F. W. A. Oetling found it in the products of the fusion of felspathic basalt. M. Vucnik, and B. Vukits found magnetite among the products of mixtures of anorthite and hedenbergite, albite and hedenbergite, olivine and augite, elæolite and augite, and elæolite and diopside. This subject was discussed by H. L. Alling, A. Bauer, R. Beck, G. Berg, K. Bogdanovich, K. Busz, R. A. Daly, O. A. Derby, S. Foslie, P. Geiger, V. M. Goldschmidt, V. Hämmerle, A. G. Högbohm, E. Hussak, E. P. Jennings, H. E. Johannson, J. F. Kemp, T. Kjerulf, L. de Launay, W. Lindgren, G. Medanich, K. Petrasch, H. Sjögren, R. B. Sosman, A. C. Spencer, O. Stutzer, A. E. Törnebohm, H. S. Washington and E. S. Larsen, and G. H. Willams, etc. According to F. W. Clarke, magnetite occurs as an accessory mineral in rocks of all classes, and it sometimes forms the principal constituent. It is most abundant in rocks rich in ferromagnesian minerals—*e.g.* the norites, diabases, gabbros, or peridotites; but it may be also associated with nepheline rocks and anorthites. In many cases it forms large ore masses which are highly titaniferous; indeed, some ores shade by imperceptible graduations into ilmenite with over 40 per cent. of titanic oxide; they frequently contain spinel, and corundum. The magnetite-ilmenite ores were studied by S. Brunton, F. F. Osborne, P. Ramdohr, G. M. Schwartz, M. Kamiyama, J. T. Singewald, and C. Warren.

In many cases, magnetite is not of direct igneous origin. H. Rösler observed it in clay deposits from rivers and seas. C. R. van Hise found it associated with grünerite and actinolite in the slates and cherts in the great iron deposits of Lake Superior region, and the adjacent parts of Michigan, Wisconsin, and Minnesota. The magnetite of the Mesabi district is, according to C. K. Leith, derived from the leaching of a hydrated iron silicate which he called *greenalite*. C. W. von Gümbel, and L. W. Collet and G. W. Lee observed magnetite in the freshly formed sediments at the bottom of the sea. The mineral *itabirite* (*vide* ferric oxide) is thought by E. Hussak to have been formed as a chemical sediment. Observations on the formation of magnetite in this way were made by K. Bogdanovich, F. F. Osborne, P. Krusch, R. Brauns, J. Ahlburg, G. Rose, etc. The formation of magnetite in colloidal soln. has been discussed by G. Berg, K. C. Berz, S. Hilpert, and H. Stremme. C. R. van Hise also added that magnetite may be formed from marcasite and pyrite, and from the oxidation of siderite, and by further oxidation, it may pass into hæmatite and limonite, and through the agency of carbonated waters, transformed back into siderite. L. de Launay discussed the reduction of hæmatite to magnetite by the reducing action of bituminous substances associated with quartz veins at Grängesberg, Sweden. A. J. Moses described magnetite pseudomorphs after hæmatite; and E. Döll, after breunnerite; E. L. Perry, after chrysotile; and A. Liversidge found magnetite present in many minerals and rocks.

The occurrence of magnetite as an inclusion in meteorites was reported by J. Antipoff,[4] J. J. Berzelius, A. Brezina, S. Cloez, E. Cohen, A. Damour, A. Daubrée, J. M. Davison, C. G. Ehrenberg, E. E. Howell, A. Krantz, S. Meunier, C. F. Mohr, J. Murray and A. F. Renard, F. Pisani, G. vom Rath, C. von Reichenbach, G. Rose, C. U. Shepard, G. Tschermak, and G. H. F. Ulrich. Magnetite also occurs in some atmospheric dusts.

Magnetite, ferrosic oxide, or *pierre d'aimant*, may be formed as an accidental product in industrial processes or products. Thus, it forms a large proportion of the *smithy scale* or *iron scale* of the blacksmith. G. E. Allan and J. Brown [5] assume that the seat of the magnetization in the case of the created ore, etc., is ferrosic oxide. E. L. Perry observed fibrous magnetite formed after chrysotile on Casper Mountain, Wyoming. J. F. L. Hausmann observed magnetite formed in the masonry of a lead furnace at Goslar; A. Laurent, in an iron furnace at Châtillon-sur-Seine; H. Wieser, in a blast-furnace at Plons; G. M. Schwartz, in iron ores that had been sintered; J. B. J. D. Boussingault, in a roasting furnace for iron ores at Rio (Pyrenées-Orientales); J. F. L. Hausmann, F. Sandberger, and T. Scheerer, in the sole of a puddling furnace; and A. Krantz, A. Lacroix, and H. von Dechen, in the *débris* from fires at Hamburg, etc. W. G. Müller, and J. Spiller observed it in crystals among the iron residues obtained in the reduction of nitrobenzene to aniline; R. Kattwinkel, in steam-pipes 20 years old; C. F. Rammelsberg, in the sulphate pan of a Leblanc soda works; E. Svalander and J. Landin, in an iron pan used for heating a mixture of sodium chloride and hydrosulphate; J. H. L. Vogt, at the bottom of a converter smelting copper ore; F. K. L. Koch found that iron plates laid beneath the hearths of iron-smelting furnaces and exposed to a red-heat are in the course of 6 or 10 years completely converted by the moisture of the soil into magnetic oxide, partly crystalline and partly amorphous. The same compound is said to be formed on the under-side of refining hearths where the iron comes in contact with water vapour—*vide supra*, the composition of rust. A. Laurent and C. Holms observed that on the hearths of puddling furnaces there is formed a mixture of ferrous silicate and magnetic oxide; and the latter crystallizes in geodes in regular tetrahedra, truncated octahedra, and rhomboidal dodecahedra. J. H. L. Vogt observed that magnetite occurs in furnace slags; E. Keller, in blast-furnace and reverberatory furnace mattes; M. Faraday, in pottery; P. P. Sustchinsky, in porcelain from Carlsbad; J. W. Mellor, in bone-china; and A. Hopwood, in fired clay-ware. R. Boyle observed that fired bricks are magnetic, and if the red-hot brick be allowed to cool in the same position it becomes magnetized in the same direction as the earth's magnetic field; and J. B. Beccaria also observed that bricks or ferruginous stones struck by lightning become permanently magnetized in the same direction as the earth's magnetic field. G. Gherardi also established the existence of a permanent magnetism in all kinds of ancient and modern clay-wares, and showed that edifices made from magnetic bricks must have an influence on measurements of terrestrial magnetism, a subject studied by J. Lamont, F. Kohlrausch, R. W. Wilson, and C. C. Marsh. G. Folgheraiter said that the various clay-wares found in excavations and ancient tombs afford an indelible record of the state of the earth's magnetism at the epoch and place of manufacture, and thereby furnish an indirect means of measuring the secular variation of the magnetic inclination of the earth since the clay-wares were manufactured. Observations on this subject were made by O. A. Gage and H. E. Lawrence, F. Pockels, B. Brunhes and P. David, and P. L. Mercanton.

The preparation of ferrosic oxide.—According to E. Mitscherlich,[6] in the rapid combustion of iron, either in oxygen or air, ferrosic oxide is formed. When iron is heated to dull redness in air it acquires a thin film which has successive shades of yellow, red, blue, and grey; and the analyses of R. Akermann and C. G. Sarnström, A. Laurent, and J. F. L. Hausmann gave for the product $FeO.Fe_2O_3$. R. Ruer and M. Nakamoto found that when ferric oxide is heated in nitrogen for a long time at 1150°, the product is ferrosic oxide with 2 per cent. of dissolved ferrous oxide; and when the ferric oxide is melted at 1550°, the product is ferrosic oxide with 4 per cent. of dissolved ferrous oxide. P. Ramdohr discussed this reaction. According to C. G. Mosander, the outermost layer of the scale formed when iron is heated in air, is ferrosic oxide, but within, the composition approximates $Fe_3O_4.nFeO$. The skin of oxide which is formed may be detached by bending or hammering the cold metal, or by plunging the hot metal into cold water. The product is called *hammer-slag*, *iron scale*, or *scaly iron*. The scale formed in the steel-rolling mills is called *roll scale*. C. G. Mosander found the external layer in one case approximated to $FeO.Fe_2O_3$, and the inner layer to $6FeO.Fe_2O_3$. If the oxidation be allowed to continue, the ferrosic oxide forms ferric oxide. Thus, J. Percy found the outermost layer in one case approximated Fe_2O_3; in the middle layer, $7FeO.3Fe_2O_4$; and the inner layer, $5FeO.Fe_3O_4$. F. S. Barff applied rust-protective coatings to iron by exposing the surface of iron at about 730° to the action of steam for several successive 1-hour treatments with intermediate cooling in air. R. M. Bozorth obtained X-radiograms of the products. He found three layers containing three oxides in the following sequence and thickness: Fe_2O_3, $0{\cdot}2\mu$; Fe_3O_4, $2{\cdot}0\mu$; and FeO, $97{\cdot}8\mu$. P. P. Fedotéeff examined the structure of the same protective coating produced at 1000° to 1100°. Octahedral crystals with deep, etched pits were observed, but no layer formation could be detected. The layer of oxide was optically homogeneous, though chemically it was richer in ferrous oxide next to the metal. L. B. Pfeil observed that when iron and steels are oxidized at a red-heat in air, the scale which is formed normally contains three layers: (i) an outer layer mainly ferric oxide—about 70 per cent. ferrosic oxide and 30 per cent. of ferric oxide; (ii) a middle layer with ferrous and ferric oxides in the proportion 3 : 1; and (iii) an innermost layer mainly ferrous oxide—*vide supra*, the corrosion of iron.

The oxide coatings produced by F. S. Barff, and G. Bower for the protection of iron and steel from rusting, were discussed by J. Percy, G. W. Maynard, S. Cornell, P. Askenasy, Simson and Co., R. Kattwinkel, R. Stumper, B. H. Thwaite, C. Platt, G. Weigelin, W. E. Ruder, A. H. Sang, P. S. Brown, and M. Matwéeff. Other ways of producing the oxide coating have been suggested—*e.g.* by the action of carbon dioxide at an elevated temp. (G. and A. S. Bower, Western Electric Co., and G. R. Tweedie); by treating the metal with a bath of fused alkali (M. Honigmann); immersion in a bath of fused alkali nitrate with or without manganese dioxide (W. B. Greenleaf, C. S. A. Tatlock, and E. Blassett); and by anodic oxidation in alkali-lye (A. de Méritens, and L. Revillon).

According to K. A. Hofmann, in the oxidation of iron, a layer of ferric oxide is first formed on the surface; the adjacent iron then acts as a reducing agent, causing a graduation from ferric oxide through a zone of magnetic iron oxide and ferrous oxide to an underlying layer of metallic iron. The finer the grain-size, and therefore the greater the free surface area, the higher the proportion of ferric oxide in the product. Iron containing finely disseminated ferric oxide gave a pyrophoric product after a short reduction in hydrogen below 600°. Exothermic absorption of oxygen on the surface of this material in air causes a rise of temp. proportional to the ratio surface : mass. Spontaneous combustion takes place if this ratio is sufficiently large. The pyrophoric property is removed by heating for a long time, or at a high temp. in an inert atmosphere. P. Oberhoffer and K. d'Huart regarded hammer-slag as a mixture of ferrous and ferric oxides which approximated Fe_3O_4; but P. Oberhoffer also suggested that it might be a solid soln. of ferrous and ferric oxides.

Observations *sur les battitures de fer* were also made by P. F. G. Boullay, G. Bower, and P. Berthier, who gave for its composition $4FeO.Fe_2O_3$; J. W. Döbereiner, who gave $3FeO.Fe_2O_3$; and M. Beaujeu and C. Méne, who gave Fe_8O_9 and $Fe_{11}O_{12}$. E. J. Maumené gave $20FeO.9Fe_2O_3$, *i.e.* $Fe_{38}O_{47}$, which is very near Fe_3O_4. H. Chandra, A. Kaufmann and F. Haber described a bluish-black oxide of the composition $2FeO.3Fe_2O_3$, or Fe_8O_{11}, obtained by the action of potassium nitrate on a boiling soln. of ferrous sulphate rendered alkaline with ammonia; and H. Chandra, and O. Hauser obtained a $4FeO.Fe_2O_3$ by dehydrating the hydrate (*q.v.*). E. J. Kohlmeyer also obtained indications of the formation of $FeO.3Fe_2O_3$; $3FeO.5Fe_2O_3$; and $3FeO.4Fe_2O_3$; and complex products were obtained by H. Wicht—*vide infra*, solid soln. of ferric oxide and ferrous oxide—but R. Ruer and M. Nakamoto, and A. Simon and T. Schmidt could not confirm this. H. St. C. Deville considered that the oxide $FeO.Fe_3O_4$, or rather Fe_4O_5, is formed when steam acts on iron at an elevated temp.; but P. P. Fedotéeff and T. N. Petrenko showed that at 1000° to 1100°, the oxidation with steam or carbon dioxide proceeds $Fe \rightarrow FeO \rightarrow Fe_3O_4$; and with mixtures of steam and air, $Fe \rightarrow FeO \rightarrow Fe_3O_4 \rightarrow Fe_2O_3$. F. Wüst obtained $2FeO.Fe_2O_3$ by heating ferric oxide in vacuo at 1100°; and $3FeO.Fe_2O_3$, at 1200°. J. W. Döbereiner heated ferrous carbonate and obtained $3FeO.Fe_2O_3$; E. Glasson, $4FeO.Fe_2O_3$; and J. N. von Fuchs, A. Knop, and C. F. Rammelsberg, $5FeO.2Fe_2O_3$; whilst from the oxalate, C. F. Rammelsberg obtained $4FeO.Fe_2O_3$. The physical properties of these mixtures or solid soln. were examined by G. K. Burgess and P. D. Foote, E. Greulich, S. Hilpert and J. Beyer, R. B. Sosman and J. C. Hostetter, and H. Wicht. Analyses of mill scale were reported by A. Ledebur.

What was formerly called anhydrous *æthiops martialis*, or *l'oxyde de fer noir*, or *black oxide of iron*, approximates to ferrosic oxide, and was prepared by the incomplete oxidation of iron by air or steam. F. Küspert described a demonstration experiment for the combustion of iron in oxygen. Near the beginning of last century, ferrosic oxide was prepared by oxidizing iron in air by J. L. Gay Lussac, F. Stromeyer, and H. Davy. J. J. Berzelius showed that ferric oxide dissociates forming ferrosic oxide when it is heated, so that ferrosic oxide is formed when iron is heated in air at a high enough temp. even if ferric oxide were first produced. O. Bauer and E. Deiss, and A. Kropf said that the principal product obtained by burning iron in oxygen is ferric oxide; most others say ferrosic oxide. E. Mitscherlich obtained ferrosic oxide in octahedral crystals by burning iron in a blast-flame. W. G. Mixter, and W. A. Roth observed that the conversion of iron into ferrosic oxide is not complete when iron burns in oxygen, even at 12 to 15 atm. press. When the non-oxidized iron is removed by a magnet, W. G. Mixter obtained a product approximating Fe_3O_4. H. Wicht found that the fused product obtained by burning iron in oxygen has 2·5 to 10 FeO, Fe_2O_3; A. Mittasch's product with oxidizing gases under press. was Fe_3O_4; R. W. G. Wyckoff and E. D. Crittenden's product approximated Fe_3O_4; and E. Deiss and H. Leysaht added that with the slow combustion of iron in oxygen, ferric oxide is formed, and with rapid combustion, ferrosic oxide.

F. Bergius found that the reaction between iron and liquid water under press. furnishes ferrosic oxide in a form which is easily reduced; and E. V. Shannon regarded magnetite as a transient intermediate and unstable stage in the atmospheric oxidation of meteoric iron to limonite; and A. Payen, H. Ost, N. J. B. G. Guibourt, A. Ackermann, E. Deiss and G. Schikorr, and J. Huggett observed its formation in the earlier stages of the rusting of iron in aerated water. According to J. L. Gay Lussac, and C. Despretz, red-hot iron in contact with steam forms hydrogen and ferrosic oxide. Red-hot iron filings repeatedly sprinkled with water also yield the black oxide. Unlike C. N. A. de Haldat du Lys, H. V. Regnault found that the oxidation of heated iron by steam does not progress farther than ferrosic oxide. J. A. N. Friend and co-workers found that when iron is heated in steam to 820° to 950°, it acquires a film of magnetic oxide, and the layers underneath contain various proportions of ferrous oxide associated with the magnetic oxide in solid soln. If the iron is in thin sheets, the product, with a prolonged heating in steam, is all ferrosic oxide. S. Hilpert and J. Beyer observed that the composition of the oxide so obtained is variable; thus, if ferric oxide be heated to 700°, in a current of hydrogen, sat. with water vapour at 30°, contains 85 per cent., and at 800°, 92 per cent. of ferrous oxide. P. P. Fedotéeff and T. N. Petrenko added that ferrous oxide is first formed and that a continuous series of solid soln. is formed; and that the end-product of the reaction at 1000° to 1100° is ferrosic oxide. G. Chaudron observed that below 570° the reaction is $3Fe+4H_2O \rightleftharpoons Fe_3O_4+4H_2$; and above 570°, ferrous oxide is first formed: $Fe+H_2O \rightleftharpoons FeO+H_2$, and then ferrosic oxide: $3FeO+H_2O \rightleftharpoons H_2+Fe_3O_4$. H. Moissan found that when iron is heated to dull redness in a current of hydrogen, saturated with steam at 90°, ferrosic oxide is formed.

The equilibria between ferrosic oxide in the presence of carbon monoxide and carbon dioxide, and in the presence of hydrogen and water vapour, have been discussed previously in connection with ferrous oxide and with the reactions in the blast-furnace; likewise also the range of stability has been discussed in connection with ferric oxides. H. Moissan showed that if reduced iron is heated to 440° in a current of carbon dioxide, ferrosic oxide is produced. J. Donau observed that if iron wire be heated to 1200° in a current of carbon dioxide, crystals of ferrosic oxide exhibiting magnetic polarity are formed; the presence of moisture facilitates the formation of large crystals. P. P. Fedotéeff and T. N. Petrenko obtained similar results with carbon dioxide as were obtained with steam at 1000° to 1100°. G. Chaudron represented the reaction below 570° by $3Fe+4CO_2 \rightleftharpoons Fe_3O_4+4CO$; and above that temp. ferrous oxide is first formed: $Fe+CO_2 \rightleftharpoons FeO+CO$, and this product is subsequently oxidized to ferrosic oxide: $3FeO+CO_2 \rightleftharpoons Fe_3O_4+CO$. The range of stability of the phases FeO, and Fe_3O_4 in the system: C–O–Fe has been previously discussed. G. Lepetit obtained ferrosic oxide by the action of a 3 : 1 mixture of carbon dioxide and carbon monoxide on iron at 700° and 720° at a press. of one to one-third atm.

Iron can be oxidized to ferrosic oxide by other oxidizing agents. L. N. Vauquelin, E. J. Kohlmeyer, and C. F. Bucholz prepared ferrosic oxide by heating to a high temp. an intimate mixture of powdered iron and ferric oxide tightly packed in a closed crucible. According to J. Percy, the magnetic oxide is formed by boiling an excess of iron filings with water and freshly precipitated, undried, hydrated ferric oxide. The water is decomposed with the evolution of some hydrogen, and the boiling is continued until sufficient ferrous oxide has been formed to convert the ferric oxide into the magnetic oxide. W. Spring exposed a mixture of iron and ferric hydroxide to a press. of 1000 to 1200 atm. and obtained evidence of the formation of ferrosic oxide. W. Bruhns heated a mixture of finely powdered iron and amorphous titanic oxide with hydrofluoric acid at 270° to 300° for 24 hrs. Numerous plates of ilmenite and octahedra of magnetite were formed. C. Doelter obtained the crystals without the fluoride. E. Weinschenk added iron to an ammoniacal soln. of copper oxide, and heated the mixture to 151°, in a sealed tube, for 6 hrs. S. Laszczynsky oxidized iron by heating it in a bath of chlorates or perchlorates; and W. B. Greenleaf, C. S. A. Tatlock, and E. Blassett, by heating it in a bath of alkali nitrate- -W. Vaubel found that ammonium nitrate also converts iron into ferrosic oxide—*vide supra*, the production of an oxide coating to protect iron from rusting. A. Gorgeu prepared magnetite by adding iron to molten iron sulphate; it is said that the sulphate acts catalytically, being alternately reduced to sulphite by the iron and oxidized to sulphate by the oxygen of the atmosphere. Instead of iron, iron sulphide can be used, and instead of iron sulphate, alkali sulphate or sulphide, or sulphur can be used. F. Martin and O. Fuchs obtained ferrosic oxide by heating iron with sulphates of the alkaline earths; and K. A. Hofmann and K. Höschele by heating iron with magnesium chloride in a weakly reducing atmosphere.

The formation of ferrosic oxide in the reaction: $4FeO=Fe+Fe_3O_4$ observed by G. Chaudron to occur below 570° has been discussed in connection with ferrous oxide. It is also formed by treating ferrous oxide by processes employed for converting iron into ferrosic oxide. H. V. Regnault, and C. R. A. Wright and A. P. Luff obtained ferrosic oxide by the oxidation of hammer-slag, and roll-scale. It was also obtained by F. Wöhler by heating the hydrate, $Fe_3O_4.H_2O$, in a closed vessel, and by H. Moissan at a temp. of 300° in an indifferent gas. T. Sidot observed that octahedral crystals of ferrosic oxide are produced when ferric oxide is heated for a long time at a high temp., but not sufficient to fuse the oxide, and he added that the product exhibits magnetic polarity if the tube containing the oxide be placed in the earth's magnetic meridian. According to A. Simon and T. Schmidt, in the decomposition of ferric oxide at a constant press. of 10 mm., the isobar for the decomposition has a sharp break at 1300°, corresponding with the complete conversion of ferric to ferrosic oxide, without the formation of any solid soln., or intermediate oxide. The X-radiograms of ferric oxide were of an unknown type; those of ferrosic oxide, of the spinel type; and those of partially decomposed ferric oxide corresponded with a mixture of ferric and ferrosic oxides, and included no other lines. G. Rose obtained ferrosic oxide by heating ferric oxide with borax in a reducing flame; H. V. Thompson, by heating ferric oxide with an excess of sodium chloride for several hours; K. A. Hofmann and K. Höschele, by heating ferric oxide with magnesium chloride in a weak reducing atmosphere; F. Knapp, by heating 40 per cent. of ferric oxide with glass as a flux, and subsequently removing the glass by treatment with hydrofluoric acid; and E. Weinschenk, by strongly heating a mixture of ferric oxide, ammonium chloride and sulphur—if the temp. be not high enough, iron disulphide is produced. According to O. Mügge, and A. A. Read, when ferric oxide is maintained at 1500° in nitrogen, or, according to H. Moissan, if it be heated in the electric furnace, in air, it is converted into magnetite. H. Wicht said that the product obtained by fusion varies in composition between FeO and Fe_2O_3. H. Moissan thought that ferrosic oxide represents a definite stage in the reduction of ferric oxide or its hydrate at 350° to 400° in hydrogen, but, as shown in connection with ferrous oxide, the reduction is a continuous process. H. Moissan stated that if ferric oxide is heated to dull redness in hydrogen, saturated with water vapour at 90°, ferrosic oxide is formed. S. Hilpert and J. Beyer recommended heating the ferric oxide at 400° in hydrogen, saturated with water vapour at 50°, and so arranged that the gas and vapour passes over a heated copper spiral before it passes over the ferric oxide. H. Moissan heated, at 420°, ferric oxide in carbon monoxide and obtained ferrosic oxide; G. Lepetit preferred a 1 : 3-mixture of carbon monoxide and dioxide at 700° to 720° and at one to one-third atm. press. R. Schenck, and A. Laurent obtained ferrosic or ferrous oxide by a similar process. H. R. Gregory and G. MacDonald used producer gas; and K. Elbe, and S. Lilja, organic residues from distillation processes. L. de Launay obtained impure ferrosic oxide by heating in a sealed tube, at 250°, a mixture of ferric oxide and petroleum.

J. Durocher prepared ferrosic oxide by heating to redness a mixture of ammonium carbonate and ferrous chloride—some hæmatite is also formed; H. St. C. Deville and H. Caron, by melting iron fluoride and boric acid in a platinum crucible suspended above the fluoride, and all contained in a hermetically sealed carbon crucible; H. St. C. Deville, by passing hydrogen chloride over ferrous oxide heated at a high temp.; J. L. Gay Lussac, F. Stromeyer, A. Gautier, and E. A. Parnell, by passing steam over ferrous chloride at a dull red-heat; and A. Gorgeu, by heating molten ferrous chloride to bright redness in an incompletely closed crucible; J. von Liebig and F. Wöhler obtained the magnetic oxide as a heavy, black powder by fusing in air a mixture of ferrous chloride at a low red-heat with dry sodium carbonate and extracting the sodium carbonate with water. C. von Hauer obtained ferrosic oxide by heating to redness ammonium ferrous chloride, and also by passing a mixture of air and steam over heated ferrous chloride; E. Stirnemann, by the action of the vapour of ferric chloride and water on heated china clay, or a mixture of silica, sodium aluminate, and calcium carbonate; or, by heating in a bomb for 12 hrs., at 570° to 580°, a mixture of ferrous and ferric chlorides and water (5 : 8 : 2); and M. Kuhara, by boiling a soln. of ferrous chloride, in the absence of air, for many hours along with finely powdered calcspar, siderite, pyrites, or iron silicate—if some ferric chloride be also present, some hæmatite is formed. R. Klemm could not verify this.

J. S. C. Wells found that at 200°, precipitated iron sulphide forms a mixture of ferrosic and ferric oxides. H. V. Regnault found that when steam is passed over red-hot iron sulphide, ferrosic oxide is formed, and A. Gautier showed that the reaction in a closed vessel is reversible : $3FeS+4H_2O \rightleftharpoons Fe_3O_4+3H_2S+H_2$. According to W. S. Millar, iron sulphides are oxidized to ferrosic oxide when heated in sulphur dioxide. According to A. Gorgeu, iron sulphides act energetically on fused alkaline sulphates, with evolution of a large quantity of sulphur dioxide, and ultimate formation of magnetite and an alkaline sulphate. The alteration in weight is due to the loss of the sulphur originally present in the sulphide, and the absorption of 1·33 times its weight of oxygen by the iron in the sulphide. The yield is better the greater the intermediate formation of a double alkaline ferrous sulphide, and is best of all when a mixture of sodium sulphide and sulphite is used instead of the sulphate. F. Kuhlmann obtained ferrosic oxide by heating calcium chloride and ferrous sulphate in a closed crucible.

H. Moissan obtained ferrosic oxide by heating ferrous carbonate slowly in a current of nitrogen, or carbon dioxide at dull redness—if heated rapidly some ferrous oxide is produced. F. Duffschmid added that the composition of the product varies from $3{\cdot}2FeO.Fe_2O_3$ to $3{\cdot}5FeO.Fe_2O_3$. A. Gautier obtained ferrosic oxide by heating siderite to dull redness in a current of steam ; and H. Krämer, by heating the siderite in a mixture of 2 vols. of carbon dioxide and 1 vol. of carbon monoxide. L. H. Twenhofel observed that when ferric oxalate is heated to 550° in a current of carbon dioxide, ferrosic oxide is formed ; and K. A. Hofmann and K. Schumpelt, likewise obtained it by heating ferric formate at 150° in a rapid current of moist carbon dioxide. T. Ishiwara observed the formation of magnetite in the oxidation of iron carbide, Fe_3C. W. Ipatéeff and N. Kondyreff obtained crystals of ferrosic oxide by the action of hydrogen at 250° and 135 atm. press. on a soln. of ferrous cyanide—if ferrous formate or acetate is used, much ferric oxide is also formed ; W. Ipatéeff and A. Kisseleff also obtained ferrosic oxide with soln. of potassium ferrocyanide or ferricyanide at 350°, and 200 atm. press. ; and with ferrous sulphate soln. at 330°, and 200 atm. press. ; but with soln. of ferrous nitrate, ferrosic and ferric oxide were produced in proportions dependent on the temp., press., and time of action. Water gas at 330 atm. press. forms magnetite when its acts on a soln. of ferrous acetate at 350° to 360°.

H. Debray obtained crystals of magnetite by heating to redness a mixture of ferric phosphate with 3 to 4 parts of potassium or sodium sulphate. H. Grandeau added that a temp. of 1400° to 1500° is necessary for the development of the crystals ; if the temp. is too low, a complex alkali ferric phosphate is formed. M. Schläpfer obtained magnetite in his experiments on the hydrothermal decomposition of the calcium carbonate with iron silicate, and slowly cooling the mass ; and A. Gautier, and A. Brun, by heating iron silicates at 750° to 800° in a current of steam. F. Fouqué and A. Michel-Lévy, H. Andesner, F. Angel, K. Bauer, C. Doelter, W. Hämmerle, G. Medanich, J. Morozewicz, K. Petrasch, H. H. Reiter, J. H. L. Vogt, and M. Vucnik obtained magnetite by melting ferruginous silicates—*vide supra.*

R. Phillips found that if a mixture of ferrous sulphate and sodium carbonate be treated with sufficient potassium chlorate added all at once, hydrated ferric oxide is formed, but if added in small portions at a time, the black ferrosic oxide is formed and is not affected by subsequent addition of the chlorate. W. Gregory found that when a soln. of ferrous sulphate is divided into two equal parts, and one part is oxidized and mixed with the other, and both precipitated from the boiling soln. by ammonia, a black, highly magnetic oxide is formed—*vide infra,* hydrated ferrosic oxide. J. Attfield described a similar process. In C. F. Wülfing's process, as described by F. J. R. Carulla, some ammonia is added to a ferrous liquor

– say, waste liquor used for pickling iron—and air is blown into the mixture to oxidize the lower oxide. More ammonia is added to decompose completely the ferrous salt in soln., and the combination of the two oxides is brought about by means of heat and steam, or air press. The product is used as a magnetic oxide paint for protecting iron from corrosion. According to F. A. Abel and C. L. Bloxam, when ammonia is added to a soln. of a ferrous salt, a white precipitate is formed if air be excluded; in contact with air, the precipitate becomes bluish-green, dark green, and finally black. In this state the precipitate is insoluble in water. If a mixture of ferrous and ferric salts be similarly treated, two distinct precipitates are formed, namely, the bluish-white ferrous hydroxide, and the brown ferric hydroxide. On standing for a short time, or on boiling, a reaction takes place between the two hydroxides, and one of the magnetic oxides results. S. Hilpert said that it is impossible for the two precipitates in such a mechanical state of division to react with one another. For a reaction to take place, one of them must be dissolved. Ferric hydroxide is insoluble in water and in soln. of ammonium salts, but ferrous hydroxide is easily soluble in an excess of ammonium salt. The combination of the two hydroxides is therefore brought about by the precipitated ferrous hydroxide dissolving, and in this state penetrating and diffusing through the ferric hydroxide. The combination occurs slowly if there is no great excess of the ammonium salt, but with much greater rapidity in the presence of a considerable excess. If the precipitation is made in a conc. soln. of ammonium chloride, only ferric hydroxide is precipitated, but this immediately combines with the dissolved ferrous hydroxide with such violence and rapidity that the soln. becomes quite hot. Hence it is easy to produce the magnetic oxide by adding the mixed salt soln. to an excess of aq. ammonia. If the precipitation is carried out without excluding air, or with an insufficient excess of ammonia, the product is never homogeneous, but consists of ferric hydroxide which has combined with some of the ferrous hydroxide, and of ferrous hydroxide which has been partly oxidized, and thus rendered insoluble. If the salts in soln. are compounded so as to furnish Fe_3O_4, the composition of the precipitate will approximate to this formula. If a soln. of ammonium chloride, containing ferrous and ferric salts in the proportions required for Fe_3O_4, be boiled for several hours, the combination is never complete and some ferrous hydroxide remains dissolved so that the precipitate contains some unchanged ferric hydroxide. It is thus difficult to prepare the definite compound $FeO.Fe_2O_3$ by this method, and much more so with respect to other complexes $(FeO)_m(Fe_2O_3)_n$. O. Baudisch and L. A. Welo found that nitric oxide is a good reagent for oxidizing precipitated ferrous oxide to hydrated ferrosic oxide when the gas is bubbled through the freshly prepared pulp. The subject was studied by E. Deiss and G. Schikorr.

The manufacture and use of ferrosic oxide has been described by the Aciéries de Gennevilliers, G. Bredig and co-workers, W. Eminger, P. Fireman, T. Goldschmidt, A. T. Larson and C. N. Richardson, J. Laux, A. Lucas, Metall-Gesellschaft A.-G., E. Müller, E. A. C. Smith, and H. Wicht; and the preparation of *magnetite electrodes*, by P. Askenasy, P. Askenasy and J. Neustadt, H. Blackman, Chemische Fabrik Buckau, Chemische Fabrik Griesheim-Elektron, Consortium für Elektrochemische Industrie, P. P. Fedotéeff and T. N. Petrenko, F. A. J. Fitzgerald, J. F. Ginsberg, H. C. Hubbell, S. Laszczynsky, B. Lepsius, W. Seeger, and M. de Kay Thompson and T. C. Atchison.

The physical properties of ferrosic oxide.—Magnetite occurs in iron-black crystals, or massive with a laminated, coarse or fine, granular structure. It may also occur as an impalpable powder. The mineral is opaque, but thin dendrites in, say, mica are nearly transparent, and their **colour** is pale brown to black. According to A. W. Wright,[7] thin films are greyish-brown in transmitted light. According to F. E. E. Germann, the black pigment employed by the prehistoric North American Indians was magnetite. F. J. R. Carulla found that the mixed oxides, prepared by C. F. Wülfing's process, containing Fe_3O_4 associated with Fe_2O_3, varied over the range black, bluish-black, brownish-black, greenish-black, to green. J. B. L. Romé de l'Isle, and R. J. Haüy showed that magnetite forms octahedral **crystals**

belonging to the cubic system; and H. St. C. Deville showed that the crystals are characteristic of those belonging to the spinel family. Magnetite crystallizes in the holohedral cubic system; but cubic crystals are rare. The habit is more commonly octahedral or dodecahedral, with the faces striated parallel to the (110) : (111)-edge. The crystals are sometimes considerably modified. L. Brugnatelli, R. Scheibe, G. Kalb, and H. P. Whitlock have described various forms of crystals. The crystals are rarely rhombohedral. J. del Pan, and J. Morozewicz said that rhombododecahedral forms separate from magmas rich in ferrous and ferric oxides. Magmas rich in iron may give skeleton forms, grains, and rods. C. Doelter found the number of nuclei developed in unit volume in unit time is relatively large, but the **velocity of crystallization** is small. F. Sauerwald and G. Elsner found that the mechanical strength of ferrosic oxide increases with the temp. of calcination, and this is attributed to an increase in the adhesive force between the surface of the crystallites. **Twinning** occurs about the (111)-plane, and, according to A. Cathrein, O. Mügge, K. Chudoba, and H. Sjögren, sometimes polysynthetic twinning furnishes laminæ which produce striations on an octahedral face, and often a pseudo-cleavage. The **cleavage** is not distinct; but, according to A. Grühn, A. Cathrein, O. Mügge, and J. Strüver, an octahedral parting is often highly developed. According to F. Becke, J. Beckenkamp, F. Rinne and H. Mielke, F. F. Osborne, G. Kalb, O. Mügge, and L. Brugnatelli, the **corrosion figures** developed by hydrochloric, nitric, and sulphuric acids and potassium hydrosulphate on an octahedral face are inverted triangular pits often having truncated edges; rectangular pits appear on the dodecahedral faces; while on a cubic face, quadrilateral elevations are produced by dodecahedral planes, or planes nearly coinciding with them. The chief etching zone, in which the planes forming the corrosion figures lie, is that of the trigonal trisoctahedra, and a secondary zone of the tetragonal trisoctahedra. K. Veit studied the gliding planes.

Observations on the crystals were also made by E. Artini, F. Becke, J. Beckenkamp, J. Blumrich, G. Boeris, A. Breithaupt, W. C. Brögger, S. Brunton, H. Bücking, A. des Cloizeaux, H. Credner, J. D. Dana, H. von Dechen, C. Doelter, G. Flink, J. H. Gladstone, B. Granigg, A. Gorgeu, P. Groth, W. Haidinger, B. J. Harrington, C. Hartmann, E. Hatle, J. A. Hedvall, F. Hessenberg, F. R. van Horn, E. Hussak, L. Jaczowsky, P. von Jeremejeff, M. Jerofejeff, K. Jimbo, G. Kalb, J. F. Kemp, G. A. Kenngott, F. von Kobell, N. von Kokscharoff, A. Lacroix and C. Baret, J. Lehmann, C. C. von Leonhard, G. Leonhard, A. Lévy, L. Liebener and J. Vorhauser, A. Michel-Lévy, W. H. Miller, J. Millosock, T. Monticelli and N. Covelli, J. Morozewicz, O. Mügge, P. Niggli, S. Nishikawa, A. E. Nordenskjöld, T. Petersen, M. Pictorsky, F. A. Quenstedt, G. von Rath, C. F. Rammelsberg, F. Rinne and H. Mielke, H. Rosenbusch, G. Roster, A. Sadebeck, F. Sandberger, A. Scacchi, R. Scheibe, M. Schläpfer and P. Niggli, A. Schmidt, H. Schneiderhöhn, G. M. Schwartz, J. B. Scrivenor, G. Seligmann, G. Silberstein, S. T. Singewald, H. Sjögren, F. S. Starrabba, J. Strüver, E. Tacconi, T. Wada, C. H. Warren, E. Wildschrey, G. Woitschach, T. L. Walker and A. L. Parsons, H. P. Whitlock, J. F. Williams, F. Zambonini, V. R. von Zepharovich, etc.

According to W. H. Bragg, the **X-radiograms** correspond with a space-lattice of the diamond type—**5.**·39, 8—in which if *a* represents the length of the side of a cube containing one molecule, $a=4{\cdot}18$ A.; the face diagonal has a length 5·92 A., and the cube diagonal, a length 7·25 A. A cube containing eight molecules of $Fe''(Fe'''_2O_4)$ has twice these dimensions. In order to maintain the trigonal symmetry, the four oxygen atoms, ○, Fig. 511, are arranged at the corners of a regular tetrahedron, and the tetrahedron is so oriented that the lines drawn from the centre to the four corners of the tetrahedron are parallel to the four diagonals of the crystal cube. The oxygen tetrahedra take the place of the carbon atoms of the diamond, and are arranged so that the four perpendiculars from the corners on the faces are parallel to the four cube diagonals. The bivalent atoms of iron, ●, Fig. 511, are placed one at the centre of each oxygen tetrahedron. In order to satisfy the conditions of symmetry, the tervalent atoms of iron, ⊙, Fig. 511, are arranged so that each of four atoms of iron, *D*, *E*, *F*, *G*, Fig. 511, is placed on one of the four perpendiculars from the tetrahedron on opposite faces, and half-way

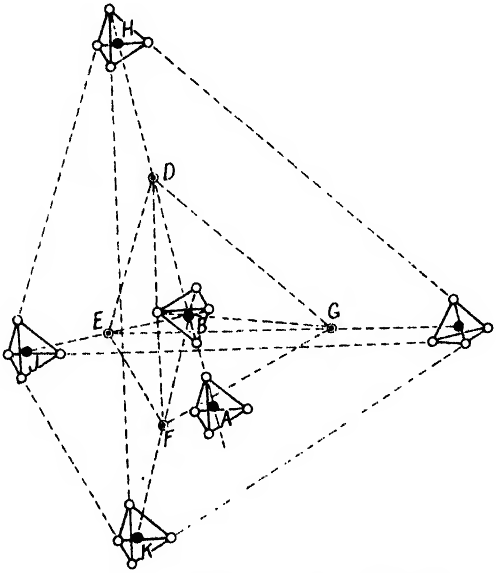

Fig. 511.—Illustration of the Trigonal Symmetry of Magnetite.

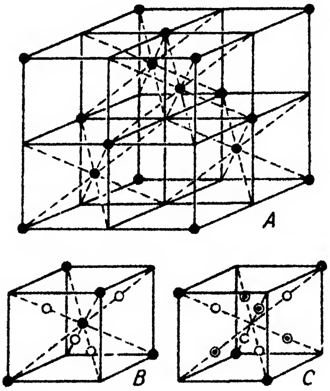

Fig. 512.—The Space-Lattice of Ferrosic Oxide.

between two tetrahedra so as to be shared equally by them. In the diagram, Fig. 511, illustrating the trigonal symmetry, *BH*, *BJ*, *BK*, and *BG* are trigonal axes; $BD=DH=BE=EJ=BF=FK=BG=5{\cdot}4$ A.; and $AB=3{\cdot}60$ A. The structure was depicted another way by S. Nishikawa who represented the lattice of ferrosic oxide by Fig. 512. The eight Fe''-atoms of the eight $\mathrm{Fe}''(\mathrm{Fe}'''_2\mathrm{O}_4)$ molecules are arranged like the carbon atoms in the diamond, *A*, Fig. 512; two cubes of the unit cell are represented by *B* and *C*, Fig. 512. Four of the cubes, *B*, Fig. 512, contain a Fe''-atom in the middle, and each of the four cubes, *C*, Fig. 512, has Fe'''-atoms on the diagonals at the corners of tetrahedra. The oxygen atoms are also situated on the diagonals of the small cubes at the corners of tetrahedra. Observations on this subject were made by J. A. Hedvall, P. Niggli, H. Groebler and P. Oberhoffer, P. F. Kerr, H. Forestier, G. Frebold and J. Hesemann, A. Simon and T. Schmidt, J. Cates, and M. L. Huggins—see Fig. 512. According to R. W. G. Wyckoff and E. D. Crittenden, the unit cube of magnetite has an edge of 8·37 A.; W. H. Bragg gave 8·30 A.; A. A. Claassen, 8·40 A.; G. L. Clark and co-workers, $a=8{\cdot}374$ A.; J. Thewlis, 8·4 A.; T. Gebhardt, 8·367 A.; and S. Holgersson, 8·40 to 8·417 A., or 8·412 A. for natural and 8·417 A. for artificial magnetite. J. A. Hedvall, G. Frebold and J. Hesemann, and S. Holgersson obtained identical values for natural and synthetic ferrosic oxide. According to J. Thewlis, there are two kinds of iron atoms in the $\mathrm{Fe}_3\mathrm{O}_4$ lattice, namely $\mathrm{Fe}^{\cdot\cdot}$ and $\mathrm{Fe}^{\cdot\cdot\cdot}$, and one kind of oxygen atom. Each $\mathrm{Fe}^{\cdot\cdot}$-atom is in the middle of a tetrahedron of oxygen atoms; and each $\mathrm{Fe}^{\cdot\cdot\cdot}$-atom is in the middle of an octahedron of oxygen atoms. Each oxygen atom is at the corner of three octahedra and one tetrahedron of oxygen atoms—*cf.* Fig. 514 in connection with ferric oxide. According to L. A. Welo and O. Baudisch, J. Thewlis, and R. B. Sosman and E. Posnjak, the lattice of ferrosic oxide can accommodate oxygen atoms up to $\mathrm{Fe}_2\mathrm{O}_3$ without change—*vide infra.* K. T. Compton and E. A. Trousdale, A. H. Compton and O. Rognley, S. Holgersson, and M. de Broglie observed no change in the relative intensities or positions of the X-ray spectral lines when ferrosic oxide is placed in a magnetic field. According to R. W. G. Wyckoff and E. D. Crittenden, if an excess of ferrous iron is associated with the ferrosic oxide, it appears as a separate phase, which disappears when an equivalent amount of alumina, silica, or zirconia is added, as promoter for the ferrosic oxide used as a catalyst. With alumina, ferrous aluminate is formed and enters into solid soln., whilst the composition of the oxide tends towards that of ferrosic oxide. The unit cube of magnetite containing potassium aluminate differs but little in size from the unit cube of ferrosic oxide, and it is impossible to say whether or not solid soln. occurs. Promoters maintain a large surface of iron in catalysis by inhibiting sintering of the reduced metal, so that the crystals of the latter grow only very slowly. M. L. Huggins discussed the electronic structure; and J. Forrest, the magnetic lattice.

The **microstructure** of magnetite was examined by A. Lacroix, P. Ramdohr, O. Mügge, C. H. Warren, S. Brunton, S. T. Singewald, G. M. Schwartz, and H. Schneiderhöhn; **inclusions** of ilmenite, etc., by B. Granigg, L. Thiébaut, and E. Hussak. O. Mügge studied the **corrosion figures** of magnetite and other spinels. W. Haidinger, A. Scacchi, C. F. Rammelsberg, J. W. Gruner, G. Seligmann, and H. Bücking discussed **overgrowths** or **parallel growths** of magnetite with hæmatite; J. W. Gruner, with spinel; J. D. Dana, and A. Lacroix, with mica; J. F. Williams, with hypersthene; A. Breithaupt, with chlorite; T. Nordström, with bronzite; F. J. Pope, F. Becke, A. Cathrein, J. W. Gruner, and M. Kamiyama, with ilmenite; and G. Seligmann, A. Cathrein, and O. Mügge, with rutile; and P. von Jeremejeff, with perowskite. J. H. L. Vogt regarded the Norwegian titanomagnetite as a mixture of magnetite and ilmenite. The miscibility of magnetite with $FeTiO_3$, $FeTi_2O_4$, in basaltic slags was studied by V. M. Goldschmidt. B. J. Harrington considered that the titanium in many titaniferous magnetites can be regarded as being present as Ti_2O_3, or as $FeTiO_3$, in which tervalent iron replaces tervalent titanium. E. Hussak considered that the titanium in the *titanomagnetites*—of A. Vendl, J. Szabo, W. G. Miller, A. Knop, T. Nordström, A. Cathrein, F. Schaearzik, and P. Rozlozsnik and E. Emszt—is present rather as inclusions, and that titanomagnetite *kein selbständiges Mineral ist.* R. Ramdohr found that in the slow cooling of titanomagnetite, ilmenite separates in plates; spinel also separates out, as $MgO.Al_2O_3$, or $FeO.Al_2O_3$. The subject was also discussed by M. K. Palmunen. L. W. Fisher studied the isomorphism of the mineral with kreittonite, dysluite, gahnite, magnesioferrite, and spinel. C. U. Shepard described slender, rhombic prisms of magnetite occurring on the cubic octahedra and dodecahedra of magnetite of Monroe, New York; and he called the mineral **dimagnetite,** since its composition is the same as that of magnetite. J. D. Dana regarded dimagnetite as a **pseudomorph** of magnetite possibly after ilvaite.

As indicated above, S. Hilpert [8] and co-workers believe that ferrous and ferrosic oxides form a series of solid soln., perhaps with limited miscibility, and perhaps with the formation of intermediate compounds. The analyses of substances equivalent to hammer-slag—*vide supra*—indicate that various mixtures may be formed. Such mixtures were also obtained by A. Matsubara, E. Terres and A. Pongracź, R. Ruer and M. Nakamoto, L. Wöhler and O. Balz, and others. E. D. Eastman found that up to 1100° ferrosic and ferrous oxides do not form a continuous series of solid soln. though they do dissolve in one another to a limited extent. Iron can dissolve 20 to 25 molar per cent., *i.e.* 6 to 8 per cent., oxygen, although metallic iron is not appreciably soluble in the oxide—*vide supra*, ferrous oxide. O. Mügge concluded from his study of the reduction products of hæmatite, and the oxidation products of magnetite, that magnetite itself is a solid soln. of ferrosic oxide in cubic ferrous oxide. R. W. G. Wyckoff and E. D. Crittenden examined a mixture containing 75·24 per cent. total iron; 3·34 per cent. free iron, 40·49 per cent. ferrous iron, and 31·41 per cent. ferric iron. This showed under the microscope crystals of ferrosic oxide embedded in a fine-grained eutectic mixture of magnetite and ferrous oxide. If magnetite can dissolve ferrous oxide, and if the latter can dissolve magnetite, at ordinary temp., there should be a shift in the lines of one or other or both of the structures. A comparison of the results with those with ferrosic oxide gives no evidence of solid soln., at ordinary temp., of ferrous oxide in ferrosic oxide. H. Groebler and P. Oberhoffer, however, obtained the X-radiograms indicated in Fig. 507—*cf.* Fig. 513, ferrous oxide—with mixtures containing the proportions of ferrous, and ferrosic oxide indicated. The lines with Nos. 1 to 3 with up to about

5 per cent. ferrous oxide have the shift characteristic of solid soln. In No. 4, new lines appear along with the lines of the solid soln., and these are the lines of ferrous oxide; they persist with samples up to No. 9, and they can be recognized in samples Nos. 10 to 12 along with the lines of metallic iron. At a reduction temp. of 800°, therefore, 5 per cent. of ferrous oxide can form a solid soln. with ferrosic oxide; with higher proportions, the ferrous oxide occurs as a second solid phase, and with about 31·9 per cent. Fe_3O_4, the ferrosic oxide lattice disappears, and the lines due to that of ferrous oxide alone appear. The iron dissolved in ferrous oxide, Nos. 10 to 12, causes no shift of the lines, thus indicating the absence of a solid soln. The vanishing of the X-ray spectrum of magnetite when the composition approaches 61 per cent. of FeO, and 31·9 per cent. of magnetite is explained by assuming that magnetite begins to take on the cubic lattice of ferrous oxide at this dilution, and that the extra oxygen atoms are distributed haphazard in the interstices between the other iron and oxygen atoms. They call the oxygen atoms that fail to take part in the X-ray spectrum "vagabond atoms"—*der überschüssige Sauerstoff frei im Gitter vagabundiert.* R. M. Bozorth, in his examination of the ferrosic oxide protective coatings on iron, observed no evidence of the formation of solid soln. of ferrous and ferrosic oxide, because he found no evidence of a variation in atomic spacing greater than 0·5 per cent. Negative evidence in the application of the X-ray method does sometimes occur—*e.g.* it fails to show iron tritacarbide in steel specimens where the Fe_3C areas and crystals are plainly visible under the microscope. A. Simon and T. Schmidt could detect no solid soln. in the conversion of ferric to ferrosic oxide by heat.

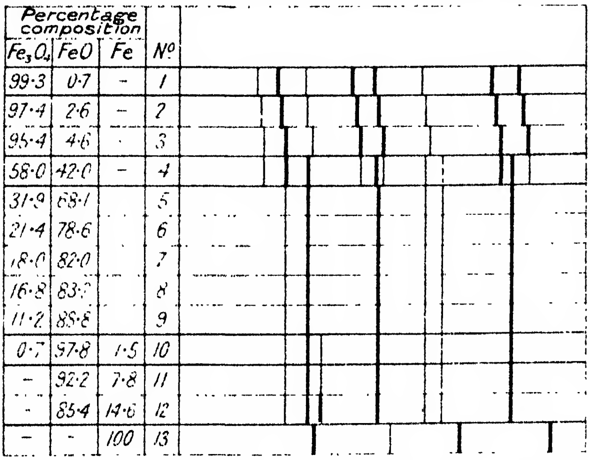

FIG. 513.—Diagrammatic X-ray Spectra of Iron Oxides Lower than Fe_3O_4.

According to H. Moissan,[9] and M. Berthelot, there are two **allotropic forms** of ferrosic oxide. Ferrosic oxide prepared by heating ferric oxide or metallic iron, reduced by hydrogen, in a current of hydrogen sat. with aq. vapour at 90°; or by heating ferrous carbonate to dull redness in a current of carbon dioxide; or by heating reduced iron in a current of carbon dioxide at 440°, is a black, magnetic powder of sp. gr. 4·86; it is readily attacked by conc. nitric acid; and when heated, becomes incandescent, forming ferric oxide. The other modification of ferrosic oxide is produced when ferric oxide, obtained by oxidizing the first modification, is heated above 1500°, when oxygen is given off leaving a black magnetic oxide of sp. gr. 5·00 to 5·09; it is almost unattacked by boiling conc. nitric acid, and does not form ferric oxide when heated. Indeed, it is one of the most stable oxides of iron. When the low temp. form of ferrosic oxide is heated to whiteness in a current of nitrogen, it agglomerates, increases in density, no longer forms ferric oxide when heated in air, and is, indeed, identical with the second, inert form of ferrosic oxide. The fact that the high temp. form does not give ferric oxide when heated is explained by assuming that when the lower temp. form of ferrosic oxide is converted into ferric oxide, the heat evolved is less than that evolved when the low temp. form is converted into the high temp. form, and therefore the formation of ferric oxide from the high temp. form of ferrosic oxide would be an endothermic reaction—*vide infra,* the thermal expansion (P. Chévenard), the sp. ht. (G. S. Parks and

K. K. Kelley, R. W. Millar, and A. Piccard and co-workers). electrical conductivity (C. C. Bidwell, J. Königsberger, and J. Königsberger and K. Schilling), the thermoelectric force (C. C. Bidwell), and magnetic properties (P. Weiss and co-workers, J. Königsberger, G. E. Allan, F. Rinne, J. Huggett and G. Chaudron, and P. Chévenard) of this oxide; and also the calorescence of ferric oxide. J. A. Hedvall observed no difference in the crystalline structure, for the X-radiograms of the alleged allotropic forms are the same. According to L. A. Welo and O. Baudisch, the catalytic activity of different samples of magnetite varies with the mode of preparation, those made by precipitation of a mixture of ferrous and ferric sulphate being much more active than those made by precipitation of ferrous sulphate and subsequent partial oxidation. The activity of active magnetite is not destroyed by oxidation, but both activity and magnetic properties are lost on heating at 550°. Comparison of the water absorption and X-ray diffraction spectra of active and inactive oxides indicates that the crystals of the former are smaller than those of the latter. It is thought that both magnetic properties and catalytic activity are related to the spatial arrangement of the atoms within the molecule. In addition to the change which occurs at the Curie point, C. C. Bidwell reported breaks in the curves of electrical conductivity and thermoelectric force between 600° and 800°; and H. H. Reiter, a transformation point at 1260°.

The **specific gravity** of magnetite, or ferrosoferric oxide, ranges from 4·96 to 5·40—average, 5·16. R. Böttger[10] gave 4·960 to 5·094; G. A. Kenngott, 4·90 to 5·20 for compact magnetite, 5·168 to 5·180 for crystalline magnetite, and 5·27 after heating for a long time; H. Kopp gave 5·12 at 0°; C. F. Rammelsberg, 5·106 to 5·185; H. Arsandaux, 5·065; W. Herapath, 5·300 at 16·5°; P. F. G. Boullay, 5·400 to 5·480; E. Madelung and R. Fuchs, 5·1718; V. Quittner, 5·252; S. Holgersson, 5·194; H. Nathorst tabulated the sp. gr. of the Swedish magnetites and found that they ranged from 4·24 to 5·11. The presence of impurities in the mineral must make the sp. gr. vary. E. Wilson and E. F. Herroun obtained a low value—4·10 to 5·06—and E. Madelung and R. Fuchs a high one—5·5471. F. Sauerwald and G. Elsner, and P. Chévenard examined the effect of heat on the sp. gr.; and J. J. Saslawsky the observed and calculated mol. vol. L. Playfair and J. P. Joule, 5·453 at 3·9°. H. Moissan gave 4·86 for ferrosic oxide prepared at a low temp., and 5·00 to 5·09 for that prepared at a high temp.; and for the artificial crystals, A. Gorgeu gave 5·21 to 5·25. W. Biltz studied the mol. vol. The **hardness** of magnetite is 5·5 to 6·5; and A. Gorgeu gave for the artificial crystals, 6·0 to 6·5; J. Donau gave 6·0 for a sample prepared at 1100° to 1200°; and for a sample obtained from the sulphide, 6·0 to 6·5. P. Pfaff found that the scratching hardness of magnetite on an octahedral face is 22 when the hardness of talc is unity. P. J. Holmquist compared the hardness offered in the slitting machine; J. L. C. Schröder van der Kolk, the cleavage and hardness; E. Friederich, the hardness, at. mol., and valency; G. A. Kenngott, and J. L. C. Schröder van der Kolk, the hardness and at. vol.; and A. Reis and L. Zimmermann, and S. Holgersson, the hardness and the lattice structure. A. Grühn studied the **gliding planes** of the crystals under press. up to 30,000 atm. F. D. Adams tried the effect of **compression,** up to 43,000 lbs. applied in 17 mins., on a crystal of magnetite, and found that the mineral broke to pieces, and that the fragments had the form of little plates which separated from the crystal parallel to the octahedral faces. There were no signs of plastic deformation. P. W. Bridgman gave for the compressibility, $\beta=0\cdot0_{6}59$ or $dv/v_0=5\cdot397p-2\cdot01p^2$ at 30°, and $dv/v_0=5\cdot376p+2\cdot01p^2$ at 70°, where dv denotes the decrease in vol. with a rise of press. of p kgrms. per sq. cm. for values of p below 12,000 kgrms. per sq. cm. L. H. Adams gave $\beta=-0\cdot0_{6}55$, and $d\beta/dp=0\cdot0_{11}4$; and E. Madelung and R. Fuchs gave $0\cdot0_{6}54$ to $0\cdot0_{6}57$ megabars per sq. cm. when the value for mercury is $3\cdot86\times10^{-6}$. F. Sauerwald and G. Elsner made some observations on the mechanical strength of samples heated to different temp. F. B. Hofmann made some observations on the accumulation of the powder at the boundary surface of water and organic liquids.

H. Kopp[11] observed that the cubic coeff. of the **thermal expansion** of magnetite is 0·000029 between 17° and 50°; and F. Pfaff gave for the mean linear coeff. 0·00009540. H. Forestier observed a break in the dilation curve between about 570° and 965°. G. Chaudron and H. Forestier observed that the dilation increases continuously up to 570° and then decreases. There is a sudden fall at 695°. With artificial magnetite, a contraction was observed; and at 550° the expansion was normal. P. Weiss and G. Foëx observed an anomaly at 570°; at 0°, $\alpha=0{\cdot}0_58$, and at 570°, $\alpha=0{\cdot}0_424$; above 570° there is a decrease in the value of α; and at 680°, there is a break in the curve attributed to the effects of the Curie transformation, although P. Chévenard observed that the change in Curie's constant between 625° to 765° did not influence the expansion perceptibly. T. Okamura studied the subject. H. de Sénarmont found that the **thermal conductivity** of magnetite in different directions is the same, and the isothermal lines are circular. J. Kruckenberg gave $k=0{\cdot}003$ to 0·006 cal. per cm. per degree per second for the thermal conductivity of magnetite. F. E. Naumann gave 0·1641 for the **specific heat** of magnetite; H. V. Regnault, 0·16023 between 10° and 99°; H. Kopp, 0·153 to 0·159; R. Ulrich, 0·1687 between 20° and 98°; and A. Abt, 0·16505 to 0·16582 between 15° and 96°. W. Bertram gave:

	96·5°	219°	448°	586°	678°	738°	783°
c .	0·1592	0·1766	0·1982	0·2095	0·2137	0·2176	0 2188

and $c=0{\cdot}1487+0{\cdot}000148(\theta-20)-0{\cdot}0_7725(\theta-20)^2$. P. N. Beck gave:

	101°	198°	301°	395°	496°	540°	580°
Sp. ht. .	0·16791	0·17572	0·18509	0·19341	0·20346	0·20788	0·21235

for which $c=0{\cdot}161178+0{\cdot}0_3111114\theta+0{\cdot}0_61551\theta^2$. There is a transition point at 585°, after which:

	593°	620°	648°	704°	726°	748°	791°
Sp. ht. .	0·21336	0·21437	0·21519	0·21735	0·21835	0·21952	0·22259

for which $c=0{\cdot}161699-0{\cdot}002969610\theta+0{\cdot}0_523718\theta^2$. There are striking peaks in the sp. ht. curve at −156° and at 593°. The latter is approached the more gradually as the temp. is raised, but falls off precipitately after the peak is passed. This type of peak is characteristic of ferromagnetic materials as they pass their Curie points and become paramagnetic. P. Weiss and P. N. Beck showed that as magnetite passes from the ferromagnetic to the paramagnetic state at the critical temp., heat is rapidly absorbed, so that the sp. ht. rises to a maximum, then decreases, and again increases. The mean values of the sp. ht., $dQ/d\theta$, at different temp. are indicated in Fig. 514. K. Honda and J. Okubo consider that the discontinuity near the Curie point is not an effect of magnetic energy, but rather an effect of the heat of the transformation of iron from one form to another. O. C. Ralston added that it is doubtful if the peak in the curve, Fig. 514, is a discontinuity in the sp. ht., but the tip of the peak rather represents the point on a magnetization-temperature curve, where the ferromagnetism is being lost more rapidly before the point is reached where only paramagnetism remains. H. A. Lorentz calculated $\delta c=0{\cdot}0644$ for the differential of the sp. ht. on the assumption that the magnetic molecule is $\frac{1}{3}Fe_3O_4$. P. Weiss and co-workers showed that at the Curie point $d/(\delta c)/d\theta$ will be zero. J. R. Ashworth, and A. Dumas discussed the relation between δc and the Curie point. I. Maydell studied the mol. ht. J. R. Ashworth studied the relations between the thermal and magnetic constants.

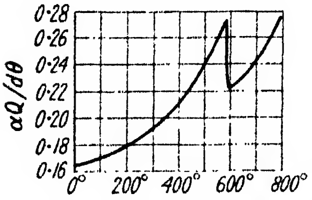

FIG. 514.—The Effect of Temperature on the Specific Heat of Magnetite.

P. Weiss and co-workers gave for the sp. ht. of artificial magnetite and of the natural mineral from Traversella, Piedmont:

	300°	400°	500°	550°	585°	585°	593·5	593·5	625°	670°
Natural .	—	-	0·259	0·281	0·299	0·2255	0·226	0·226	0·229	0·232
Artificial .	0·199	0·222	0·255	0·277	0·295	0·295	0·300	0·221	0·223	0·226

They also observed a difference in the results between 18° and 175° for samples that had and had not been previously heated to 300°. M. Tigerschiöld calculated a mol. ht. of 36·08 at 17°, from A. Matsubara's observations on gaseous equilibria. G. S. Parks and K. K. Kelley gave for the sp. ht. per gram:

°K .	90·0°	96·9°	153·2°	193·5°	197·2°
C_p .	0·0488	0·0550	0·0968	0·1186	0·1205
°K .	276·3°	278·7°	292·1°	295·0°	—
C_p .	0·1513	0·1525	0·1558	0·1570	- -

and R. W. Millar, for the mol. ht.:

°K .	60·5°	87·6°	100·7°	110·4°	114·7°	124·8°	153·7°	206·2°	261·1°
C_p .	5·495	10·36	13·67	19·25	36·27	18·95	22·63	28·59	32·68

The results are plotted, along with those for ferrous oxide, in Fig. 504. W. A. Roth and W. Bertram gave for the sp. ht., c, between $\theta°$ and 20°, $c=0{\cdot}1487+0{\cdot}0_3148(\theta-20)-0{\cdot}0_7725(\theta-20)^2$; and for the mol. ht., at $\theta°$:

	100°	200°	300°	400°	500°	600°	700°
C .	39·59	45·12	49·66	53·20	55·73	57·23	57·74

J. Lehmann found that when magnetite is heated, and suddenly cooled by cold water, irregular cracks appear on the octahedral and dodecahedral faces. F. Sauerwald and G. Elsner studied the sintering of powdered ferrosic oxide. According to S. Hilpert and E. J. Kohlmeyer, purified ferrosic oxide has a **melting-point,** or rather the f.p., 1527°; and there is a break in the cooling curve between 1250° and 1350°. E. J. Kohlmeyer later gave 1600°; O. Ruff and O. Goecke, 1538°; B. Garre, 1527°; J. Kleffner and E. J. Kohlmeyer, 1580° in an atm. of nitrogen; J. C. Hostetter and H. S. Roberts, 1590°; and R. B. Sosman, 1580°. P. Curie's value, 1377°, is too low. A. Brun gave 1260° for the m.p. of magnetite from Zermatt; and C. Doelter found that the mineral begins to soften at 1195°, and is fluid at 1210°, and that its m.p. is approximately the same as that of orthoclase; C. Schubert gave 1080° to 1090°. Observations were also made by H. H. Reiter. The low values obtained with the natural mineral are usually attributed to the presence of impurities. R. Ruer and M. Nakamoto found that a mixture of ferrous and ferrosic oxides (4 : 96) begins to melt slightly over 1550°.

J. A. Hedvall said that the oxide is stable at a red-heat. R. Ruer and M. Nakamoto found that in a current of nitrogen ferrosic oxide begins to decompose over 1300°, and that the composition of the oxide heated to 1500° is Fe : O=1 : 1·32. P. T. Walden found that ferrosic oxide does not show an appreciable **dissociation pressure** at 1350°; but A. Simon and T. Schmidt said that it amounts to about 1 mm. at 1350°. H. von Jüptner calculated for the reaction: $2Fe_3O_4=6FeO+O_2$, $\log [O_2]=\log p=32254T^{-1}+1{\cdot}75 \log T^{+2{\cdot}8}$; and for the reaction: $Fe_3O_4=3Fe+2O_2$, $\log [O_2]=\log p=-29628T^{-1}+1{\cdot}75 \log T^{+2{\cdot}8}$. The dissociation press., in atm., are:

	600°	1000°	1400°	1800°	2000°	2400°
p .	$0{\cdot}0_{46}8038$	$0{\cdot}0_{24}6252$	$0{\cdot}0_{14}1850$	$0{\cdot}0_{9}3783$	$0{\cdot}0_{7}2817$	$0{\cdot}0_{4}1889$
$p1$.	$0{\cdot}0_{41}1914$	$0{\cdot}0_{21}2642$	$0{\cdot}0_{12}1389$	$0{\cdot}0_{7}1088$	$0{\cdot}0_{6}5792$	$0{\cdot}0_{3}2346$

No determinations of the dissociation press. have been made; but estimates have been made by L. Wöhler and co-workers, A. Matsubara, K. Hofmann, W. Biltz, A. McCance, and F. Wüst and P. Rütten. The reduction of magnetite by platinum shows that some dissociation of magnetite occurs; and the gain of 3 per cent. excess ferrous oxide when ferrosic oxide is heated to 1550° shows that the oxygen press. at this temp. is appreciable. This explains a possible difficulty in determining the m.p., since the m.p. will be lowered by the contamination of the ferrosic oxide with ferrous oxide.

H. Dulong, and T. Andrews made some observations on the **heat of formation** of ferrosic oxide. According to M. Berthelot, this amounts to $(FeO,Fe_2O_3)=4\cdot4$ Cals.; but W. G. Mixter found 9·2 Cals. for the thermal value of this reaction. H. le Chatelier gave for $3Fe_2O_3$(calcined)$=2Fe_3O_4+O-45\cdot18$ Cals.; and H. von Jüptner, 52·4 Cals. O. Ruff and E. Gersten gave $(3Fe,2O_2)=265\cdot2$ to 267·1 Cals.; E. D. Eastman and R. M. Evans, 258·0 to 266·98 Cals.; L. Wöhler and R. Günther, 264·8 Cals.; M. Berthelot, 267·4 to 270·8 Cals.; W. A. Roth and co-workers, 265·7 Cals.; J. Jermiloff, 274·6 Cals.; A. C. Halferdahl, 267·28 Cals.; W. D. Treadwell, 247·2 Cals. at 1000°; W. G. Mixter, 265·7 Cals.; O. Doepke, and W. A. Roth, 265·4 Cals.; M. Tigerschiöld, 217·0 Cals.; and H. von Jüptner, 270·8 Cals. W. A. Roth and co-workers gave $FeO+Fe_2O_3=Fe_3O_4+7\cdot0$ Cals. G. Preuner calculated for the heat of oxidation of iron to ferrosic oxide at 960°, 237,740 cals., and E. Baur and A. Glässner, 236,240 cals. at 960°, and 267·38 Cals. at 490°. The best representative value is 265·7 Cals. E. D. Eastman and R. M. Evans gave for the heat of formation $Q=-2{,}643{,}630+11\cdot00T+0\cdot0112T^2-0\cdot00000248T^3$, from the carbon monoxide reduction equilibrium; and $Q=-256{,}377-3\cdot76T-0\cdot006594T^2+0\cdot0000296T^3$, from the hydrogen reduction equilibrium. A negative heat of formation, of course, means an evolution of heat. H. le Chatelier gave for the $(3FeO,O)=76\cdot6$ Cals.; O. Ruff and E. Gersten, 85·8 Cals.; and H. von Jüptner, 73·7 Cals. H. von Jüptner gave $3Fe_2O_3=2Fe_3O_4+O+52\cdot4$ Cals., and H. le Chatelier, $3FeCO_3+O=Fe_3O_4+3CO_2+0$ Cals. W. G. Mixter found the heat of formation of fused magnetite to be 265·2 Cals., and ordinary magnetite 265·7 Cals., leaving 0·5 Cal. for what he called the heat of polymerization, assuming, of course, that the error of experiment is zero. U. Hofmann and E. Groll calculated for the reaction $3Fe+4CO_2=Fe_3O_4+4CO-5380$ cals., when $[p_{CO_2}]^4=K[p_{CO}]^4$, at 1 atm. press.:

	550°	500°	450°	400°	350°	300°	250°
K .	0·927	—	2·22	—	6·25	—	22·1
p_{CO} .	0·5048	—	0·451	—	0·388	—	0·316
Q .	—	10,295	—	9273	—	8148	— cals.

and for $Fe_3O_4+6CO=Fe_3C+5CO_2+41{,}850$ cals., when $[p_{CO}]^6=K[p_{CO_2}]^5$:

	550°	500°	450°	400°	350°	300°	250°
$\log K$	−1·13	—	−2·82	—	−5·01	—	−7·96
p_{CO} .	0·415	—	0·260	—	0·130	—	0·046
Q .	—	46,023	—	45,097	—	44,000	— cals.

M. Berthelot gave 46·8 cals. for the **heat of solution** of ferrosic oxide in hydrochloric acid. E. D. Eastman calculated the **free energy** of ferrosic oxide to be:

	600°	700°	800°	900°	1000°
Free energy .	−198,320	−190,425	−182,550	−174,735	−166,980 cals.

Observations on the subject were made by F. Wüst and P. Rütten, and A. McCance. R. Dallwitz-Wegener discussed the subject. G. S. Parks and K. K. Kelley gave 81·0 for the **entropy**, 27·10 Cals. for the heat of formation, and −246·8 for the free energy at 25°; whilst R. W. Millar gave 34·69 for the entropy at 25°. A. C. Halferdahl gave −83·1 units for the change of entropy in the formation of magnetite at 25°. O. C. Ralston calculated from the sp. ht. data, values for the change in entropy, δS, which occurs when a mol. of Fe_3O_4 is formed from its elements:

	25°	100°	200°	300°	400°	500°	585°	700°	800°
δS .	−81·5	−78·9	−76·3	−71·7	−71·1	−68·1	−65·4	−63·9	−63·7

The calculations of E. D. Eastman and R. M. Evans, and G. N. Lewis and M. Randall furnish for the free energy $-264{,}630-11T\log T-0\cdot112T^{-2}+0\cdot00000124T^3=11\cdot34T$, from the carbon monoxide equilibrium; and from the hydrogen equilibrium, $-256\cdot320-3\cdot76T\log T+0\cdot0066T^2-0\cdot00000T^3+40\cdot56T$. O. C. Ralston gives as the best representative value $-269{\cdot}246-8{\cdot}1425T\log T+0{\cdot}000341T^2+136{\cdot}332T$. The free energy of magnetite is

	25°	100°	200°	400°	585°
cals. .	−241,500	−235,415	−227,800	−212,980	−199,278

	700°	900°	1100°	1300°
cals. .	−19,960	−176,995	−162,195	−148,163

S. Loria[12] found for artificial magnetite, with light of wave-length λ=439, 589·6, and 665·5$\mu\mu$, the **indices of refraction** respectively 2·46, 2·42, and 2·45; and the **extinction coefficients** respectively 0·69, 0·55, and 0·50; and S. Loria and C. Zahrzewsky obtained similar results for natural ferrosic oxide, viz.:

λ . .	4390	4660	5030	5330	5896	6330	6655	7040
μ . .	2·46	2·43	2·42	2·41	2·42	2·44	2·45	2·42
k . .	0·69	0·66	0·60	0·57	0·55	0·53	0·50	0·45

W. W. Coblentz found the **ultra-red reflecting power** rises uniformly from about 4 per cent. at 1μ to 38 per cent. at 13μ. S. Holgersson calculated 27·55 for the **molecular refraction** with the μ^2 formula. Observations on the **emissivity** of ferrosic oxide were made by H. le Chatelier and co-workers, B. Monasch, and E. Domek. G. K. Burgess and R. G. Waltenberg gave for light of wave-length $0{\cdot}65\mu$, 0·63 when the value for platinum is 0·33; they also gave for the molten oxide 0·53. G. K. Burgess and P. D. Foote found the monochromatic emissivity, E', at different temp. to be:

	800°	900°	1000°	1100°	1200°
E' . .	0·98	0·97	0·95	0·93	0·92

and the total emissivity, E:

	500°	600°	700°	800°	900°	1000°	1100°	1200°
E . .	0·85	0·85	0·87	0·87	0·87	0·88	0·88	0·89

Surfaces of molten iron and steel quickly acquire a coating of oxide whose outer surface is essentially magnetite. The above results furnish a table of corrections for optical and radiation pyrometers sighted on surfaces of iron oxide consisting mostly of magnetite. The temp. drops through the layer of oxide, so that the true temp. of the metal beneath the oxide layer is higher than it is at the outside of the oxide layer. Thus, for observations with optical and radiation pyrometers:

Observed temp. .		500°	600°	700°	800°	900°	1000°	1100°	1200°
True temp.	Optical .	—	600°	700°	801°	902°	1004°	1106°	1210°
	Radiation	530°	630°	735°	835°	940°	1040°	1145°	—

P. D. Foote studied the Kerr effect; there is a maximum in the curve for the Kerr effect at which the **electromagnetic rotation** changes; and there is probably also a minimum. P. Dziewulky made observations on the magneto-optic rotation. S. Loria, and H. E. J. G. du Bois studied the effect of magnetic fields of different strength; S. Loria, H. E. J. G. du Bois, and L. R. Ingersoll, the effect of light of different wave-lengths; and P. Martin, the effect of temp. J. Kerr observed that a suspension of finely powdered ferrosic oxide is doubly refracting in a magnetic field. J. L. Glasson studied the X-ray spectrum. C. Doelter observed that magnetite, like the spinels generally, is fairly opaque to the **X-rays,** standing in this respect between quartz and rock salt. A. Dima found the **photoelectric effect** with magnetite to be very small; and F. Krüger and E. Taege observed that if some hydrogen sulphide is present the effect is more marked. C. H. Kunsman found that a fused mixture of iron oxide with 1 per cent. of an alkali or alkaline earth oxide, with or without alumina, when used as a hot anode, or employed as a coating for platinum anode, gave, after partial reduction, steady **positive ion currents** up to 10^{-4} amp. per sq. cm. in a vacuum of 10^{-6} mm. A. J. Dempster observed no reflection of positive ions by crystals of magnetite. E. Rupp and E. Schmid studied the reflection of electrons from films of ferrosic oxide. A. W. Wright obtained by cathodic spluttering in vacuo a thin mirror of magnetite which was greyish-brown in transmitted light. E. T. Wherry found magnetite to be a poor radio-detector.

R. J. Haüy[13] found that magnetite acquires a negative charge of **frictional electricity** when rubbed with a handkerchief; and H. F. Vieweg studied the subject. F. Crook noted that it is attracted by a rubbed stick of shellac. P. Weiss studied the **electrostatic moment** of magnetite. The observations of J. F. L. Hausmann and F. C. Henrici, F. von Kobell, G. Cesaro, E. Wartmann, F. Beijerinck, and W. Skey showed that the **electrical conductivity** of ferrosic oxide is less than that of copper. E. Weintraub found the conductivity of magnetite to be $0{\cdot}0116\times10^4$ mhos per cm. cube when that of copper is 64×10^4 mhos per cm. cube. The conductivity increases with rise of temp. H. Bäckström found that at 40° the **electrical resistance** of rods cut parallel to the cubic and the dodecahedral normals are the same. The electrical resistance decreases slowly with a rise of temp. A. Abt found that the resistance of a cm. cube of magnetite from Moravitza ranged from 7·06 to 4900 ohms; the variation is attributed to the variation in the proportion of contained quartz as impurity. R. D. Harvey, and H. Löwy studied the subject. The effect of variations of temp. were measured by S. P. Thompson, H. Bäckström, C. C. Bidwell, and C. Fery. S. L. Brown gave 562·5 ohms per cm. cube for the sp. resistance, R, of fused magnetite at 20° and for the resistance at $\theta°$ between $-3°$ and 365°, $R=562{\cdot}5(1{\cdot}82-0{\cdot}0524\theta-0{\cdot}00057\theta^2)$. C. Doelter found that the electrical resistance is 1·198 ohm at 15°, it is 0·614 ohm at 115°; and between 500° and 600° the results were irregular. J. Königsberger and K. Schilling measured the electrical resistance, R_E ohms, of artificial ferrosic oxide, at different temp., Fig. 515. The results show a break at about 530°, and a minimum at 220°. A number of samples broke on passing 530°. For α-ferrosic oxide:

	15°	82°	192°	221°	240°	280°	410°	485°
R . .	0·00794	0·00582	0·00446	0·00434	0·00435	0·00446	0·00770	0·0112

and for β-ferrosic oxide, there is a minimum at 815°:

	550°	605°	660°	710°	755°	815°	840°	905°
R . .	0·0069	0·0068	0·0064	0·0059	0·0056	0·0054	0·0055	0·0060

S. Veil also noted a discontinuity in the conductivity curve between 500° and 600° at the Curie point; C. C. Bidwell attributed the effect at 600° to 800° to a partial oxidation of the ferrosic oxide. Observations were also made by B. Young, R. von Haslinger, E. Renschler, T. Okamura, and J. Königsberger. E. Wilson and E. F. Herroun found that the resistance of magnetite varies with the impressed voltage, the resistance decreasing as the potential difference was increased. The effect of heating and subsequently cooling to the ordinary temp., was to diminish both the resistance and the temp. coeff., whilst the application of magnetic force or compressive stress also caused a decrease in resistance. A press. of 887 kgrms. per sq. cm. decreased the resistance 1·1 to 3·9 per cent. In one case a sample with high magnetic retentivity behaved exceptionally, its resistance being scarcely affected by variation in the applied potential difference or by alternating changes of temp.; furthermore, the application of a magnetic field made relatively little difference in the resistance, although this was diminished by compressive stress. C. W. Heaps found that for a magnetic field of strength 4000 to 5000 gauss, the ratio dR/R attains a maximum. T. W. Case observed no change in the electrical resistance on exposure to light. The electrical resistance of compressed powders was

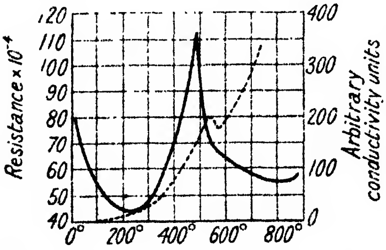

FIG. 515.—The Effect of Temperature on the Electrical Resistance of Magnetite.

measured by J. Königsberger and K. Reichenheim, F. Streintz, S. Veil, R. von Hasslinger, J. Königsberger, B. Young, E. Renschler, and C. C. Bidwell. R. von Hasslinger inferred that with artificial ferrosic oxide, the conductivity at high temp. is electrolytic; but C. Doelter said that the conductivity is electronic, *i.e.* metallic, both at ordinary and at elevated temp. The subject was discussed by O. Lehmann, J. Königsberger and co-workers, R. von Hasslinger, W. Nernst, and S. Veil.

Some observations on the **thermoelectric force** of magnetite were made by T. J. Seebeck, and W. G. Hankel. J. Weiss and J. Königsberger found that the thermoelectric force of magnetite against copper is 6×10^{-5} volt per degree, so that the current flows through the warm junction to the copper. S. L. Brown and L. O. Shuddemagen represented the results for the Fe : Fe_3O_4 couple by $E=0{\cdot}427(\theta-20)$; and they found the thermoelectric force of the couples of magnetite with iron, copper, and cuprous oxide to be:

	Fe			Cu			Cu_2O		
Hot junction .	90°	517°	639°	102°	315°	550°	92°	312°	650°
Voltage . .	0·030	0·211	0·300	0·035	0·125	0·225	0·112	0·405	0·770

C. Féry also measured the thermal e.m.f. of magnetite against iron; and C. C. Bidwell, against platinum—at 200°, the temp. coeff. of the e.m.f. was −0·00005 volt per degree; and in the curve representing the effect of temp., there is a transformation point between 700° and 800°.

P. Béchtereff found the **electromotive force** of the cell with molten sodium hydroxide $Fe_3O_4 \mid NaOH + KMnO_4 \mid C$ rises with temp. up to 0·9 volt, and then gradually falls as the mixture approaches its b.p. C. A. L. de Bruyn observed that the e.m.f. of the cell $Fe_3O_4 \mid 0{\cdot}1N\text{-}Fe^{\cdot\cdot}SO_4 + Fe^{\cdot\cdot\cdot}{}_2(SO_4)_3 \mid N\text{-}KCl,Hg_2Cl_2 \mid Hg$ is a little less than the observed value for platinum. The results are:

$Fe^{\cdot\cdot}$ . .	67·5	48·5	36	16	1 per cent.
$Fe^{\cdot\cdot\cdot}$ . .	32·5	51·5	64	84	99 ,, ,,
E . .	0·334	0·366	0·378	0·401	0·480 volt.

G. Tammann also made some observations with magnetite containing some hæmatite, and found for the cell $Fe_3O_4 \mid 4N\text{-}ZnSO_4 \mid Zn$, 1·20 volt; $Fe_3O_4 \mid PbCl_2$ sat. soln. $\mid Pb$, 0·60 volt; $Fe_3O_4 \mid 2N\text{-}CuSO_4 \mid Cu$, 0·14 volt; and $Fe_3O_4 \mid Ag_2SO_4$ sat. soln.$\mid Ag$, 0·03 volt. H. Bäckström observed that while the electrical conductivity of magnetite is isotropic, different **electrode potentials** are developed by the contact of different faces of a crystal with electrolytes, and consequently different faces of the crystal in the electrolyte set up a difference of potential and an electric current results. A. von Hansen also found that an octahedral face is negative towards a cubic face. Irregular results were obtained using different concentrations of hydrochloric or sulphuric acid. W. D. Treadwell found the potential, *E* volt, of ferrous oxide against ferrosic oxide from measurements of the cell $FeO,Fe_3O_4 \mid$ electrolyte $\mid O_2$, to be:

	875°	950°	970°	980°	1000°	1010°	1020°	1090°	1100°
E . .	0·967	0·898	0·915	0·927	0·897	0·880	0·890	0·856	0·838

E. Baur and co-workers, working with the cell $FeO,Fe_3O_4 \mid$ electrolyte $\mid CuO,Cu_2O$, obtained $E=0{\cdot}9$ volt at 900°. Calculations based on equilibrium data in an atm. of hydrogen and steam were made by E. Baur and A. Glässner, G. Chaudron, G. Preuner, W. D. Treadwell, and L. Wöhler and R. Günther. R. C. Wells measured the electrode potential of magnetite in *N*-soln. of sulphuric acid, and found 0·91 volt; potassium chloride, 0·40 volt; and sodium hydroxide, −0·22 volt; P. Béchtereff found the potential of magnetite against molten sodium hydroxide to be the same as that of iron, cobalt, nickel, platinum, gold, silver, copper, and constantan between 330° and 650°. This is taken to mean that the observed result is a gas potential and not the potential of ferrosic oxide. E. Renschler studied the behaviour of ferrosic oxide electrodes and found that as a cathode the oxide behaves similarly to iron, but as anode it is characterized by a lower potential. In the electrolysis of ammonium sulphate and sodium chlorate—for the preparation of persulphate or perchlorate—the yields with the ferrosic oxide anode are very small, and in this respect the behaviour resembles that of platinized platinum; and in the electrolysis of a soln. of ammonium sulphate, the electrode is attacked. In the electrolysis of iodide soln., the behaviour is very like that of platinum; with bromide soln., the yield is less than with platinum; and with chloride soln., without a diaphragm, the yield is smaller than with platinum, and falls below 66 per cent. If the electrodes are smooth, the yields are higher; and if rough, the electrode is strongly attacked and the current efficiency is reduced. The oxygen over-voltage measured by H. C. Howard is in normal sodium chlorate soln. 0·4 to 0·6 volt less than is the case with platinum. B. la Croix von Langenheim said that in a 16 per cent. soln. of sodium hydroxide, a magnetite cathode is slowly reduced. Observations were made by P. P. Fedotéeff, and K. Elbs.

Magnetite shows the property of ferromagnetism to a marked degree *vide supra*, iron. A. L. Hölz[14] stated that in a strong magnetic field, the ratio of the permanent **magnetism** of magnetite to that of glass-hard steel is as 1·5 : 1; and A. Abt gave 1·82 : 1 to 2·21 : 1. Observations were made by C. B. Greiss, F. F. Hornstein, and G. A. Kenngott. P. Weiss found the saturation intensity of magnetization ranges from 435 to 469 gauss. H. E. J. G. du Bois obtained a limit to the intensity of magnetization, I=350, showing that saturation is complete when the magnetizing force H=1·500. V. Quittner gave I_∞=482 gauss; P. D. Foote, 290 gauss; S. Loria, 360 gauss. For artificial ferrosic oxide, P. Weiss gave 476·5 gauss; S. Loria, 450 gauss; and A. Droz, 455 gauss. A. Droz, and P. Weiss obtained different values for the saturation value of the intensity of magnetization with crystals sectioned about different axes of symmetry. P. Weiss and H. K. Onnes found the saturation intensity at −257·2° to be 90·75 gauss; and at −253°, 95·9 gauss. The subject was investigated by P. Weiss, W. Kopp, W. Lenz, and W. H. Keesom. L. A. Welo found that the remanent magnetism increases under press., so that at 1200 atm. and a field-strength of 40 gauss, there is a 45 to 50 per cent. increase. H. E. J. G. du Bois also observed:

Magnetic force, H	500	1000	2000	1200
Intensity of magnetization, I . .	325	345	350	350
Induction, B	8361	9041	10,084	20,084
Permeability μ	16·7	9·0	5·0	1·7

E. Wilson and E. F. Herroun observed that with a field-strength of H=55 gauss, the maximum permeability, μ=35; the coercive force, H_c=20·7 gauss; and the remanent induction, B_r=1168 gauss; for compressed powder, the permeability, μ, attains a maximum of 9·16 with H=103. C. W. Heaps found the permeability of a magnetite crystal ranged between 1·2 to 1·38 as the field-strength was raised to 5000 gauss. Magnetite with a high maximum susceptibility may give a smaller remanence than samples with a smaller maximum susceptibility. Observations were made by A. Abt, E. Becquerel, J. C. Stearns, G. R. Wait, L. F. Bley, J. Donau, P. Elias, C. B. Greiss, and A. L. Holz. For the hysteresis loops of magnetite, by R. B. Sosman and E. Posnjak, *vide* Fig. 526. The relation between the remanence of remanent magnetism, B, and the field strength, H, is illustrated by Fig. 516, with that for nickel for comparison. C. W. Heaps studied the Barhausen effect; and T. D. Yensen, the magnetization of thin films.

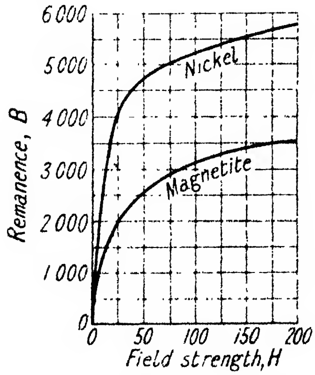

FIG. 516.—Field-strength—Remanence Curve for Magnetite.

M. C. Bandy supposed that loadstone has been formed by lightning striking outcrops of magnetite ore. H. Forestier observed that the remanence of natural and artificial magnetite is increased after heating and cooling. P. Erman, M. Faraday, W. M. Mordey, and E. Colardeau made some observations on this subject. J. Kunz discussed the magnetic moment of the elementary magnets. G. R. Wait studied the permeability of magnetite in alternating fields of high frequency; V. Quittner, the magnetic hysteresis, and A. Perrier, the effect of temp. on the hysteresis. The relation between the magnetization and the strength of the field was measured by C. Benedicks, G. G. Bring, and H. Nathorst. R. Chevallier observed that with artificial ferrosic oxide, the intensity of magnetization, *I* gauss:

Field-strength, *H*		0	60	120	180	195	gauss
I	increasing, *H*	0	3	7·7	12·6	13·8	,,
	decreasing, *H*	2·3	6·2	9·9	13·2	13·8	,,

F. Stutzer and co-workers gave $75\cdot00\times10^{-6}$ to $97\cdot35\times10^{-6}$ for the coeff. of magnetization of magnetite; E. Wilson and E. F. Herroun found the susceptibility to be 300×10^{-6} to 615×10^{-6}; and W. R. Crane, 37×10^{-6}. H. Wilde attributed the apparent increase in magnetism on raising the temp., to a surface resistance which disappears on raising the temp., on increasing the magnetizing force, or on diminishing the mass of the substance. The magnetic susceptibility of magnetite is dependent on the field-strength, *H*, and E. Wilson and E. F. Herroun observed that the change is greater the larger the susceptibility. E. Holm investigated this subject; and W. Sucksmith, and J. W. Fisher studied the gyromagnetic effect obtained when the magnetization of magnetite is conducted in a rotary field. M. Faraday, P. Erman, and E. Becquerel observed that at a red-heat, the magnetism of magnetite is lost, but is restored again on cooling. F. Rinne showed that the magnetizability of magnetite gradually rises with increasing temp. and then suddenly falls; whilst on cooling, the phenomena are reversed. P. Curie found that there is an inversion in the magnetic susceptibility of magnetite at about 535°; E. H. Barton and W. Williams said 557°; F. Rinne, 575°; H. E. J. G. du Bois, 555°; J. Huggett and G. Chaudron, 570°; S. Veil, 550°; P. Weiss and P. N. Beck, 580° and 588°; P. Weiss, A. Piccard and A. Carrard, 593·5°; P. Weiss, A. Piccard and A. Carrard, 593°; Chemische Fabrik Griesheim-Elektron, 585°; P. Weiss and G. Foëx, 581°; S. Wologdine, 525°; G. E. Allan, 550°; T. Ishiwara 580° for the natural and 510° for artificial magnetite; and H. Takagi, 515° for natural material. R. Forrer studied the subject. K. Honda and T. Sone's value, 690°, refers to an artificial sample with much ferric oxide; for natural magnetite they gave 580°. The actual temp. is influenced by the magnitude of the induction or of the magnetizing force. Attempts have been made to detect discontinuities in other physical properties at the Curie point. P. Chévenard observed a break in the thermal expansion curve of magnetite at about 570°, and G. Chaudron and H. Forestier, a similar one with ferrosic oxide; G. E. Allan observed a thermal effect accompanying the magnetic transformation; and J. Königsberger and K. Schilling found a break in the electrical conductivity curve of magnetite near 530°. S. Veil also made observations on this subject; L. F. Bates, J. R. Ashworth, and L. A. Welo and O. Baudisch studied the relation between the Curie point and the intensity of magnetization; and G. R. Wait, the permeability in oscillating fields.

The reciprocal of the magnetic susceptibility, χ, when plotted against the absolute temp., T, usually gives a straight line, $C=\chi(T-\theta)$, where θ denotes the *Curie point*, or the temp. of magnetic inversion; C is called the *Curie constant*. P. Curie found that between 850° and 1360°, the magnetic susceptibility, χ, decreases regularly with a rise of temp., $T°$, so that $\chi\times10^6=28,000T^{-1}$. According to P. Weiss and G. Foëx, when the results are plotted, the curve consists of a series of four straight lines:

	581° to 622°	622° to 680°	680° to 710°	710° to 770°	770° to 900°	900° to 1360°
Curie point .	581	558	—	433	194	0
Curie constant .	0·00445	0·00682	—	0·0105	0·0180	0·028

P. Weiss argued that wherever the line changed direction, a new form of magnetite is responsible for some other physical change. No other investigator has noticed changes in other physical properties corresponding with those for the magnetic change reported by P. Weiss. P. Curie's curve shows no sharp change in direction. The following is a selection from the data :

	−138°	−21·5°	19°	215°	610°	627°	656°	913°	1332°
$\chi \times 10^6$	22·1	36·8	37·6	37·0	50·2	45·0	31·0	13·8	10·6

By the method of treatment, the samples must have been converted into ferric oxide before the measurement was made. The critical temp. of inversion is not sharply defined. Observations were also made by H. Takagi. L. H. Adams and J. W. Green found that pressure has no perceptible influence on the critical temp. The passage from the ferromagnetic to the paramagnetic state was formerly thought to be accompanied by a sharp discontinuity. The results of P. Weiss and P. N. Beck show that the change is not abrupt. Actually, the intensity does not fall to zero, but rather to a low, nearly constant value. The susceptibility is reversible ; but between 920° and 680°, the susceptibility on the cooling curve is rather less than on the heating curve. C. H. Li found that the magnetic properties changed abruptly at −160°, the temp. at which R. W. Miller observed that the thermal capacity suddenly increases to a maximum.

J. Hugget and G. Chaudron found the transformation point on the temperature-magnetization curve of magnetite occurs at 570°, there are anomalies when the magnetite is heated in air owing to superficial oxidation. There is the irreversible Curie point at 570°. If magnetite be heated in air at 330° it forms an unstable, strongly magnetic compound with a composition between Fe_2O_3 and Fe_3O_4. Martite and oligist are unstable at 570° and 675°. K. Renger observed that the effect of a magnetic field of H gauss on the transformation temp. θ, is $\theta = 563 + 0{\cdot}08H$, and P. Weiss gave

H . . .	0	1438	2903	5094	8144	10,430	11,930
θ . . .	563°	566°	567·5°	569°	570·4°	571°	572°

R. Forrer observed that, at −153°, magnetite has a singular change of state which manifests itself by a discontinuous variation in magnetization due to an abrupt decrease in the coeff. of magnetic hardness. It does not affect the magnetic moment, or the law of thermal variation of saturation. T. Okamura studied the phenomenon at low temp. W. Sucksmith and H. H. Potter discussed the P. Weiss relation between the sp. ht. and the magnetization of magnetite ; and J. R. Ashworth, the application of an equation of state—*vide* iron. K. T. Compton and E. A. Trousdale, and A. H. Compton and O. Rognley showed that no change in the structure of single crystals occurs in a strong magnetic field. E. Wedekind, and E. Wilson and E. F. Herroun studied this subject ; and P. Weiss the residual magnetism. Y. Kato and T. Takei made magnets of iron oxide.

S. Hilpert and J. Beyer prepared mixtures of ferrosic and ferrous oxides, which were non-magnetic, by reducing ferric oxide in a stream of hydrogen and steam at 400° to 1100°. No crystalline structure was observed in the black masses. The higher the proportion of contained ferrous oxide, the more rapid the dissolution in acids. The magnetic susceptibility fell to zero with proportions of ferrous oxide approximating 74 per cent. of ferrous oxide. It is considered that when all the ferrosic oxide is in solid soln. in the ferrous oxide, it loses its ferromagnetism. This is in agreement with the failure of the X-radiograms to detect ferrosic oxide in the mixture. The bend in the curve with between 20 and 25 per cent., say 21·5 per cent., of ferrous oxide probably represents a sat. solid soln. of ferrous in ferrosic oxide. The complex $2FeO.Fe_2O_3$ occurs at 23·6 per cent. of ferrous oxide. W. Borchers found that the ferrous and cuprous sulphides in copper mattes reduces the ferric oxide as far as $2FeO.Fe_2O_3$. A solid soln. with 74 per cent. of ferrous oxide is hence taken to represent a sat. soln. of Fe_3O_4 in FeO at about 1000°. The kink in the curve with 61 per cent. of FeO, corresponding with $6FeO.Fe_2O_3$, may have no significance. J. Huggett and G. Chaudron partially reduced ferric oxide in hydrogen, and homogenized the samples by heating them for 30 hrs. at 650°. The products containing ferrous oxide split up with ferrosic oxide and iron near 300° ; at 575°, a magnetic anomaly occurred owing to the Curie point of magnetite ; at about 600°, the decomposition components of the ferrous oxide recombined so that another magnetic anomaly occurred. P. Weiss and G. Foëx observed a faint trace of magnetism in artificial ferrosic oxide up to 678°, but R. B. Sosman attributed this to the presence of a little magnetic ferric oxide produced by the oxidation of the magnetite. H. Takagi did not obtain a discontinuity in some samples of magnetite when heated between 600° and 900°. H. Sachse studied the magnetizability of ferrosic oxide dispersed in alumina, silica, or strontium sulphate.

Lord Kelvin (W. Thomson) found that crystals belonging to the cubic system are magnetically isotropic, but this is not the case with magnetite, for the crystals are magnetically anisotropic. According to P. Weiss, the magnetic permeability of magnetization varies with the inclination of the magnetizing field to the crystallographic axis ; thus, the results with rods cut parallel to the axes (111), (110), and (100), or parallel to the cube, octahedron, and rhombic dodecahedron faces, expressed in c.g.s. units, for an external field *H*, a total magnetism *I*, and a remanence B_r, are :

(111)	*H* . .	22·9	43·3	79·1	146·2	239·3	326·8	436·0
	I . .	172·4	263·8	347·0	399·0	414·3	418·2	422·2
	B . .	49·6	61·0	70·5	75·9	75·6	75·6	75·2
(110)	*H* . .	19·7	38·4	75·0	144·5	238·1	316·5	499·6
	I . .	162·2	249·3	323·0	376·6	392·1	403·8	410·1
	B . .	40·5	50·8	58·6	63·4	63·7	64·6	65·6
(100)	*H* . .	18·1	39·8	78·4	151·9	251·7	342·4	435·6
	I . .	174·1	233·4	271·3	307·5	340·6	365·2	387·0
	B . .	61·6	74·0	83·6	89·3	89·7	90·6	89·3

These results show that magnetite is magnetically anisotropic. The ælotropic magnetic properties of magnetite show that the theories which regard magnetization as resulting from the orientation of particles of fixed magnetic moment are not sufficient to explain the magnetization of crystalline bodies. The subject was discussed by V. Quittner, J. Beckenkamp, W. Voigt, J. Kunz, S. Sano, C. H. Li, W. Peddie, F. Wallerant, K. Honda and J. Okubo, G. R. Wait, A. Droz, and B. Bavink. J. C. Stearns tried unsuccessfully to detect a change in the intensity of the X-ray beam reflected from a crystal of magnetite when under the influence of a magnetic field. He concluded that electrons revolving in orbits within the atom cannot account for ferromagnetism.

C. W. Heaps and J. Taylor observed the Barkhausen effect with dark-coloured magnetite showing well-developed cleavage planes, but not with specimens showing rounded corners, and uneven faces. The subject was discussed by J. Beckenkamp, and W. Voigt. Observations were also made by B. Bavink, F. Rinne, A. Droz, V. Quittner, E. Wilson and E. F. Herroun, and E. Wilson—*vide supra*, the formation of magnetite in bricks, etc. For the hysteresis loop, see Fig. 291.

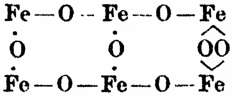
E. Wilson observed that with tensile stresses up to 130 kgrms. per sq. mm. in a given field, the susceptibility of magnetite at first increases with stress, decreases, and then it exhibits a reversal as in the case of iron. The magnetic force at which the percentage increase in permeability has a maximum value is less than the force for which the maximum susceptibility occurs. I. Kruckenberg observed no proportionality between the change in length, *dl*/*l*, of magnetite and the permeability. According to K. Yamada, the coercive force of magnetite is greater than that of soft iron ; and the intensity of magnetization is about half that of nickel. The hysteresis resembles that of iron in weak fields. The energy dissipated during a cycle for $H=+288$ is about 54,400 ergs. The change of length in weak fields is slow, but goes on increasing at a steady rate, so that the maximum elongation was not attained with several hundred gauss.

C. W. Heaps found that the magnetostriction of an octahedral crystal of magnetite along the three axes, with field-strengths, H, up to 5000 gauss, gave curves which were all similar in form—first convex towards the H-axis, and then concave, tending towards a maximum near 5000 gauss. With a longitudinal field of 5000 gauss, the diagonal axis expands 30×10^{-4} per cent., the trigonal axis, 12×10^{-4} per cent.; and the tetragonal axis contracts 4×10^{-4} per cent. With an equal transverse field, the percentage changes are a contraction of the diagonal axis of 44×10^{-4} per cent., a contraction of the trigonal axis of 28×10^{-4} per cent., and an expansion of the tetragonal axis of 4×10^{-4} per cent. respectively. The effect perpendicular to a plane is independent of the direction of the field in that plane. No departure from cubic symmetry was established. The magnetostriction curve is supposed to be the resultant of two superposed effects, and the Villari reversal probably a consequence of the heterogeneous crystal arrangement in the iron. F. Gross said that since ferrosic oxide is the only magnetic oxide of iron, it is not improbable that the magnetic properties of iron in general are due to the presence of the atomic group:

A. Krause and J. Tulecki attributed the magnetic properties to the presence of the group:

$$--\mathrm{Fe}{<}{}^{\mathrm{O}}_{\mathrm{O}}{>}\mathrm{Fe}--$$

and represented the constitution (*vide* γ—Fe_2O_3):



Magnetite crystals are sometimes magnetically polarized, and they form strong permanent magnets; indeed, the history of magnetism is closely associated with the discovery of the lodestone by the ancients. On the other hand, most natural magnetite is not polarized; and the cause is unknown. The natural magnetite which possesses polarity like a magnetic needle, or magnet, is called *loadstone*. There are all gradations between ordinary magnetite with little or no polarity, and that in which a fragment will pick up large iron nails. W. H. Newhouse and W. H. Callahan, and W. H. Newhouse suggested the loadstone is generally formed from oxidized magnetite—ferromagnetic ferric oxide—which possesses a higher remanence than ordinary magnetite—ferro-ferric oxide. The polarity is further supposed to have been induced by a concentration of the earth's field chiefly at the ends of an ore body, but occasionally at points within magnetite ore bodies due to irregularities of mineralization or the faulting. J. W. Gruner does not agree with this conclusion, and added that no brownish oxidized ore was observed by himself, or by P. Ramdohr, or F. F. Osborne. The polar magnetism of magnetite was studied by T. L. Walker, and F. Hornstein. W. Sucksmith found the ratio for the gyromagnetic effect to be about 0·495—*vide supra*, the magnetism of iron.

As previously indicated, S. Hilpert assumed that the magnetic qualities of magnetite, regarded as ferrous ferrite, $FeO.Fe_2O_3$, and of other ferrites are dependent on the presence of the acid anhydride, Fe_2O_3. E. Take assumed that the magnetic properties of Heusler's non-ferrous alloys depend on the spacing and arrangement of the atoms; J. Forrest, and R. B. Sosman also assumed that with magnetite, ferromagnetic ferric oxide, and iron, the magnetic properties are bound up with the spacing and arrangement of the iron atoms without regard to the other atoms present. The argument is mainly based on the inversion temp. at which the magnetism in all these substances is lost. A. H. Compton and O. Rognley observed that magnetization and demagnetization have no effect on the crystal structure of magnetite. J. R. Ashworth studied the relations between the thermal and magnetic constants; and K. Gosh, the relation between the electrical conductivity and magnetism.

The chemical properties of ferrosic oxide.—The transformation of magnetite in nature into hæmatite, martite, etc., has been discussed by J. Roth,[15] W. L. Uglow and F. F. Osborne, K. C. Berz, P. Jeremeieff, A. Lacroix, B. Stälhare and T. Malmberg, J. F. Williams, W. H. Newhouse, W. H. Newhouse and W. H. Callahan, L. H. Twenhofel, A. Reuss, and C. R. van Hise. The general characteristic of ferrosic oxide prepared at high temp. is its resistance to many chemical agents, and accordingly, W. G. Günther [16] proposed using it in chemical plants for resisting chemical reagents. According to J. L. Gay Lussac, magnetite is reduced to metal by **hydrogen** at all temp. above 400°, and generally at the same temp. as water is decomposed by iron, a reaction studied by H. V. Regnault, H. Fleissner and F. Duftschmid, W. Müller, and G. Gallo. According to F. Gläser, the reduction by hydrogen begins at about 305°. P. H. Emmett and J. F. Shultz gave for the equilibrium constant, K, of the reaction: $Fe_3O_4+H_2 \rightleftharpoons 3FeO+H_2O$, $K=p_{H_2O}/p_{H_2}=1{\cdot}18$ at 700°, and 2·37 at 800°. For W. Biltz and H. Müller's observations on the ratios $Fe_3O_4 : FeO$, and Fe_3O_4/Fe, *vide supra*, ferrous oxide. The reversible reaction with hydrogen has been previously discussed—and *vide infra*, ferric oxide. M. Tigerschiöld stated that above 800°, ferrosic oxide is more readily reduced by hydrogen, and below 800°, by carbon monoxide. A. de Hemptinne found that ferrosic oxide is reduced in an atm. of dry hydrogen in an electric discharge when the oxide is in contact with one of the electrodes. K. Hofmann emphasized the importance of surface phenomena in the reduction. The reduction of molten iron oxide by hydrogen was studied by J. Reese, M. Boistel, C. Adams, C. Kröger, and S. L. Madorsky; and P. H. Emmett and J. F. Shultz studied the system: $Fe_3O_4-H_2-Fe-H_2O$.

According to H. Moissan, ferrosic oxide prepared below 500° oxidizes to ferric oxide when heated to redness in **air**, but the oxide prepared at a high temp. is not so readily changed to ferric oxide. R. Ruer and M. Nakamoto found that ferrosic oxide at 1370° is completely converted to ferric oxide, but at 1400°, the ferric oxide begins to decompose. E. Greulich said that the upper limit is 1380°. K. Honda and T. Sone found that at 1100°, magnetite in air is converted into ferric oxide; and the change is completed at 1300°. They added that below 1300°, hæmatite is more stable than magnetite. The peculiar ferromagnetic properties of ferric oxide prepared by the oxidation of magnetite have been discussed by R. B. Sosman and E. Posnjek—*vide infra*, ferric oxide. G. Friedel found that if heated in air, magnetite can be converted into martite without losing its form. The temp. at which oxidation begins depends on the grain-size of the powder, and, as shown by F. Gläser, and H. Abraham and R. Planiol, the powder prepared at a low temp. may be pyrophoric. O. Mügge found that both the natural and artificial oxide are oxidized when heated for a long time. E. Greulich observed that when magnetite is heated in air, oxidation begins at about 400°, but the ferric oxide acts as a protective skin which retards the progress of the reaction, so that even at 1000°, only 95·6 per cent. was oxidized in 100 hrs. Above that, the rate of oxidation increases more rapidly, so that it is nearly complete in 2 hrs. at 1100°, and in 1 hr. at 1200°. Above 1380° no further reaction can occur, and at 1450° the product is no more oxidized than the original magnetite. This shows that ferric oxide breaks down into ferrosic oxide at these elevated temp. At 1500° to 1550°, the product had an excess of ferrous oxide, showing that the magnetite decomposes into ferrous oxide. W. Eitel discussed the reaction $2Fe_3O_4+\frac{1}{2}O_2 \rightleftharpoons 3Fe_2O_3$. J. W. Gruner observed that oxidation begins at 150° on the octahedral faces of the crystals. G. Gilbert supposed that magnetite may form ferric oxide by surface oxidation in hot, dry climates, but more usually, hydrated ferric oxide is formed. The subject was discussed by T. M. Broderick, J. W. Gruner, R. B. Sosman and J. C. Hostetter, L. H. Twenhofel, and P. A. Wagner. L. H. Twenhofel found that in the first oxidation of magnetite, the oxygen atoms are irregularly spaced within the magnetite lattice. A. Bickel and C. van Eweyk observed that a sample of magnetic oxide of iron retained its power to give the benzidine reaction after keeping in conductivity water for 5 months, another sample (ferrosic carbonate) which was originally non-magnetic but gave a powerful benzidine reaction, with similar treatment became unable to give the reaction.

A. Gorgeu found that boiling **water** does not attack ferrosic oxide, nor was any attack observed by steam at a bright red-heat—*vide supra*, reactions in the blast-furnace. R. Müller found that water, sat. with carbon dioxide at 3·5 atm. press., dissolved from two samples of magnetite respectively 0·307 per cent. and 2·428 per cent. of ferrous oxide in 50 days. J. W. Gruner found that in 77 days, peat-water dissolved 31 parts of iron per million from powdered magnetite; and in 182 days, 41 parts. H. D. Rankin converted magnetite into a soluble form by heating it to redness, and afterwards treating it under press. with alkali-lye.

H. Moissan found that **fluorine** does not act on magnetite in the cold, but at a dull red-heat, a white fluoride is formed. H. Davy observed that **chlorine** reacts on magnetite very much more quickly than it does on ferric oxide (*q.v.*) at a red-heat; but W. Kangro and R. Flügge did not agree. They observed that at 1000°, 99·4 per cent. of iron was removed as ferric chloride in 270 hrs. L. Mathesius found that an aq. soln. of **bromine** does not act on magnetite; and H. Moissan said that the oxide prepared by the reduction process does not decolorize an aq. soln. of **iodine** provided metallic iron is absent. E. Zalinsky found that an excess of **hydrofluoric acid**, acting for 20 hrs., dissolved magnetite completely; and K. F. Stahl added that magnetite is more readily dissolved by hydrofluoric acid than it is by any other acid. E. Deussen said that it requires 5 to 10 hrs. to dissolve hammer-slag, and if a longer time be allowed, less iron is dissolved owing to the formation of a sparingly-soluble oxyfluoride. The powdered mineral is also completely soluble in **hydrochloric acid**, and J. J. Berzelius said that if the mineral be in excess, and the acid dilute, ferrous oxide passes into soln., and red ferric oxide remains undissolved. According to A. Gorgeu, magnetite is not attacked by the dil. acid (1 : 10), but it is slowly attacked by the conc. acid; when some of the solid soln. approximating Fe_3O_4 are treated with hydrochloric acid, some ferrous oxide dissolves and ferric oxide remains. J. Liebig and F. Wöhler, and V. Neuwirth noted that magnetite does dissolve in hydrochloric acid; according to G. Gilbert, it dissolves more readily in a hot hydrochloric acid soln. of stannous chloride; and A. Damour noted that the presence of potassium iodide accelerates the rate of dissolution. According to K. A. Hofmann and K. Ritter, magnetite is not attacked by a soln. of **calcium hypochlorite.** E. Müller discussed the use of magnetite electrodes in preparing bleaching liquor by electrolysis. F. Leteur showed that magnetite is readily dissolved by heating it with conc. hydrochloric acid, sp. gr. 1·18, in a closed vessel at 65° to 70°. F. Becke studied the etching of magnetite with this acid.

J. J. Berzelius, and H. Rose observed that when the mineral is heated with **sulphur**, sulphur dioxide, and ferrous sulphide are formed. A. Gautier found that at a white-heat in a current of **hydrogen sulphide**, ferrous sulphide, hydrogen, sulphur dioxide, and a little sulphur trioxide are formed; and C. Doelter found that when magnetite is heated with an aq. soln. of hydrogen sulphide at 80° to 90°, some pyrite is formed. D. L. Hammick observed that there is no appreciable reaction with **sulphur dioxide** at a red-heat. According to H. Lotz, when a plate of magnetite is exposed to the action of moist air charged with 1 per cent. of sulphur dioxide and 19 per cent. of carbon dioxide, and the plate washed with water, the ferrous oxide was most vigorously attacked:

	MgO	CuO	MnO	FeO	Al_2O_3	Fe_2O_3
Magnetite contained .	2·47	1·64	9·32	24·24	8·47	53·93 per cent.
Water contained .	0·0728	0·0208	0·0008	0·3395	0·0232	0·0052

F. Becke studied the etching of magnetite with **sulphuric acid.** O. Mügge found that a crystal of magnetite is only slightly attacked by fused **potassium hydrosulphate,** near its m.p., but at a higher temp., the mineral is vigorously attacked. F. Becke studied the etching of the crystals with this salt.

U. Sborgi and E. Gagliardo found that **boron nitride** reacts with ferrosic oxide at 750°, forming nitric oxide. J. J. Berzelius noted the formation of nitrogenized iron when ferrosic oxide is heated in dry **ammonia;** and he also observed no change occurs when hammer-slag is located with an aq. soln. of ammonium chloride. A. T. Larson and A. P. Brooks observed that ferrosic oxide is a good catalyst for the synthesis of ammonia; and A. K. Brewer showed that photochemically, the catalyst has the same photoelectric threshold as electrolytic iron. F. Emich found that **nitric oxide** converts heated ferrosic oxide to ferric oxide.

G. Tammann and G. Bätz observed that precipitated **silica** begins to react with ferrosic oxide at 800°, and with quartz at 950°. As indicated in connection with the allotropism of ferrosic oxide, H. Moissan showed that the high temp. form of this oxide is almost insoluble in boiling, conc. **nitric acid,** while the low temp. form is soluble in the conc. acid but not in dil. acid. A. Gorgeu also found that the dil. acid (1 : 10) scarcely attacks ferrosic oxide until its temp. has been raised nearly to the b.p. The conc. acid attacks the oxide slowly. H. L. Heathcote said that ferrosic oxide is more soluble in conc. than in dil. nitric acid, for acid of sp. gr. 1·4, 1·3, and 1·15 dissolved respectively 0·02332, 0·01752, and 0·00124 grm. of ferrosic oxide per 10 c.c. of acid. F. Becke studied the etching of magnetite with this acid. A. Gorgeu found that ferrosic oxide is slowly attacked by **aqua regia.** G. Hawley found that only a little magnetite is dissolved by a boiling mixture of equal vols. of conc. nitric acid and a 15 per cent. aq. soln. of sodium chlorate.

According to P. Berthier, when magnetite is heated with **carbon** it is reduced to the metal—*vide supra,* the reactions in the blast-furnace. G. Tammann and A. Sworykin discussed the reaction with carbon. H. H. Meyer found that the reduction of ferrosic oxide by sugar charcoal begins at 760°; with wood charcoal, 900°. Ferrous oxide is formed at 860° with sugar charcoal; at 880° to 920°, with coke; at 690°, with wood charcoal, or at 900° if the wood charcoal has been first heated to 1000° in nitrogen. The reaction was studied by W. Baukloh and R. Durrer. J. Bökmann studied the reaction with **iron carbide:** $Fe_3O_4+3Fe_3C \rightleftharpoons 12Fe+2CO+CO_2$. O. Meyer and W. Eilender studied the reduction of magnetite with **methane.** C. Despretz, B. Stälhane and T. Malmberg, W. Müller, F. Göbel, H. Fleissner and F. Duftschmid, and F. Leplay and A. Laurent noted that **carbon monoxide** reduces red-hot ferrosic oxide to the metallic state, and carbon dioxide is formed, and conversely that red-hot iron is oxidized to ferrosic oxide by carbon dioxide and carbon monoxide is formed. The mean of A. C. Halferdahl's values for the free energy of the reaction $Fe_3O_4+CO=3FeO+CO_2$ is $-265113+79{,}383T$, and the triple point $4FeO=Fe_3O_4+Fe$ is near 572°. The free energy of magnetite at 25° is −241,950 cals. A. Laurent observed that a mixture of equal vols. of **carbon dioxide** and monoxide converts red-hot iron into ferrosic oxide. These balanced reactions have been previously discussed—*vide supra,* ferric oxide. E. K. Riedel studied the reduction of the oxide with water-gas. A. Gorgeu found that ferrosic oxide at a bright red-heat is not attacked by carbon dioxide. C. M. Bouton discussed the reaction with methane. H. Moissan observed that ferrosic oxide is not attacked by **acetic acid** at 8°; and H. C. Bolton found that it is not attacked in a short time by boiling conc. soln. of **citric acid** or **tartaric acid;** but conc. citric acid shows signs of attacking the oxide during 8 days' exposure. F. W. O. de Coninck and A. Raynaud found that at a dull red-heat, ferrosic oxide reacts with **calcium oxalate** to form ferrous oxide, calcium carbonate, and carbon dioxide

L. Kahlenberg and J. W. J. Trautmann studied the reaction with **silicon.** J. Lenarcic found that 1 part of magnetite dissolves in 20 parts by weight of molten **labradorite** at 1220°; and C. Doelter, that fused magnetite magma at 1200° to 1230° did not attack **corundum** and **quartz,** but **olivine, leucite,** and **orthoclase** were corroded. G. Tammann and G. Bätz said that ferrosic oxide does not react with silica until oxygen is given off to form ferrous oxide. J. H. L. Vogt said that continuous series of solid soln. are formed with **spinel** and magnetite with a eutectic on the f.p. curve with 3 per cent. of spinel. P. Ramdohr studied the action of ferrosic oxide on **ilmenite,** $FeTiO_3$.

J. L. Gay Lussac and L. J. Thénard, and J. J. Berzelius found that magnetite is reduced by **sodium** or **potassium** at about 300°, and iron is formed. B. Garre said that the reaction between ferrosic oxide and magnesium begins at 575°, and evolves 710·2 Cals. of heat. R. B. Sosman and J. C. Hostetter found that in contact with **platinum** at 1200°, iron is formed and oxygen is evolved—the iron forms a solid soln. with the platinum. P. Curie did not observe any attack on platinum by ferrosic oxide at a high temp. C. T. Anderson studied the reduction of ferrosic oxide by **iron** at 1350° to 1550°; and V. Shuleikin and X. Solovova, the radiation of heat in the thermite reaction with **aluminium.**

H. Moissan observed that **calcium oxide** at a high temp. converts ferrosic oxide into calcium ferrite; A. Gorgeu, that ferrosic oxide is oxidized by molten **sodium sulphate** without changing its crystalline form; and J. W. Gruner, that 4 months' exposure to molar soln. of **sodium chloride, sodium carbonate,** or **magnesium sulphate** does not change magnetite. For the action on **ferrous sulphide,** *vide infra;* for the action on **manganous sulphide,** *vide* **12.** 64, 21. W. O. Hickok studied the action of **stannous chloride;** H. von Wartenberg and E. Prophet, the action of the oxide on **magnesia;** and H. von Wartenberg and H. J. Reusch, the action of **alumina.**

The solubility relations between **ferrous oxide** and ferrosic oxide have been previously discussed. S. Hilpert and J. Beyer[17] first pointed out the existence of solid soln. of the two oxides. P. P. Fedotéeff and T. N. Petrenko assumed that a continuous series of solid soln. of the two oxides is formed when iron is oxidized by steam between 1000° and 1100°. R. W. G. Wyckoff and E. D. Crittenden observed no evidence in the X-radiograms of the formation of solid soln. of ferrous oxide in ferrosic oxide at ordinary temp.; the elementary cells of ferrous oxide appear to be enlarged a little in the presence of much ferrosic oxide. Under the microscope, the crystals of ferrosic oxide appear to be embedded in a eutectic mixture of ferrosic and probably ferrous oxide. H. Groebler and co-workers observed that the ferrous oxide obtained by reducing ferric oxide in a mixture of equal vols. of carbon monoxide and dioxide at 800° contains 39 per cent. of ferrosic oxide and the lattice dimensions of the ferrous oxide are not altered. This phenomenon is explained in terms of the hypothesis of G. F. Hüttig that the extra oxygen exists as vagabond atoms in the spaces in the lattice. The diagram, Fig. 517, based on the observations of E. D. Eastman and R. M. Evans, R. B. Sosman and J. C. Hostetter, R. Schenck, G. Chaudron, P. van Groningen, L. Wöhler and R. Günther, A. McCance, and A. Matsubara, enables the solubilities of ferrous oxide in ferrosic oxide, and of ferrosic oxide in ferrous oxide, to be tabulated. O. C. Ralston compiled the results of these and various other observers. J. Huggett and G. Chaudron gave 31 for the percentage proportion of Fe_3O_4 in FeO; R. Schenck gave for Fe_3O_4 and FeO, and FeO in Fe_3O_4, respectively 35 and 0 at 700°; E. D. Eastman and R. M. Evans, 32 and 6·35 at 772°; R. Schenck, 32 and 0·75 at 800°; and H. Groebler and P. Oberhoffer, 39 and 5 at 800°; A. Matsubara, 38 and 6·35 at 863°; R. Schenck, 28 and 19 at 950°; S. Hilpert and J. Beyer, 26 and 21·5 at 1000°; A. Matsubara, (51) and 15·7 at 1070°, and 26 and 6·35 at 1175°. The agreement is poor. The relations between ferrous and ferrosic oxides have been summarized in Figs. 20 to 31. The curves for the solubilities of ferrous oxide in ferrosic oxide, and conversely, should approach one another so that in the molten state the two oxides should have unlimited miscibility. The constitutional diagram of C. Benedicks and H. Löfquist, Fig. 486, shows the existence of an invariant point where iron and ferrous and ferrosic oxides can coexist; below that temp., iron and ferrosic oxide are present, and above it, on one side, ferrous oxide and iron are stable, whilst on the other side, ferrous and ferrosic oxides are stable. G. Chaudron, L. Wöhler and R. Günther, and E. D. Eastman and R. M. Evans gave 570° for the temp. of the univariant point; P. van Groningen gave 571°; and J. B. Ferguson, between 526° and 577°. G. Chaudron's magnetic measurements gave between 550° and 580°; G. Chaudron and H. Forestier's dilation measurements, 570°; and M. Tigerschiöld's calculations, based on A. Matsubara's observations, gave 534°.

R. Vogel and E. Martin studied the system: $FeO-Fe_3O_4$. L. B. Pfeil's study of the system: $FeO-Fe_2O_3$ is summarized in Fig. 517. The boundaries of the Fe_2O_3-phase have not been determined, and, as shown by R. B. Sosman and J. C. Hostetter, it is probable that dissociation occurs at high temp. to form magnetite. The solubility of iron in ferric oxide is represented by the *EO*, Fig. 517; *F* occurs near 72·2 per cent. of iron, and 1590°; *G*, at 72·6 per cent. of iron, and 1430°; and *GM* and *FN* indicate a decreasing solubility as far as about 1000°; *H*, at 75 per cent. of iron, and 1430°, represents the maximum solubility of oxygen; *D*, the eutectic of iron and ferrous oxide, at 77·28 per cent. of iron, and 1370°, is in accord with the observations of F. S. Tritton and D. Hanson, and the subject was studied by R. W. G. Wyckoff and E. D. Crittenden, A. McCance, and P. Oberhoffer and K. d'Huart; *I* represents the maximum solubility of iron, in ferrous oxide, and occurs at 76·9 per cent. of iron; *IL*, the solubility curve of iron in ferrous oxide, is vertical because no decrease in solubility could be detected between 1370° and 575°; *HL* represents the solubility of magnetite in ferrous oxide; and *ML*, at 575°, represents the transition curve for all specimens containing the ferrous phase. Specimens cooled rapidly from above 575° are very slowly attacked by conc. hydrochloric acid, and specimens cooled slowly are rapidly attacked by 0·1 per cent. hydrochloric acid. In both cases the ferrous phase is preferentially attacked. In agreement with G. Chaudron, A. Matsubara, and E. D. Eastman, the ferrous phase, in all cases, is unstable at about 575°, and below that temp. decomposes into a eutectoid of iron and ferrosic oxide. P. P. Fedotéeff and T. N. Petrenko made observations on solid soln. of ferric and ferrosic oxides. Unlike R. B. Sosman and J. C. Hostetter, G. Gilbert does not consider that a solid soln. is formed under geological conditions—*vide infra,* ferric oxide.

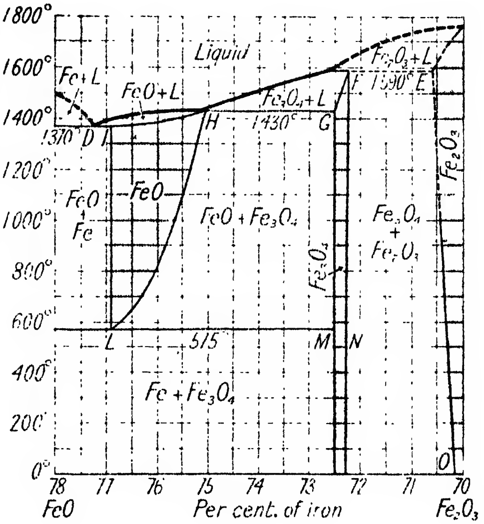


FIG. 517.—The System $FeO-Fe_2O_3$.

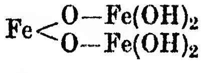
H. Wada found that active magnetic oxide administered to rabbits caused the urinary C : N ratio to increase considerably, the administration of the inactive oxide had only a slightly delayed effect.

As indicated above in connection with the preparation of ferrosic oxide, if white hydrated ferrous oxide be exposed to air, for a short time, or if a mixture of soln. of a ferrous and ferric salt be treated with alkali-lye, green **hydrated ferrosic oxide** is formed which, on exposure to air, ultimately passes into rusty brown hydrated ferric oxide. A. Ackermann,[18] E. Deiss and G. Schikorr, H. Ost, A. Payen, and N. J. B. G. Guibourt observed the formation of this hydrate by the action of aerated water on iron, when the hydrated ferrosic oxide appears as an intermediate stage of rusting. E. Ramann said that it is formed as a black film on iron when the metal is dipped in nitric acid or a soln. of some other oxidizing agent—*vide supra,* passivity. J. von Liebig and F. Wöhler, A. Krause, V. Paissakowitsch, O. Faust, and H. Chandra observed its formation in the oxidation of hydrated ferrous oxide, or of a lower oxide than Fe_3O_4, as indicated in connection with the action of air on ferrous hydroxide. M. Roloff, O. Faust, and V. Paissakowitsch noted its formation in the anodic oxidation of iron or ferrous hydroxide, in the presence of alkali-lye, or ammonia. According to J. von Liebig and F. Wöhler, F. Wöhler, H. Abich, J. Mercer, F. J. R. Carulla, C. F. Wülfing, W. Gregory, L. A. Welo and O. Baudisch, and S. Hilpert, if a hydrochloric acid soln. of magnetite, or a mixed soln. of ferrous and ferric salts in the molar proportion 1 : 1, be treated with alkali-lye, and washed, a black hydrated ferrosic oxide is formed. The mixed soln. of ferrous and ferric salts was obtained by mixing suitable proportions of soln. of the two salts; by mixing a certain proportion of nitric acid to the soln. of a ferrous salt—R. Phillips used potassium chlorate as the oxidizing agent, and L. A. Welo and O. Baudisch, potassium nitrate. J. Lefort recommended pouring the soln. of the mixed iron salts into an excess of boiling potash-lye. T. C. Estelle observed that ferrosic oxide can be hydrated by heating it with soda-lye as in the case of ferric oxide (*q.v.*). R. Böttger, and J. Noel recommended treating a soln. of ferrous sulphate with sodium carbonate, washing the precipitate once by decantation, and boiling it with conc. potash-lye. E. Soubeiran obtained by this process a precipitate which gave off carbon dioxide when treated with acids. According to E. Deiss and G. Schikorr, the brown liquid obtained by mixing ferrous and ferric hydroxide soln., rapidly changes to a green colour, and finally turns black with complete precipitation of the colloid. The green substance probably results from the combination of one molecule of ferrous hydroxide with one of ferric hydroxide, but attempts to isolate the compound have been unsuccessful. J. Preuss boiled a mixture of 4 parts of powdered iron and 5 parts of ferric oxide in water. Hydrogen is evolved, and the mixture becomes dark brown and finally black. The product is washed, wrapped in bibulous paper, and dried in hot air. The so-called *Eisenmohr*, *iron-black*, hydrated *æthiops martialis*, or *æthiops martialis Lemeryi*, was produced as a black powder, by L. Lémery, by exposing a mixture of iron filings and an excess of water for a long time in air, and frequently stirring the mixture. The light, black powder is collected from time to time. G. Cavezzali kept the iron filings moist for about 5 days, and obtained the black powder—*l'oxyde de fer noir*—by levigation. P. Sabatier and J. B. Senderens obtained the highly magnetic hydrate by the action of nitric oxide and moist air on iron; and H. Bollenbach and E. Luchmann, by boiling a strongly alkaline soln. of potassium ferricyanide and an excess of ferrous sulphate.

The composition of these products is variable, but in some cases approximates to hydrated ferrosic oxide, $Fe_3O_4.nH_2O$, where n may be 1 to 1·5. According to J. Lefort, when the precipitate is dried over calcium oxide and sulphuric acid, it approximates $Fe_3O_4.H_2O$; J. von Liebig and F. Wöhler gave $3Fe_3O_4.2H_2O$. The composition was discussed by L. A. Welo and O. Baudisch, and the constitution by O. Baudisch and P. Mayer, and E. Deiss and G. Schikorr. They represented the hydroxide formed by the simultaneous precipitation of a mixed soln. of equimolar parts of ferrous and ferrosic hydroxides as a hydrated ferrous hydroferrite: $Fe(OH)_2+Fe(OH)_3=H_2O+HO.Fe.O.Fe(OH)_2$, and in the presence of another molecular proportion of ferric hydroxide: $HO.Fe.O.Fe(OH)_2+Fe(OH)_3=H_2O+(HO)_2Fe.O.Fe.O.Fe(OH)_2$. Consequently, hydrated ferrosic oxide is considered to be a hydrated ferrous ferrite:



$$Fe\begin{matrix}\diagup O-Fe(OH)_2\\ \diagdown O-Fe(OH)_2\end{matrix}$$

According to F. Wöhler, the black hydrate forms, when dried, a brownish-black, brittle, strongly magnetic mass. J. Woost, and O. Faust measured the electrode potential of hydrated ferrosic oxide. J. von Liebig and F. Wöhler, J. Lefort, H. Abich, and N. J. B. G. Guibourt observed that the dry as well as the hydrated ferrosic oxide are equally magnetic; and A. Quartaroli added that the magnetic susceptibility of ferrosic oxide is a hundred times greater than that of the hydrated ferric oxide. L. A. Welo and O. Baudisch found that the magnetic permeability of the powder of sp. gr. 1·32, lies between 2·6 and 3·4; the remanent magnetism is about 8 per cent.; and the coercive force 14 gauss. Other preparations gave 34 per cent. remanent magnetism, and a coercive force of 149 gauss. Hydrated ferrosic oxide contains about 7 per cent. of water, which, according to J. Lefort, is given off at about 90°—*cf.* hydrated ferrous oxide.

J. von Liebig and F. Wöhler observed that hydrated ferrosic oxide is stable in air; whilst J. Lefort found that the moist oxide is slowly oxidized, but the dried oxide is stable. O. Faust, and L. A. Welo and O. Baudisch found that the hydrated oxide is apt to oxidize when it is being washed and dried. S. Hilpert said that it can be almost wholly dehydrated in vacuo over conc. sulphuric acid; and J. Lefort, F. Wöhler, S. Hilpert, and H. Abich added that when it is heated in the absence of air, all the water can be expelled. The precipitated hydrate cannot be dried by heat, because it readily oxidizes in air to form ferric oxide. F. Wöhler added that in the preparation of the hydrate, the iron does not reduce the ferric oxide directly, .but the reduction is effected by the nascent hydrogen produced by the action of the iron on the water. In the words of F. Wöhler, "the ferric oxide does not give up oxygen to the iron, but induces the decomposition of the water by its predisposing affinity for ferrous oxide"; and he added that zinc is not oxidized by boiling it with water and hydrated ferric oxide. The hydrates of alumina and chromic oxide do not oxidize the iron. F. Wöhler, J. Preuss, and J. Lefort observed that hydrated ferrosic oxide forms a yellow soln. when treated with hydrochloric acid; J. Lefort found that it is soluble in hydriodic acid; and in conc. sulphuric acid. S. Hilpert observed that the freshly precipitated hydrate is oxidized under water by persulphates. O. Faust said that the hydrate is not soluble in aq. ammonia in the presence of ammonium salts; E. Ramann, that it is readily soluble in dil. nitric acid, and but sparingly soluble in the conc. acid; and J. Lefort, that it is sparingly soluble in phosphoric acid, in arsenic acid, and in hydrocyanic acid, and soluble in acetic, oxalic, and tartaric acids. Some salts of ferrosic oxide regarded as a base have been reported—*vide infra.*

J. Lefort obtained a precipitate $6FeO.Fe_2O_3.4H_2O$ from a soln. of 6 eq. of ferrous sulphate and 1 eq. of ferric sulphate. O. Hauser, and H. Chandra obtained a hydrated ferrosic oxide by the action of a hot, conc. soln. of potassium hydroxide on ferrosic ammonium carbonate; when the product is dried at 100° its composition is $4FeO.Fe_2O_3.5H_2O$, or $Fe_6O_7.5H_2O$. It is readily acted on by air, yielding hydrated ferric oxide. A. Kaufmann, L. A. Welo and O. Baudisch, F. Haber, and H. Chandra also prepared the hydrated oxide $Fe_8O_{11}.nH_2O$, or $2FeO.3Fe_2O_3.nH_2O$, by adding 22 grms. of a 20 per cent. soln. of ammonia with 21 grms. of crystalline ferrous sulphate dissolved in 200 grms. of water, to the boiling soln. of 2·55 grms. of nitric acid, and boiling for 15 mins.—*vide supra* for the anhydrous oxide. J. Woost measured the potentials of the precipitated hydrates; and P. Fireman, F. J. R. Carulla, C. F. Wülfflng, A. Kaufmann, and F. Haber discussed the application of the hydrated oxide as a black pigment.

§ 30. Ferric Oxide

> Il fait dans un plus grand nombre de substances terreuses encore la fonction de principe colorant. On pourroit dire, du moins par rapport au règne minéral, que quand la nature prend le pinceau, c'est très-souvent le fer oxydé qui est sur la palette.—R. J. Haüy.

In his *Περί λίθων*, written 325 B.C., Theophrastus referred to **hæmatite,** or rather *αἱματίτης*—from *αἷμα*, blood—a mineral so named because it had the appearance of having been formed of concreted blood ; although, according to A. H. Baumgärtner,[1] and K. C. Schmieder, it is not certain if Theophrastus really referred to that mineral now known as hæmatite. The ancient Greek also described a second kind of hæmatite—*αἱματίτης ξανθή*—which had a yellowish-white colour, and which was probably a yellow ochre or limonite known for a long time as brown hæmatite. In the first century, Dioscorides, in his *Περί ὕλης ἰατρικῆς* (**5**. 143, *c.* 40), also mentioned the same mineral ; and Pliny, in his *Historia naturalis* (**36**. 25, 37, 38, *c.* 77), said that *hæmatites* is a stone of a blood-red colour which, when powdered, yields a tint like that of blood or of saffron. Pliny also said that *schistos* and *hæmatites* have a certain affinity. These varieties were discussed by A. Nies. Virgil, in his Æneid (**10**. 174), thus referred to the deposits of the mineral on the island of Elba—*Ilva . . . insula inexhaustis chalybum generosa metallis.* (Elba, an island distinguished by inexhaustible iron-mines.) Allusions to *hæmatites*, or *Blutstein* and *schistos*, or *Glasköpfe*, were described by G. Agricola, J. L. Bausch, and A. B. de Boodt.

J. G. Wallerius[2] described three varieties of this mineral : (i) *Minera ferri specularis* ; (ii) *Hæmatites ruber* ; and (iii) *Ochra tritura rubra—Speglande Eisen-*

glimmer ; R. J. Haüy, described (i) *Fer oxydé rouge ;* and (ii) *Fer oligiste ;* and J. B. L. Romé de l'Isle, (i) *hématite*, or *terre martiale en stalactites ;* and (ii) *Mine de fer grise* or *fer spéculaire.* Among the older mineralogists, the term hæmatite included fibrous, stalactitic, and other solid, massive varieties as well as limonite and turgite—*vide infra.* J. D. Dana gives the following classification of the main varieties of hæmatite: (i) *Specular hæmatite—specularite*—has a metallic lustre, and the crystals are often glossy or shining—hence the term *specular iron,* or *Eisenglanz,* or *oligiste.* When the structure is foliated, the mineral is called *micaceous hæmatite,* or *Eisenglimmer ;* and if the micaceous hæmatite is soft and unctuous, it is called *Eisenrahm.* The term *hæmatite* is also used for some of the less hydrated natural ferric oxides. W. L. von Eschwege, E. Hussak, F. Zirkel, W. Haidinger, and A. Pelikan called the mineral *specular schist,* or *itabiryte*—or *itabirite*—from Itabira, Brazil—is a schist—*Eisenglimmer-schiefer*—containing much specular hæmatite in grains or scales, or in the micaceous form. (ii) *Compact columnar hæmatite,* or *fibrous hæmatite,* occurs in radiating masses with a submetallic or metallic lustre, and coloured brownish-red to iron-black. It is also called *red hæmatite.* When it occurs in reniform masses with a smooth fracture, it is called *kidney ore, bloodstone, Glaskopf,* and *Eisenniere.* (iii) *Red ochre*—the *Rotheisenocker* of A. G. Werner—is a red, earthy variety. The so-called *reddle* or *ruddle, Röthel* or *Rothstein,* and *red chalk,* are varieties of red ochre mixed with more or less clay. (iv) *Clay ironstone—Thoneisenstein* or *argillaceous hæmatite* is brownish-black, reddish-brown or deep red, and hard; with a submetallic lustre or no lustre. It is mixed with more or less clay or sand. The reddish variety with a jasper-like texture is called *jaspery clay ironstone ;* and the variety occurring in minute, flattened concretions, *lenticular iron ore,* or *fossil ore*—according to A. F. Foerste, the *oolitic ore* from the Clinton group, Ohio—has the remains of bryozoan corals. According to A. Frenzel, A. Breithaupt called a variety of jaspery clay ironstone *jaspohämatite.*

The mineral is very widely diffused in nature ; it was analyzed by C. F. Bucholz,[3] and J. H. Hassenfratz. At first, the proportion of oxygen was regarded as variable —*e.g.*, by A. Breithaupt, R. Kirwan, and A. G. Werner. Analyses were reported by A. Schmidt, J. Loczka, A. Koch, J. Königsberger and O. Reichenheim, A. F. Brainerd, J. Königsberger, F. von Kobell, G. B. Hogenraad, C. F. Rammelsberg, M. Dittrich, R. Rohrer, A. Bergeat, M. F. Heddle, A. J. Moses, F. Zambonini, etc. Artificial preparations were analyzed by C. F. Bucholz, J. L. Gay Lussac, F. Stromeyer, J. J. Berzelius, T. Thomson, J. W. Döbereiner, J. Samsonowicz, and H. St. C. Deville. The results are in agreement with the formula for **ferric oxide,** or *iron sesquioxide,* Fe_2O_3. C. F. Rammelsberg, M. Dittrich, R. Rohrer, A. Schmidt, J. Loczka, and A. Koch found some crystals free from titanic oxide, but several others reported the presence of titanic oxide—J. J. Berzelius, H. Rose, F. von Kobell, L. J. Igelström found in some Swedish samples molybdenum, and thallium ; W. N. Hartley and H. Ramage observed spectroscopically in various samples, Rb, Na, Mn, Cu, Ag, Ca, Pb, Ga, In, Tl, and Ni.

The formation of ferric oxide from the colloidal or hydrated oxide, etc., has been discussed by J. M. van Bemmelen,[4] O. Ruff, H. Wölbling, H. W. Fischer, H. Stremme, L. Hugounenq and J. Loiseleur, F. F. Osborne, A. N. Zavaritsky, M. Godlewicz, G. W. Stose, E. C. Harder and T. C. Chamberlin, J. Johnston and E. D. Williamson, R. B. Sosman, and O. Mügge ; and its formation in nature by the oxidation of siderite, by H. Wölbling.

What might be called the accidental formation of ferric oxide has been noticed under various conditions in chemical and metallurgical processes. E. Mitscherlich [5] observed ferric oxide crystals in the masonry of a pottery oven where salt was used for the glazing; J. Knett, in salt-glazed stoneware—*vide infra, aventurine glazes ;* J. J. Nöggerath, in some clay of the Wieliczka salt-mine after some timber in the vicinity had been burned; F. Kuhlmann, and A. des Cloizeaux, ferric chlorides ; J. F. L. Hausmann, in the masonry of a blast-furnace in the Harz ;

J. B. J. D. Boussingault, in cavities in a furnace at Ria, Pyrénées-Orientales; F. von Hochstetter, A. Arzruni, H. Vater, C. F. Rammelsberg, and K. B. Doss, in the masonry of the sulphate-furnaces of soda-works of Hruschau, Silesia, and of Schönebeck, Magdeburg; and A. Krantz, in the remains of a fire in Hamburg. J. Knett observed that crystals of ferric oxide are formed in salt glazes; and W. G. Fearnsides, when the vapours from salty coals meet atmospheric air in the firebricks, and when damp iron-stone is calcined in the open by salty coal in the interior of the heap: and M. Bellière found the crystals on pottery in a salt-glazing kiln. A deposit of crystalline hæmatite is formed as a sublimate, covering all the surfaces fairly thickly, and cementing together the neighbouring iron-stone blocks just where the vapours from the interior meet the air. H. E. Merwin and J. C. Hostetter observed the formation of hæmatite crystals in the attempt to reduce the amount of iron in glass pots by passing chlorine into the covered pot for several hours at 1100°; where the effluent chlorine and ferric chloride vapour meets the air, crystals of hæmatite are formed. C. E. Munroe observed the formation of hæmatite in the iron pipes alternately carrying hydrogen chloride and air in Deacon's process for chlorine; W. Müller found hæmatite crystals in the residues obtained in the reduction of nitrobenzene to aniline. A. Payen found crystals of specular ferric oxide in the iron-rust of a building reputed to be 700 to 800 years old. The deposit of ferric oxide which appears on glass globes and reflectors of gas lamps is attributed by H. E. Roscoe and L. T. Thorne, H. Morton, and A. Guntz to the decomposition of traces of iron carbonyl in the gas which was formed from the iron used as desulphurizing agent.

The preparation of ferric oxide.—Ferric oxide is the end-product of the oxidation of iron, of its lower oxides or hydroxides, and of many of its salts. In some cases the product is well crystallized, and in other cases it appears as an amorphous powder, although J. A. Hedvall [6] pointed out that the oxide is always crystalline even when it appears as an impalpable powder. A. Arzruni has compiled a bibliography of the modes of preparing artificial crystals of hæmatite. As pointed out by E. L. Schubarth, the early chemists knew that when iron is roasted in air, it forms ferric oxide—*vide supra*. W. Günther, and D. Tassara described technical applications of the process of oxidation: and R. O. Snellenberger found that the presence of ferrous or cupric sulphate accelerates the oxidation of iron by air. P. Sabatier and J. B. Senderens observed that iron reduced by hydrogen at a low temp., when heated to 200°, burns with incandescence, forming ferric oxide; L. W. Winkler, P. P. Budnikoff, and W. Müller made analogous observations. Burnt, pyrophoric iron was found by J. A. Hedvall to yield ferric oxide when it is heated to 1000° in air. According to P. P. Fedotéeff and T. N. Petrenko, the end-product of the oxidation of iron in air at 1000° to 1100° is ferric oxide, and ferrous and ferrosic oxides are formed as intermediate products. C. N. A. de Haldat du Lys stated that steam acts on iron turnings at a red-heat, forming rhombohedral crystals of ferric oxide, but H. V. Regnault obtained ferrosic oxide, not ferric oxide, by this procedure. H. Arctowsky obtained crystals by the action of the vapour of ammonium chloride and air on red-hot iron. J. L. Gay Lussac passed the vapour of nitric acid over red-hot iron and obtained ferric oxide; P. Sabatier and J. B. Senderens found that iron, reduced by hydrogen below 400°, burns vigorously in contact with nitrogen peroxide, forming ferric oxide; and iron reduced at a dull red-heat requires heating to 340° for complete oxidation. F. Emich said that finely-divided iron heated in a current of nitric oxide forms ferric oxide, but at 200°, P. Sabatier and J. B. Senderens said that the product approximates to ferrous oxide. According to L. Hackspill and R. Grandadam, if iron is heated with alkali hydroxide, carbonate, nitrate, or sulphate in vacuo, it is oxidized to ferric oxide. S. Meunier found that large, glistening plates of ferric oxide are produced when an intimate mixture of potassium dichromate, ferrous carbonate, and iron (148; 58 : 56 grms.) is covered with a layer of cryolite and strongly heated in a crucible. L. Ott likewise obtained crystals by cooling a soln. of iron in molten sodium heptamolybdate. A. C. Becquerel covered an iron plate with a paste of lead chromate, then cemented thereon a glass plate so as to prevent the evaporation of water, and found that crystals of both ferric and ferrous oxides are formed as well as iron chromate and lead oxide. C. Monnett, and R. Lorenz obtained the hydrated oxide by using an iron anode in the electrolysis of a soln. of alkali chloride.

The lower oxides, and the hydrated oxides generally furnish ferric oxide when roasted in air. T. W. Richards and G. P. Baxter obtained the oxide of a high degree of purity for their at. wt. determinations by roasting the hydrate precipitated by ammonia from a soln. of the nitrate. Analogous processes were employed by A. F. Benton and P. H. Emmett, A. Simon and T. Schmidt, and C. R. A. Wright and A. P. Luff. C. Monnett also oxidized hydrated ferrous oxide. G. Friedel obtained ferric oxide pseudomorphous with magnetite by heating magnetite for several hours in the oxidizing blowpipe flame. J. Gill, and J. Laux oxidized magnetite. W. C. Hansen and L. T. Brownmiller observed that precipitated ferric oxide changes to hæmatite at 300°. The natural hæmatites contain a deficiency of oxygen eq. to 0·4 to 5·0 per cent. of ferrous oxide. Such a product requires heating in air for a long time before it takes up enough oxygen to approach ferric oxide in composition. E. Greulich found 1 hour's heating at 1200° will suffice, but at 1000°, 100 hrs. are necessary. O. Baudisch dissolved iron, derived from the carbonyl, in hydrochloric acid, and obtained γ-$Fe_2O_3.OH$, by autoxidation in the presence of pyridine. This on dehydration gave what he called *active iron*, γ-Fe_2O_3. C. M. Loane made the active oxide by the low temp. oxidation of pyrophoric iron.

A. Frenzel also heated in a covered crucible the hydrated oxide contaminated with much ammonium chloride and obtained rhombohedral crystals; and E. Millosevich observed the formation of the crystals around furmaroles emitting vapours of iron chloride. T. L. Phipson prepared crystals similar to those found on Vesuvius, by the action of the vapour of ammonium chloride on ferric oxide at a high temp. H. Arctowsky also obtained hæmatite crystals *de la plus grande beauté* in a similar way. W. Bruhns obtained red hexagonal plates by heating in a sealed tube a mixture of water, hydrated ferric oxide mixed with a little ammonium fluoride; C. Doelter, and G. Friedel obtained a similar crystal by working without the ammonium fluoride at 450° to 500°—at about 280°, powdered ferric oxide is formed. P. P. Budnikoff and K. E. Krause found that all the water is expelled from the hydrate at 650°. The preparation of ferric oxide by heating the hydrated oxide in various ways was described by H. and W. Pataky, J. Laux, H. F. Saunders, A. R. Davis, O. S. Neil, W. H. Giles and H. A. Wilson, R. and C. Steinau, G. Lunge and F. M. Lyte, J. Gill, P. Fireman, and J. F. N. Macay; and by heating the hydroxide with water, by N. M. Culloch, and T. Storer and C. J. A. Taylor. R. Willstätter and co-workers prepared ferric hydroxide from ferric ammonium alum, ammonia, and ammonium sulphate in weakly alkaline soln., and dried it by acetone. H. de Sénarmont heated hydrated ferric oxide suspended in water or in a sat. soln. of sodium or calcium chloride for 48 hrs. at 200°, or 8 days at 160° to 180°, and obtained ferric oxide as a red powder, by working at 300°; some tabular crystals were formed. Similar results were obtained by heating a soln. of ferric chloride with sodium or calcium carbonate; and H. N. Stokes, likewise, by heating pyrite or marcasite with alkali-lye. A. Vesterberg obtained pseudomorphs of ferric oxide after ferric sulphate by heating hydrated ferric oxide, prepared as a pseudomorph after ferric sulphate.

J. D. Hedvall prepared ferric oxide of different colours by roasting ferrous sulphide for 4 hrs. at 600°; pyrohotite for 10 hrs. at 700°; and marcasite for 6 hrs. at 700°. Likewise, also, by roasting ferrous sulphate for 9 hrs. at 700°; and ammonium ferrous sulphate for 5 hrs. at 700° and then 3 hrs. at 1000°. A. Gorgeu obtained ferric oxide crystals by heating ferrous or ferric sulphate or a mixture of the two in fused sodium sulphate. J. A. Reavell, and O. S. Neill obtained the oxide for use as a pigment in this way; and E. Mitscherlich, M. Lachaud and

C. Lepierre, and H. O. Hofman and W. Mostowitsch obtained crystals of hæmatite by roasting ferric sulphate, or ammonium ferrous sulphate. V. Rodt found that the hydroxide obtained by oxidizing hydrated ferrous or ferric sulphide is FeO(OH) and free sulphur, no FeS_2 is formed. If the product is heated to 210°, the oxide is ferromagnetic. A. Matthiessen and S. P. Szczepanowsky mixed purified ferrous sulphate and dried sodium sulphate in nearly equal proportions, and introduced it gradually into a red-hot platinum crucible. The mass was kept in fusion until the evolution of sulphur dioxide ceased. The crucible was then allowed to cool, and the fused mass extracted with water. If the temp. be properly regulated, the whole of the iron was left as a very fine crystalline oxide. This oxide was thoroughly washed by decantation in order to remove every trace of the sodium sulphate. C. F. Rammelsberg, and A. Ditte used sodium chloride in place of sodium sulphate. Processes involving the production of iron sulphates and the conversion of the sulphate to ferric oxide, so as, in some cases, to recover the sulphur, were described by R. Phillips, J. C. Heckman, E. A. Parnell, K. Shibata and T. Kohno, O. S. Neill, J. Leech and J. Neale, T. Terreil, C. V. Bacon, R. Vidal, C. A. Weeks, A. J. Moxham, J. McFetridge, M. N. d'Andria, E. F. J. Duclos, and A. Crossley and H. A. Allport. F. Wibel found that a soln. of copper and ferric sulphates, heated to 210° for 10 hrs., furnished scaly crystals of ferric oxide.

The various halides of iron furnish ferric oxide when heated in air or oxygen. J. L. Gay-Lussac heated molten ferrous chloride in a stream of oxygen and found that chlorine was evolved and ferric oxide formed ; with moist air in place of oxygen, some hydrogen chloride was also evolved. J. A. Hedvall found that 4 hrs. at 600°, or 1 hr. at 1000°, sufficed. A. Gorgeu heated ferrous chloride in a partially closed crucible, and obtained ferric oxide at a dull red-heat and ferrosic oxide at a bright red-heat. H. Schulze studied the reaction. A. Duboin prepared red plates of ferric oxide from a molten mixture of ferrous chloride, and potassium hydrofluoride and fluoride. J. A. Hedvall roasted ammonium ferrous chloride 4 hrs. at 600°, and obtained ferric oxide; and E. Stirnemann obtained microscopic, hexagonal plates by heating ferric oxychloride, FeOCl, at 450° in a sealed tube. J. L. Gay Lussac, and H. Schulze also obtained ferric oxide by heating ferric chloride in a current of oxygen; G. F Hüttig and H. Garside washed out any unchanged chloride with alcohol. T. Katsurai and T. Watanabe obtained crystals with the structure of hæmatite by heating a soln. of ferric chloride in an autoclave at 150°. J. L. Gay Lussac prepared crystals of ferric oxide resembling the so-called *sublimed hæmatite* found on the walls of the crater of Vesuvius, by decomposing heated ferric chloride by steam ; he assumed that the mineral is formed in nature by the action of steam on a mixture of sodium chloride and iron sulphate ; and that silicates in the presence of sodium chloride are decomposed by steam. R. Bunsen discussed the products; and E. Stirnemann, the process. M. Coppola, E. A. Parnell, E. W. Wescott, S. J. Levy and G. W. Gray, D. Tyrer, and P. Tschirwinsky also prepared the crystals by J. L. Gay Lussac's process. H. E. Merwin and J. C. Hostetter observed the formation of crystals of hæmatite in the removal of iron from fireclay pots at 1000° to 1100°. H. St. C. Deville found that amorphous ferric oxide becomes crystalline if it is heated to redness in a current of hydrogen chloride ; this is supposed to explain how crystals of ferric oxide have been formed in the cavities of volcanic lava. The habit of the crystals varies with the temp., and W. Bruhns obtained rhombohedral prisms of ferric oxide along with some ferrosic oxide by working at about 960°. P. Hautefeuille and A. Perrey passed a mixture of hydrogen chloride and steam over amorphous ferric oxide and obtained crystals resembling hæmatite. As indicated above, T. L. Phipson, A. Frenzel, G. A. Kenngott, and H. Arctowsky obtained crystals of the oxide by the action of the vapours of ammonium chloride on ferric oxide at a high temp. E. Weinschenk observed some ferric oxide crystals are formed in the synthesis of pyrites from a mixture of ferric oxide, sulphur, and ammonium chloride. A. Daubrée also obtained the crystals by the action of the vapour of ferric chloride on heated quicklime. J. M. van

Bemmelen and E. A. Klobbie thought that calcium ferrite is more likely to be produced. J. Durocher prepared the oxide by heating to redness a mixture of ferrous chloride and ammonium carbonate—some ferrosic oxide is formed at the same time; and M. Kuhara, by the action of soln. of iron chlorides or sulphates on carbonates or silicates at 100°—R. Klemm could not verify this. A. J. Evans, and E. Mitscherlich obtained ferric oxide by heating the nitrate; and A. F. Benton and P. H. Emmett recommended 135 hrs. at 525°; whilst J. A. Hedvall said the reaction is completed in 4 hrs. at 700°, and in 1½ hrs. at 1000°. T. W. Richards and G. P. Baxter said that the product is practically free from gas after being heated many hours at 900°. Dark red, finely powdered ferric oxide was obtained by F. K. Bell and W. A. Patrick by heating the basic nitrate 2 hrs. at 900°, and 1 hr. more at 900° after powdering the product. B. Lambert and J. C. Thomson heated the nitrate in iridium in preference to platinum vessels.

L. Brandt recommended the following process for preparing ferric oxide of a high degree of purity, and for use in the standardization of the soln. used in the volumetric determination of iron. H. Kinder said that the process does not remove phosphorus if it be present in the initial products.

Iron, as free as possible from phosphorus and cobalt, is dissolved in hydrochloric acid, and after dilution and precipitation with hydrogen sulphide, the filtrate is evaporated to a small vol., oxidized with nitric acid, evaporated to dryness with hydrochloric acid, dissolved in water, and extracted with ether, whereby an ethereal soln. of ferric and ferrous chlorides is obtained. The ether is distilled off and the residue, dissolved in a little dil. hydrochloric acid, is completely reduced with sulphur dioxide with the addition of a trace of iodine, and the clear ferrous chloride soln. precipitated with an excess of ammonium oxalate. The ferrous oxalate, after thorough washing, is finally ignited in quartz-glass vessels to constant weight.

G. Schmidt, J. Pelouze and E. Frémy, and F. Duftschmidt produced ferric oxide by roasting ferrous carbonate; and J. A. Hedvall added that 4 hrs. at about 700°, or 2 hrs. at 1000°, may suffice. O. L. Erdmann and R. F. Marchand, and O. Pattenhausen obtained finely divided ferric oxide by heating ferrous oxalate to redness in air or oxygen; A. Vogel recommended 200°; and H. Moissan, a dull red-heat. J. A. Hedvall discussed the effect of time and temp. on the colour of the product—*vide infra*. The process was also examined by T. W. Richards and G. P. Baxter, G. Frebold, H. Kinder, and L. Brandt—*vide supra*. J. M. Eder and E. Valenta recommended roasting ammonium ferric oxalate at 160° to 170°; J. A. Hedvall, ferric acetate for 6 hrs. at 700°, or 2 hrs. at 1000°. V. N. Ipatieff and W. Werchowsky precipitated ferric oxide from soln. of ferric acetate at 350° by hydrogen at 230 atm. press.; and at 400°, by hydrogen at 420 atm. press. L. Brandt, and A. Terreil obtained ferric oxide by roasting potassium ferrocyanide; V. N. Ipatieff and I. N. Kondyreff, by the action of hydrogen under press. on a soln. of ferric thiocyanate; and A. Mittasch and co-workers, by oxidizing iron carbonyl.

G. Rose, C. Doelter, and W. Florence observed that some six-sided plates of ferric oxide were formed when ferric oxide is heated with borax in the oxidizing flame of a blowpipe. C. von Hauer obtained crystals of hæmatite by heating a mixture of powdered ferric oxide and borax, and washing the product with hydrochloric acid. F. Fouqué and A. Michel-Lévy observed that ferric oxide crystals are often formed when ferruginous silicates are melted, but J. H. L. Vogt observed that crystals of ferric oxide are rarely, if ever, found in ordinary furnace slags. According to J. H. L. Vogt, and F. W. Clarke, ferric oxide can separate from silicate magmas only when ferrous compounds are either absent, or present only in subordinate proportions, because ferrous oxide unites with ferric oxide to form magnetite. Hence, magnetite is characteristic of rocks rich in ferromagnesian minerals, while hæmatite occurs chiefly in the more siliceous and felspathic granites, syenites, trachytes, rhyolites, andesites, and phonolites; and it is also found in the crystalline schists; magnetite, however, is the more common pyrogenic mineral. In igneous rocks, as F. W. Clarke has shown, ferrous oxide generally exceeds the ferric oxide—the proportions being roughly as 1·3 : 1·0, and this excess seems to determine the more frequent formation of magnetite. Ferric pyrite, and ferrous pyrrhotite appear to follow the same rule of association. J. Morozewicz also observed that ferric oxide is formed only in silicates with a low proportion of ferrous iron, and is produced by melting acidic rather than basic silicates.

Spangles of what is possibly ferric oxide are frequently developed in pottery glazes highly charged with ferric oxide; and when deliberately produced, the products are called *aventurine glazes*, *sunstone glazes*, etc., though aventurine effects are produced in glazes and glasses in other ways. In the case of glazes highly charged with ferric oxide, the firing temp. and rate of cooling are important factors in producing the effects. The subject was discussed by H. Mäckler, P. Ebell, L. Petrik, etc. The formation of ferric oxide in molten silicates was also examined by F. Angel, C. Doelter, V. Hämmerle, G. Medanich, J. Morozewicz, K. Petrasch, H. H. Reiter, and J. H. L. Vogt. F. Kuhlmann crystallized the oxide from molten calcium chloride; and F. Parmentier, from molten potassium molybdate. H. B. Kosmann described a deposit of strongly magnetic limonite at Harteberg, Silesia; the hydrated ferric oxide contained no ferrous oxide, and he ascribed the ferromagnetic property to a "peculiar molecular grouping." Ferromagnetic hæmatite occurs as a light chocolate-brown powder in the gossan deposit at the Iron Mountain, California, and M. Sarzeau, and J. L. Smith described minerals which may have been ferromagnetic ferric oxide, but the evidence is not clear. P. A. Wagner observed it near Johannesberg, South Africa, and the deposit was described by G. Gilbert. P. A. Wagner proposed to call it **maghemite.** The term *oxymagnite* was suggested by A. N. Winchell. G. Frebold and J. Hesemann believe that the ferromagnetic hæmatite is formed in nature only under a restricted supply of oxygen up to the temp. of 320°, whilst ordinary hæmatite is produced at a lower temp. J. Huggett observed that natural hæmatite and martites always contained some magnetic oxide.

J. Robbins described the preparation of a **ferromagnetic ferric oxide,** Fe_2O_3, by the oxidation of magnetite by heating it in air, or by fusing it with potassium nitrate. He showed that the product was free from ferrous iron, and that it could not in consequence owe its magnetic properties to the presence of ferrosic oxide, as is the case with ordinary magnetic hæmatite. The magnetic variety was also prepared by F. J. Malaguti by the oxidation with potassium chlorate of ferrous hydroxide and other hydrated iron oxide, and subsequent ignition. W. L. Dudley, O. Hauser, and A. Frenzel also obtained it by heating hydrated ferric oxide. A. Liversidge observed that some specimens of iron rust are ferromagnetic even when free from ferrous iron. This product was also obtained by E. F. Herroun and E. Wilson. R. Chevallier heated in air, at 350°, commercial, powdered, black magnetic oxide containing some free iron. H. Abraham and R. Planiol reduced ferric oxide with hydrogen or carbon monoxide at 500°, and obtained magnetite which on rapid re-oxidation at high temp. gives red, paramagnetic ferric oxide, but on slow oxidation in air at 200° to 250° gives yellowish-brown, strongly magnetic ferric oxide. R. B. Sosman and E. Posnjak prepared the ferromagnetic oxide by oxidizing precipitated ferrosic oxide, and also by dehydrating lepidocrocite, $Fe_2O_3.H_2O$, whilst they found that dehydrating goethite, Fe_2O_3,H_2O, gives only paramagnetic ferric oxide. J. Huggett obtained analogous results.

E. Wedekind and W. Albrecht concluded that the hydrated oxides are always more magnetic than the corresponding oxides; that in the range of 22 to 43 per cent. of water, the magnetic susceptibility decreases as the water of hydration increases; and that oxyhydrates, like artificial goethite, precipitated in the usual manner and heated in an autoclave, at various press., are ferromagnetic—*vide infra*, hydrated ferric oxide. This subject was discussed by E. F. Herroun and E. Wilson, G. Chaudron and A. Girard, G. Gilbert, W. H. Newhouse and W. H. Callahan, P. A. Wagner, W. H. Newhouse, and L. H. Twenhofel. L. A. Welo and O. Baudisch obtained the ferromagnetic oxide by precipitating hydrated ferric oxide from a soln.

of eq. proportions of ferrous and ferric sulphates, by means of an excess of a hot, conc. soln. of sodium hydroxide. The black precipitate is then washed, dried, and oxidized at 220° to 230° in air. O. Hauser, A. Kaufmann and F. Haber, and S. Hilpert prepared the ferromagnetic oxide by oxidizing magnetite, or ferrous hydroxide, with soluble, oxidizing agents. R. Chevallier treated conc. soln. of ferrous sulphate with an excess of sodium hydroxide, and oxidized the resulting ferrous hydroxide by hydrogen dioxide. The precipitated oxide was dried several weeks in vacuo. The more conc. the soln. of sodium hydroxide, and the greater the excess, the more highly magnetic was the resulting ferric oxide. The optimum temp. of precipitation was 45° to 50°; when the precipitation was made at a higher temp., the product was less magnetic. R. Chevallier added that these products lost their ferromagnetic qualities if heated to 100° for an hour, or to 200° for a few minutes, whereas the ordinary forms of ferromagnetic ferric oxide retain their magnetic qualities up to about 600°. O. C. Ralston considers that R. Chevallier produced some sodium ferrite, or ferrate, which contaminated his ferric oxide, and that the observed magnetism was due either to these products directly, or to their decomposition products. S. Veil obtained ferromagnetic ferric oxide by oxidizing ferrous sulphide suspended in water, and afterwards dehydrating the resulting hydrated ferric oxide; C. L. Jackson and J. H. Derby, by roasting ferrous iodide; L. V. Pratis, by heating a mush of ferrous sulphate obtained by the action of iron on dil. sulphuric acid; M. Sarzeau, by boiling a soln. of ferrous hydrocarbonate; F. Frankenburger and co-workers, by the action of water on lithium ferric nitride, Li_3FeN_2; F. J. Malaguti, and E. F. Herroun and E. Wilson, by roasting ferrous oxalate, citrate, or tartrate, or ferric acetate.

U. R. Evans [7] obtained **films of ferric oxide** on strips of iron by anodic oxidation in $0{\cdot}1N$-NaOH; or by dipping the iron in a soln. of iodine in a 10 per cent. soln. of potassium iodide. A. Krause obtained films on glass and porcelain from hydrosols peptized by acids. A. Kundt obtained films by cathodic spluttering of iron in a tube not completely freed from oxygen. W. N. Hartley obtained films in an analogous manner; F. H. Constable, by heating a layer of a paste made of ferrous oxalate or ferric oxide with oleic acid, and subsequently oxidizing the film of grey iron; and H. Zocher and K. Jacobsohn by the slow hydrolysis of ferric chloride soln. V. Kohlschütter and J. L. Tüscher, G. Jander and A. Winkel, and S. S. Kistler prepared an **aerosol** by vaporizing the metal in an electric arc, and carrying the vapour by a current of air, or other gas, into a chamber where it is suddenly chilled. A. Mittasch obtained the finely-divided oxide by burning iron carbonyl alone or mixed with other combustible or inert gases. J. Y. Johnson sprayed the carbonyl mixed with a combustible vapour, say alcohol, into a spray of air or oxygen, and ignited the mixture with platinized asbestos. W. E. Gibbs, and S. S. Kistler studied the aerosol.

Ferric oxide is produced as a by-product in the roasting of pyrites to obtain sulphur dioxide for the manufacture of sulphuric acid: $4FeS_2+11O_2=2Fe_2O_3+8SO_2$. Ferric oxide is also formed when iron, or ferrosic oxide, or hydrated ferric or ferrous oxide is heated for a considerable time in contact with air, and the product was once called *crocus martis adstringens;* while the ferric oxide obtained by deflagrating a mixture of iron filings with three times its weight of nitre, and removing the soluble alkali by washing with water, was called *crocus martis zwelferi;* and the ferric oxide obtained by igniting ferrous or ferric sulphate was called *colcothar*, and also *caput mortuum vitrioli.* Yellow or yellowish-red ferric oxide was generally called *crocus martis*, a term which appears in the Latin version of Gebert: [8] "Mars is filed and calcined until it is well rubified and become an impalpable powder which is called *crocus martis.*" L. Lémery called the black oxide of iron *æthiops martis;* Basil Valentine, and A. Libavius describe the preparation of these red oxides in various ways. J. Zwelfier, in 1652, obtained what he called *crocus martis* by heating iron with nitre and afterwards washing out the soluble matters. In the sixteenth century the *caput mortvum vitriolis* of the alchemists was also a by-product in the preparation of fuming sulphuric acid (*q.v.*). Basil Valentine called it *colcothar* or *colchotar*. E. O. von Lippmann discussed the origin of the terms.

According to F. E. E. Germann, the red pigment employed by the prehistoric North American Indians was hæmatite. The roasting of ferrous sulphate, obtained in the weathering of iron pyrites, furnishes ferric oxide for use as a pigment; and the pigment is also obtained from waste acidic liquors in the pickling of iron, etc. The ferrous salt is oxidized to the ferric state by nitric acid or bleaching powder, and the ferric hydroxide precipitated by lime. Ferric oxide is produced by roasting ferrous oxide, carbonate, or other salt of a volatile acid—*e.g.* T. L. Phipson, and A. Vogel recommended the oxalate.

The physical properties of ferric oxide.—The **colour** of the ferric oxide is determined by the time and temp. of the roasting of the ferrous salt. J. A. Hedvall said that the possible colours range from bright yellow to bluish-black. He said that when ferric oxide is heated at 650° to 1000° all the varieties become brown or dark violet, and above 1000°, they become black or bluish-black. This statement does not cover the facts. A. Salvetat found that the orange-red ferric oxide, or *rouge orange*, can be obtained only when some zinc or aluminium salt is associated with the ferrous sulphate, and the mixture is calcined at a dull red-heat—*rouge sombre*. L. A. Keane, J. H. Yoe, and F. H. Scheetz attributed the yellow colour of some pigments and of bricks to the very finely divided ferric oxide being prevented by alumina from agglomerating to red ferric oxide. Free alumina, however, is rarely present in the brick clays, which burn buff-yellow. According to A. Salvetat, a nasturtium-red, or *rouge capucine*, is produced by calcining the ferrous sulphate at the lowest possible temp., dull redness; a blood-red, or *rouge sanguine*, is produced if the temp. be rather higher than dull redness; flesh-red, or *rouge de chair*, is obtained at a still higher temp.; and by working at progressively higher and higher temperatures, the colours pass from carmine-red, or *rouge carmine*, to red-lake or *rouge laquex*, to pale violet-red, or *rouge violatre pale*, to violet-red, or *rouge violatre*, which is obtained at a very high temp. Darker tints are produced by associating more and more manganese salt with the ferrous sulphate, and calcining the mixture at a very high temp. In this way were obtained deep violet-red, or *rouge violatre foncé*; very deep violet-red, or *rouge violatre très foncé*; and iron-grey, or *gris de fer*. Certain manufacturers have specialized in producing particular tints, and the products have received special names—*e.g.* Pannetier's reds, etc. The varying colours of the ferric oxide are, according to L. Wöhler and C. Condrea, determined by the average grain-size of the particles rather than by variations in the mol. structure. Thus, brown and violet samples can be changed to yellowish-red by alternate grinding and washing; and G. Meir obtained low-temp. tints by separating the finest particles from deep reds prepared at a high temp. W. Ostwald suggested a similar hypothesis. J. A. Hedvall assumed that there are several stable, crystalline modifications of ferric oxide, and that the difference in the reflection of light from crystals of different shapes accounts for most of the differences in colour. The bright yellow variety consists of thin plates, and the others, of small grains or prisms. All varieties give the same X-radiogram, and belong to the same crystal system. The subject was studied by H. Wagner. When the light-yellow form darkens at 600°, the leaflets lose their forms and become granular. The subject was discussed by J. W. Mellor.

A range of various shades of red is produced by roasting hydrated iron oxides, *e.g.* the ochres, to furnish *burnt ochre*; sienna-earths, to furnish *burnt sienna*; and umbers, to furnish *burnt umber*. The colours have also received various trade-names—*e.g. Chinese red, Naples red, terra rosa, Indian red, Venetian red, Japanese red, Turkey red,* and scores of other terms are indicated in the trade catalogues. The so-called sequence of colours, *mars yellow, mars orange, mars red, mars violet,* and *mars brown,* were obtained in a similar way. Each dealer has more or less his own names for the different tints, and these are not necessarily the same as those of another dealer's. Thus one dealer's *caput mortuum* may be another dealer's *colcothar*, and *vice versa*. The Japanese red obtained by roasting *grès de Thiviers*, a ferruginous hydrated silica, is famed for its relatively great permanence of tint at a high temp. The dominant colouring oxide in all these cases is ferric oxide associated with more or less ferrosic oxide. W. H. Bruckner obtained Turkey-red tinted ferric oxide by anodic oxidation in a soln. of sodium sulphate.

According to R. B. Sosman and J. C. Hostetter, these two oxides form a continuous series of solid soln. A. Bouchonnet found similar relations between the different tints of a given ochre and the roasting temp., as those obtained by calcining ferrous sulphates. The colour of the ochres gradually deepens on heating from 100° to 250°, and between 230° and 260° changes sharply from yellow to red. The transition temp. depends on the particular ochre employed. Above this temp. the colour deepens up to 700° to 800°; and at about 900°, there is a marked contraction. Between 1000° and 1100°, the colour usually changes to black as ferric oxide is changed to magnetic or ferrosic oxide. The duration of the heating influences the colour only below 700° and above 1000°, and the rate of cooling has no influence on the tint. The sp. gr. gradually increases from the natural yellow ochre upwards with temp. to 1600°. The plasticity also decreases with rise of temp., and disappears completely at 800° to 850°. The yellow and red ochres are soluble in acids, but the varieties obtained above 950° are insoluble in cold or hot acids—excepting the hydrofluoric acid. The ochre from Vaucluse becomes magnetic even while still yellow, and this is assumed to show that an a-variety of ochre exists. The magnetic property disappears on prolonged heating, but reappears at 1600°. In general, the colour changes are attributed to differences in the average grain-size, rather than to differences in the degree of dehydration. According to T. Carnelley and J. Walker, the dehydration of the hydrated ferric oxides is complete at 500°, so that only below that roasting temp. can the tint of the pigment have any relation to the state of hydration of the product.

According to G. R. MacCarthy, the natural yellows, browns, and reds in rocks are due to the presence of ferric compounds. Hydrous ferrosic minerals are blue in colour, and are responsible for the blues frequently exhibited by clays and shales. These tints are not produced by disseminated organic matter. The greens are produced by mixture of iron-blues and iron-yellows, for no evidence of the existence of any single green compound has been found. The chocolate-red of hæmatite sometimes approaches purple, but the true purple colours of shales and slates are produced by mixtures of iron-reds and iron-blues. Anhydrous ferrosic compounds produce only greys and blacks, like the carbonaceous matter that is generally present in black, argillaceous rocks. The subject was discussed by D. S. Hager, P. Fireman, and H. Wagner. A. Veneuil said that the sapphire owes its colour to ferric and titanic oxides.

The *green colour* of the old Chinese, and Japanese celadon (or seladon) glazes can be imitated by firing suitable ferruginous glazes in the reducing atmosphere. A *blue colour* sometimes appears in glasses, glazes, and slags when they are partially devitrified. I must say that the blue opalescence effects on red Chinese glazes, and hundreds of glazes and slags which have come under my notice, do not require any hypothesis other than incipient devitrification, suggested by J. Fournet, to account for the results. However, others have seen differently. B. Silliman said that ferrous oxide can impart a blue colour to vitreous bodies; and R. Zsigmondy prepared blue glasses coloured with iron oxide under reducing conditions. J. Beckmann described blue glasses which he supposed were produced by iron oxide as tinctorial agent, and he quoted the analyses of J. F. Gmelin to show that blue colours can be produced on glasses, and enamels, and that the blue pigment on Chinese porcelain contains iron, but not cobalt. He also obtained similar results with some old Roman, blue tiles, and with some blue paint on an Egyptian mummy. J. J. Ferber also described blue volcanic slags and scoriæ which U. F. B. Brückmann said were probably used by ancient glass makers to produce blue colours.

C. J. B. Karsten, and J. J. Berzelius considered the blue colour of the slags was produced by titanic acid; C. J. B. Karsten also referred the blue colour in some cases to vanadium, and in others to a kind of artificial ultramarine. J. Fournet, M. Dartigues, and J. Percy attributed the colour to the presence of iron oxide. G. Bontempts also showed that iron oxide can impart a blue coloration to glass; and C. Mène observed that the blue colour may be developed in slags containing no tartaric acid. M. E. Chevreul favoured L. C. A. Barreswil's assumption that there is a blue coloured oxide of iron intermediate between ferrous and ferric oxide. G. R. MacCarthy argued that the green colours produced by iron oxide are derived from the blue and yellow component oxides. K. A. Hofmann and F. Resenscheck, W. Spring, and G. R. MacCarthy considered that "all iron salts which are of a decided blue colour contain both ferrous and ferric iron in the same molecule." This agrees with the observations of M. E. Chevreul, J. F. Persoz, and J. Napier. W. D. Bancroft and co-workers have prepared borate glasses coloured blue by iron oxide, and they attribute the coloration to the existence of an unstable blue modification of ferric oxide which is stabilized chiefly by ferrous oxide, and also by other substances. They report that in alkali borate glasses, ferrous oxide is colourless, ferric oxide is yellow, and mixtures of the two may be blue or green. If the ratio of ferrous to ferric oxide reaches 3 in borate glasses, the blue glass is almost free from a green tinge, and when the ratio reaches 4, the blue is well developed.

A. Nabl, and E. F. Holden referred the colour of citrene to the presence of submicroscopic hydrated ferric oxide; and a pink variety of quartz contained inclusions of red hæmatite of microscopic dimensions. W. Spring attributed the yellow colours of sedimentary rocks to hydrated ferric oxides; the reds to anhydrous ferric oxide; and the greens to ferrosic silicates. Colours obtained with special mixtures have also been described. Thus, T. Terreil obtained a red colour from a mixture of ferrous sulphate and sulphur, and the sulphur dioxide produced: $4FeSO_4+S=2Fe_2O_3+5SO_2$, was used in the manufacture of sulphuric acid. M. N. d'Andria obtained a colour by roasting a mixture of magnesium and ferrous sulphates; and others were described by N. McCulloch, A. Bunterock, H. Stein, etc.; and the manufacture of these colours is indicated in books, etc., by F. Rose, J. G. Gentele, G. Zerr and R. Rübencamp, H. Wagner, G. H. Hurst, S. Mierzinsky, and J. A. Reavell.

The colour of the ditrigonal scalenohedral and rhombohedral crystals of hæmatite is dark steel-grey or iron-black, and in thin layers it is blood-red by transmitted light; when earthy, the mineral is red. In layers of about 0·02 mm. it is transparent for red light, but in thinner layers it becomes transparent to most of the spectral rays of visible light. When warmed, the transparency decreases, but is recovered on cooling. C. F. Schönbein,[9] F. Muck, and E. J. Houston noticed that the colour of ferric oxide deepens as its temp. is raised. The reversible colour change which occurs at 650° was discussed by J. A. Hedvall. The streak of powdered mineral is cherry-red or reddish-brown. J. L. C. Schroeder van der Kolk said that the red streak becomes black when hot, and on cooling, red. The crystals of hæmatite are opaque except in thin layers. M. Lachaud and C. Lepièrre obtained ferric oxide in yellow hexagonal plates by heating ammonium ferric sulphate. According to E. A. Wülfing, the mineral is opaque down to a thickness of 0·1 mm., and then the colour passes from deep red to yellowish-red, and yellowish-grey. O. Anderson obtained plates of hæmatite 0·1μ thick, and found them to be yellow by transmitted light; with plates of increasing thickness, the colour passes from reddish-brown, to deep brownish-red, to blood-red. As indicated above, L. Wöhler and C. Condrea also found that if the grain-size of the particles is small the colour is yellow; if larger, red. W. R. Mott prepared anhydrous red and yellow ferric oxide by volatilization and found the grain-size of the yellow particles to be the smaller. According to J. Böhm, an X-ray study of ferric oxide shows that the calorescence or glow which may occur accompanies the transition of the material from the amorphous to the crystalline state. G. Chaudron and H. Forestier found that the glow which occurs between 400° and 600° is also attended by the change from the amorphous to the crystalline state. The variation in tint of preparations of pulverulent ferric oxide has just been discussed.

The observations of H. Abraham and R. Planiol, R. Chevallier, R. B. Sosman and E. Posnjak, and E. Wilson and E. F. Herroun agree that ferromagnetic ferric oxide—*vide infra*—is inclined to be yellower, and darker in colour than is the case with the ordinary paramagnetic oxide. E. Wilson and E. F. Herroun prepared samples ranging in colour from deep red to yellowish-brown; L. A. Welo and O. Baudisch, dark red; C. Frebold and J. Hesemann, reddish-brown; whilst that obtained by F. Frankenburger and co-workers by the action of water on lithium nitride is almost black.

The mineral occurs in columnar, botryoidal, lamellar—*e.g. flaky specularite*—granular, friable, or compact masses. The compact forms are brittle, the thin lamellæ are elastic; and some scaly varieties feel soft and unctuous. The fracture is subconchoidal, uneven, or earthy. N. H. Winchell, and W. S. Gresley described a form of *fibrous hæmatite*. The **crystals** may occur in thick or thin plates parallel to the (0001)-face, and they may be grouped in parallel positions or they may form rosettes. There may be other combinations. The crystals also occur in cube-like rhombohedra, with the rhombohedral (1014)-face striated, and often rounded over in convex forms. The (0001)-faces may also be striated. Hæmatite may also form columnar, botryoidal, or stalactitic shapes, or it may form lamellar masses with the thick or thin laminæ joined parallel to (0001), and bent in various ways. Some observations on the rhombohedral crystals were made by R. J. Haüy, A. Girard and G. Chaudron, and L. A. Emmerling. The trigonal-hexagonal-rhombohedral crystals were found by N. von Kokscharoff to have the axial ratio $a : c = 1 : 1{\cdot}36557$; G. Melczer gave 1 : 13654; E. Kleinfeldt, 1 : 1·3651 to 1 : 13656; and S. di Franco, 1 : 13668. **Twinning** occurs; there are penetration twins about the (0001)-plane, and the composition face may be perpendicular to the (0001)-face; twinning also occurs less commonly about the (1011)-plane producing polysynthetic twinning lamellæ showing a fine striation on the (0001)-face, and giving rise to a distinct or pseudo-cleavage parallel to (1011). This twinning was studied by F. Mohs, W. Haidinger, M. Bauer, O. Mügge, and O. V. Jereméeff. There is no definite **cleavage**, but there are partings about (0001) due to the lamellar structure, and about (1011) due to twinning. F. F. Osborne, G. Kalb, and G. Melczer studied the **corrosion figures** obtained with hydrochloric acid. Ferric oxide is dimorphous; in addition to the rhombohedral crystals just described there is a cubic form—*vide infra*, ferromagnetic ferric oxide. Numerous measurements have been made on the crystals of the rhombohedral form:

Observations on the crystals of hæmatite have been reported by A. d'Achiardi, G. d'Achiardi, G. Aminoff, A. Arzruni, M. Berek, A. Bergeat, H. Biäsch, J. R. Blum, O. B. Bøggild, A. Breithaupt, A. Brezina, T. M. Broderick, W. C. Brøgger, L. Bucca, H. Bücking, L. Busatti, K. Busz, H. Buttgenbach, M. Carrère, E. J. Chapman, J. H. Collins, L. Colomba, F. Cornu, E. Döll, H. Dufet, P. A. Dufrénoy, G. Fink, S. di Franco, W. F. Foshay, A. Frenzel, V. Goldschmidt, F. Gonnard, J. P. Graffenauer, R. P. Greg and W. G. Lettsom, P. Groth, W. Haidinger, R. W. Harre, R. J. Haüy, M. F. Heddle, F. Hessenberg, T. S. Hunt, P. V. Jereméeff, W. P. Jervis, G. Kalb, G. A. Kenngott, E. Kleinfeldt, F. von Kobell, A. Koch, A. Krantz, A. Lacroix, A. Lacroix and P. Gautier, F. von Lasaulx, E. Laval, I. Lea, C. C. von Leonhard, A. Lévy, O. M. Lieber, J. Loczka, O. Luedecke, E. Manasse, J. S. Martin, G. W. McKee, F. Mohs, A. J. Moses, F. Millosevich, O. Mügge, C. F. Naumann, J. J. Nöggerath, W. Nowacki, F. Papp, A. Pelikan, F. Pfaff, L. V. Pirsson, G. von Rath, J. B. L. Romé de l'Isle, G. Rose, P. A. de Saxe-Cobourg-Gotha, A. Sadebeck, A. Scacchi, A. and E. Scacchi, T. Scheerer, A. Schmidt, A. Schwantke, J. Schweitzer, G. Sillem, B. Silliman, L. J. Spencer, A. de Stefani, J. Strüver, P. von Sustschinsky, V. V. Syedeltschikoff, H. Tertsch, H. Traube, P. Tschirwinsky, G. Uzielli, T. Wada, E. Weinschenk, D. F. Wiser, V. von Zepharovich, K. Zimanyi, and F. Zirkel, etc. A bibliography was compiled by H. Biäsch. Observations on the artificial crystals were made by H. Arctowsky, A. Arzruni, K. B. Doss, W. Florence, G. Friedel, F. von Hochstetter, H. E. Merwin and J. C. Hostetter, W. Müller, C. F. Rammelsberg, H. Vater, etc.

L. Pauling and S. B. Hendricks, W. H. and W. L. Bragg, H. Sachse, J. A. Hedvall,

V. M. Goldschmidt, W. H. Zachariasen, W. C. Hansen and L. T. Brownmiller, P. E. Wretblad, J. Böhm and F. Ganter, and J. Topping studied the **X-radiograms** of hæmatite and corundum, and found them similar. L. Pauling and S. B. Hendricks found that the rhombohedral space-lattice of hæmatite has α-55° 17′, and the side of unit triangle, a=5·420 A.; he said that the hexahedral mol. of ferric oxide can be assumed to consist of an equilateral triangle of oxygen with a metal atom immediately above and below the centre of the triangle; and that the lattice has 3 mols. per unit prism. The side of unit triangle is a=5·035 A.; the axial ratio $a:c$=1 : 1·363, and the calculated density, 5·243. T. Katsurai and T. Watanabe gave a=5·42 A., and α=55° 17′; V. M. Goldschmidt and co-workers, a=5·42 A., and α=53° 14′; R. Brill, a=5·429 A., and α=54° 58′; S. Katzoff, a=5·4135 A., and α=55° 17·5′; L. Passerini, a=5·020 A., and c=6·860 A., $a:c$=1 : 1·366, and $v=148·6\times10^{-24}$ c.c. for the hexagonal cell, and a=5·43 A., and α=55° 6′ for the rhombohedral cell; and W. H. Zachariasen, α=58° 14′; a=5·42 A.: and $a:c$ =1 : 1·367, and the calculated density, 5·25. E. A. Harrington gave α=55° 17′, and a=5·406 A.; and P. E. Wretblad, edge of lattice=5·419 A.; α=55·28°; a=5·027 A., c=13·73 A.; and $a:c$=1 : 2·7306. A hexahedral molecule is assumed consisting of an equilateral triangle of oxygen with a metal atom immediately above and below the centre of the triangle. W. Jansen studied the fibrous varieties, and found that the crystals are hexagonal with a=5·035 A., and c=13·726 A. L. Pauling and S. B. Hendricks inferred that the arrangement of the atoms in the lattice is such that each metal atom is surrounded by 6 oxygen atoms which are not at the corners of a regular octahedron. Three of these atoms are a few per cent. nearer the metal than the others. This indicates that the location of the electrons in the outer shells of an ion causes it to have different effective radii in different directions. Each oxygen atom is surrounded by 4 metal atoms, 3 of which are nearer than the other two. The interionic distances of hæmatite are: the smallest oxygen-oxygen distance, 2·545 A.; and the metal-oxygen distances, 2·060 A. and 1·985 A. L. A. Welo and O. Baudisch, and J. Thewlis found that the lattices of ferrosic and γ-ferric oxides are analogous, and of similar dimensions. The unit cube of ferrosic oxide contains 8 molecules and is represented by $Fe_{24}O_{32}$, and the unit cube of γ-ferric oxide has 12 molecules and is represented by $Fe_{24}O_{36}$. Consequently, room for 4 additional oxygen atoms has to be found in the unit cube of Fe_3O_4. J. Thewlis' representation of the structure of ferrosic oxide has been previously discussed, and is illustrated in Fig. 518, and the structure of γ-ferric oxide with its four additional oxygen atoms is illustrated

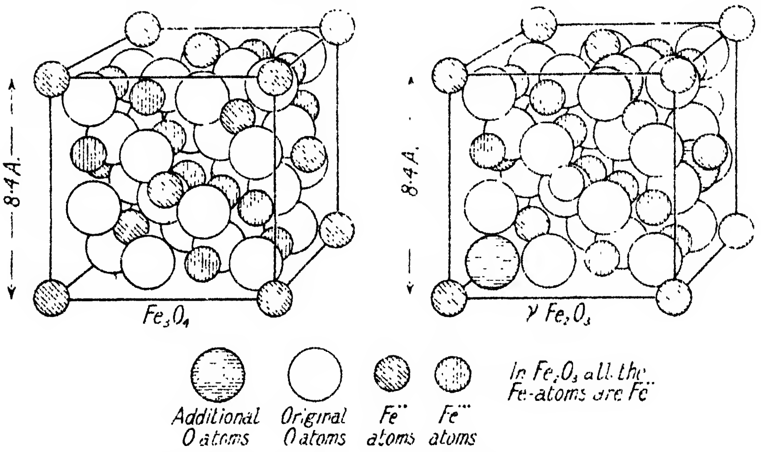

FIG. 518.—Lattice Structure of Fe_3O_4.

FIG. 519.—Lattice Structure of γ-Fe_2O_3.

in Fig. 519. One of the conditions necessary for ferromagnetism, on W. Heisenberg's theory is that each atom must have 8 nearest neighbours; H. Sachse applied this test to Fe_3O_4, α-Fe_2O_3, and γ-Fe_2O_3, and found the condition satisfied by Fe_3O_4 and γ-Fe_2O_3, but not by α-Fe_2O_3. This condition is also satisfied by J. Thewlis' representations, Figs. 518 and 519. J. Topping studied the potential energy of the crystals; and N. Akuloff and M. Degtiar, the slip-lines.

Observations on the crystals were made by A. Simon and T. Schmidt, J. Böhm, G. Kalb, P. F. Kerr, W. P. Davey, V. Schmaeling, C. Mauguin, J. Wasastjerna, and H. Groebler and P. Oberhoffer—*vide supra*, ferrous and ferrosic oxides, Fig. 512. Observations on kidney ore, by J. A. Hedvall, J. Böhm, and F. Rinne, show that it is a form of hæmatite. J. A. Hedvall, E. A. Harrington, G. Frebold, and G. Frebold and J. Hesemann found that the space-lattices of natural and artificial ferric oxides are the same. K. Honda and T. Sone observed a structural change at 1300°; whilst K. T. Compton and E. A. Trousdale could detect no change in the space-lattice under the influence of a magnetic field. R. D. Williams and J. Thewlis noted that the crystals of the α-oxide or trigonal oxide, formed from γ-lepidocrocite, are of the order of 10^{-4} cm. across, and those of the γ-oxide or cubic oxide are of the order 10^{-7} cm. across when first formed, but their final size, just before they are transformed into the trigonal form, is of the order 10^{-6} cm. The transformation occurs over the range 500° to 600°.

L. A. Welo and O. Baudisch observed a loss in catalytic power in passing from the cubic to the trigonal form, but S. Roginsky and E. Schulz found no difference in the catalytic decomposition of potassium permanganate. F. Pfaff, and J. Strüver have noticed the similarity between the crystal forms of hæmatite and corundum; and A. Hamberg, the resemblance between the crystals of ilmenite and pyrophanite. It was inferred that these minerals have a similar constituent:

$Fe(FeO_3)$	$A(AlO_3)$	$Fe(TiO_3)$	$Mn(TiO_3)$
Hæmatite	Corundum	Ilmenite	Pyrophanite

P. J. Holmquist stated that there are two crystalline forms: α-ferric oxide, stable at a low temp.; and β-ferric oxide, stable at a high temp. H. Forestier and G. Chaudron observed a break in the thermal expansion curve at 680°; R. B. Sosman and J. C. Hostetter, a sharp reversible endothermal break in the heating curve at 678°, and a small irregularity between 775° and 785°; E. J. Kohlmeyer, breaks at 1035°, and between 1250° and 1350°; and C. C. Bidwell, a break at 1320°—but these have not been established as definite transformation points. K. Honda and T. Sone observed a break in the thermomagnetic curve at 1300°; G. G. Brown and C. C. Furnas observed what they regarded as breaks in the sp. ht., and thermal conductivity curves at 360°, and calculated the thermal value of the change at 360° to 4·85 cals. per gram, or 775 cals. per mol. H. le Chatelier noted a change in the heat of formation curve at about 900°; J. d'Ans, and G. Keppeler and J. d'Ans stated that a polymorphic transformation occurs at 640°, and that is the optimum temp. for the activity of ferric oxide as a catalyst for the oxidation of sulphur dioxide; and C. C. Bidwell, a break at about 720° in the curves for the electrical conductivity, and thermoelectric force. R. B. Sosman and co-workers noted a drop in the magnetic susceptibility at 678°; L. Blanc, and G. Chaudron, at 600°; and J. Huggett and G. Chaudron observed that the Curie point occurs at 675°. C. C. Furnas found the thermal value of the change between 650° and 825°, assuming that it is all one change, to be 41·8 cals. per gram, or 6692 cals. per mol. W. G. Mixter could detect no polymerization when the ferric oxide is heated, and J. A. Hedvall observed no change in the X-radiograms. The subject was also discussed by S. Hilpert. N. Parravano and G. Malquori observed that the oxides formed by heating the hydrogel, or by roasting the chloride or nitrate, have the same X-ray spectrum, and show no evidence of polymeric forms. L. A. Welo and O. Baudisch, and R. B. Sosman and E. Posnjak found that the X-radiograms of magnetite and of ferromagnetic ferric oxide, natural or artificial, are identical. The ferromagnetic form was called by F. Haber, and J. Hesemann, γ-Fe_2O_3. There is an irreversible transformation, γ-$Fe_2O_3 \rightarrow \alpha$-$Fe_2O_3$, between 400° and 700°; and the Curie point is between 500° and 700°. At about 700°, ferromagnetic ferric oxide with the cubic lattice of magnetite or martite is transformed into paramagnetic hæmatite with rhombohedral crystals. The unit cube of magnetite may be symbolized $Fe_{24}O_{32}$, and after oxidation $Fe_{24}O_{36}$. The unit cube of magnetite thus has room enough to accommodate 4 extra oxygen atoms. A. Simon discussed the structure of ferric oxide; L. Passerini, the solubility; and O. Hahn and O. Müller, the surface by the adsorption of radium emanations.

There are thus two forms of ferric oxide— one cubic, one trigonal or rhombohedral. The observations of H. Abraham and R. Planiol, R. Chevallier, J. Huggett and G. Chaudron, S. B. Hendricks and W. Albrecht, O. Hauser, R. B. Sosman and co-workers, L. A. Welo and O. Baudisch, and E. Wedekind and W. Albrecht show that (i) the X-radiograms of the two forms are indistinguishable one from the other; (ii) the magnetic permeability of cubic ferromagnetic oxide is not distinguishable from that of ferrosic oxide; (iii) the cubic form can be changed to the more stable rhombohedral form by heating it to various temp. between 550° and 1000°; and the catalytic activity of the cubic form is greater than is the case with the rhombohedral variety. The transition temp. appears to depend on the mode of preparation. To convert ferrosic oxide to the isomorphous cubic ferric oxide, 4 oxygen atoms must be crowded into the unit lattice of the ferrosic oxide. L. A. Welo and O. Baudisch considered that the extra oxygen required for the change $2Fe_3O_4 \rightarrow 3Fe_2O_3$ can be inserted in the crystal-lattice, without undue strain, so as to leave the structure essentially unchanged. J. W. Gruner, L. H. Twenhofel, G. Frebold and J. Hesemann, J. Böhm, and P. M. Wolf and H. Zeglin discussed changes in the X-radiograms in the oxidation of magnetite to ferromagnetic ferric oxide.

J. Beyer[10] observed that the chemical reactions of iron, and ferric oxide with hydrogen and steam, and the magnetic properties of the products, agree with the assumption that solid soln. are formed between ferrous and ferrosic oxides; R. Ruer and M. Nakamoto also noted the formation of solid soln. S. Hilpert called the complexes of FeO and Fe_2O_3, other than Fe_3O_4, indefinite mixtures—*vide infra,* ferrous ferrites. R. B. Sosman and J. C. Hostetter added that ferric oxide forms a continuous series of solid soln. with ferrosic oxide (*vide infra*), and they called them **martites.** E. D. Eastman showed that at 1100° and upwards ferric and ferrosic oxides form a continuous series of solid soln., but probably the soln. is limited below 1000°. J. Beyer found a similar state of things with ferrous and ferric oxides. E. D. Eastman also said that at and above 1100°, the two oxides form a continuous series of solid soln., although there are indications that below 1000° they may not be soluble in one another in all proportions. Hæmatite is hexagonal and magnetite cubic, at ordinary temp., and hence it may appear to be a *circuluo in probando* to assume that there is a hexagonal variety of magnetite which forms a solid soln., *i.e.* an isomorphous mixture with hæmatite. According to R. B. Sosman, a consideration of the point systems from which the crystal classes can be made up, shows that there is in reality a continuous transition from cubic to hexagonal. Suppose a cubical portion of some cubic lattice to be standing on one of its corners; then if it be compressed along the vertical diagonal axis it changes into a rhombohedron which becomes flatter with increasing compression, and the rhombohedron is a hexagonal form This transition requires, of course, that the lattice of the isometric and hexagonal forms be thus transformable. The subject was discussed by T. M. Broderick, P. Geijer, G. Gilbert, A. Lavenir, C. Friedel, J. W. Gruner, and P. Ramdohr. H. Forestier and G. Chaudron discussed the formation of solid soln. with ferric oxide and chromic oxide, and alumina—*vide* aluminium and chromium ferrites. W. Biltz and co-workers found that in the spinels, $MO.Fe_2O_3$, the mol. vol. of the Fe_2O_3 in $ZnO.Fe_2O_3$ is 30·4; and in the CuO, MgO, CdO, MnO, FeO, CoO, and NiO spinels, the mol. vol. of the Fe_2O_3 is round about 33·4. Hence they infer that there are two forms of ferric oxide: α-Fe_2O_3 with mol. vol. 30·4, and γ-Fe_2O_3 with a mol. vol. 33·4.

A. Johnsen discussed carnallite and hæmatite. G. Friedel discussed **pseudomorphs** of ferric oxide after magnetite. A. Breithaupt described a cubic variety of ferric oxide occurring in octahedra or dodecahedra, like magnetite. The pseudomorph is not ferromagnetic and it was called **martite.** This mineral was examined by F. von Kobell, C. F. Rammelsberg, J. F. L. Hausmann, R. van Aubel, J. R. Blum, H. Rosenbusch, G. vom Rath, A. Lavenir, and H. Gorceix. The general conclusion is that martite is a pseudomorph after magnetite. A. Scacchi obtained a variety of ferric oxide in acicular needles, thought to be *rhombic*. It occurs in the tufa of Pianura and Fiano, Campania, and was named *raphisiderite* — from ῥαφίς, needle; and σιδήρεος, iron. Pseudomorphs of ferric oxide after *iron pyrites* were reported by H. Traube, A. Schwantke, W. F. Petterd, H. Rosenbusch, J. R. Blum, A. Krantz, E. Döll, R. P. Greg and W. G. Lettsom, G. vom Rath, H. Gorceix, and A. Lavenir; after *lievrite*, by J. R. Blum; after *siderite*, by J. R. Blum; after *cerussite*, by A. Hofmann; after *pyromorphite*, by J. R. Blum, and D. F. Wiser; after *calcite*, by A. Breithaupt, J. J. Nöggerath, J. R. Blum, G. Sillem, H. A. Miers, O. Mügge, G. Rose, A. Frenzel, and W. Haidinger; after *dolomite*, by J. R. Blum; after *fluorite*, by J. R. Blum, G. Sillem, and A. Breithaupt; after *baryta*, by A. Breithaupt, M. F. Heddle, J. R. Blum, and R. P. Greg and W. G. Lettsom; after *anhydrite*, by P. Groth, and J. R. Blum; after *olivine*, by G. Tschermak; after *bronzite*, by J. R. Blum; after *garnet*, by J. R. Blum; after *felspar*, by J. R. Blum: and after *ferric sulphate*, by A. Vesterberg. J. W. Gruner, P. Ramdohr, and G. M. Schwartz discussed **intergrowths** with ilmenite and hæmatite (*q.v.*); and H. Baumhauer, intergrowths of rutile and hæmatite.

A. Frenzel[11] gave 4·914 to 4·917 for the **specific gravity** of hæmatite; C. F. Rammelsberg, 5·075 to 5·283; G. Rose, 5·191 to 5·230; F. E. Neumann, 5·079; J. Loczka, 5·289; M. Lachand and C. Lepierre, 4·95 at 14°; A. Bergeat, 4·998 and, after separating impurities, 5·247; G. Dewalque, 4·35; M. F. Heddle, 4·8; J. Joly, 4·644 to 4·923; J. Maillard, 4·90; A. Vesterberg, 5·06; A. Breithaupt, 5·261; P. V. Jereméeff, 5·02; E. Madelung and R. Fuchs, 4·8986 to 5·1568; E. F. Herroun and E. Wilson, 4·75 to 4·91; A. Lavenir, 5·194 to 5·205; and P. F. G. Boullay, 5·225. For the artificial oxide, W. Herapath gave 5·059 for the sp. gr. at 16·5°; H. Kopp, 5·121 at 12·5°; L. Playfair and J. P. Joule, 4·679 at 3·9° for the precipitated and 5·135 for the ignited oxide. P. P. Budnikoff and K. E. Krause found the sp. gr. of the oxide calcined at different temp. to be:

	450°	650°	850°	1000°
Sp. gr.	5·102	5·183	5·190	5·195

D. Tommasi gave 5·11 for the sp. gr. of the brown oxide obtained by dehydrating the precipitate from a ferric salt by alkali-lye, and 4·95 for that of the red or yellowish-red oxide obtained by oxidizing hydrated ferrous or ferrosic oxide or ferrous carbonate; and H. Rose gave 5·169 for the precipitated and 5·037 for the ignited oxide. Heating the oxide was found by H. Rose, G. Weymann, and F. Sauerwald and G. Elsner to increase the sp. gr. Thus, L. Blanc observed that the sp. gr. of the oxide heated to 500° to 600° is 4·910; to 650° to 700°, 5·040; to 750°, 5·110; and to 850°, 5·175; R. Ruer and J. Kuschmann, 5·200 at 15°/4° for a sample heated to 700°, and 5·1597 at 15°/4° after being heated to 1000°. A. Duboin gave 5·16; B. Aarnio, 5·09; and S. Hilpert and J. Beyer, 5·1. Observations were also made by F. Muck, and O. Hauser. H. P. Walmsley found the sp. gr. of the hexahedral particles of dispersed ferric oxide to 5·274, and of the cubic form, 5·400. F. J. Malaguti and A. Lallemand found for the non-magnetic oxide dried at 300°, 4·784; for the non-magnetic oxide which has been heated to *rouge vif*, 5·144; and for the strongly magnetic oxide, 4·686. E. J. Kohlmeyer and S. Hilpert found the sp. gr. of a sample that had been fused to be 5·190; and E. J. Kohlmeyer gave 5·187 to 5·193 for samples of highly purified oxide which had been heated high enough to convert some of the ferric oxide into ferrosic oxide. L. Blanc and G. Chaudron prepared the oxide by calcining the nitrate or sulphate at different temp., and found that when made at 500° to 600°, the large grains had a sp. gr. 4·910; at 620° to 700°, the fine grains had a sp. gr. of 5·040; at 750°, the grains of increasing size had a sp. gr. of 5·110; and at 850°, the grains of increasing size had a sp. gr. of 5·175. They attributed the decrease in the grain-size between 600° and 700° to an effect of the evolution of gas accompanying disintegration, but there is a polymeric transformation at about 678°. N. Parravano and G. Malquori found that the apparent sp. gr. of small cylinders of compressed ferric oxide is scarcely changed by calcination up to 700°; but above 800°, the apparent sp. gr. increased and the cylinders were less friable. X-radiograms show that the difference between the aggregated and non-aggregated oxide is solely one of grain-size. The general results of the sp. gr. determinations show that the best representative value of ferrosic oxide is 5·12 with the sp. vol. 0·1954, and mol. vol. 31·2, whilst for natural hæmatite the sp. gr. is 5·24; the sp. vol. 0·1910; and the mol. vol. 30·5. The densities 5·25 by W. Zachariasen; 5·355 by L. Passerini; and 5·243 by W. P. Davey, were calculated from the X-radiogram data. W. Biltz, and J. J. Saslawsky compared the observed mol. vol. with that calculated by the additive law. W. Ostwald and W. Haller observed that when the produced oxide is suspended in hexane, and other organic liquids, and then separated, the sp. vol. decreases in the order CCl_4, C_6H_{14}, C_6H_6, CH_3Cl, $(C_2H_5)_2O$, $CH_3.COOH$, C_2H_5OH, and $(CH_3)_2CO$. The effect is attributed to the adsorption of solvent films—*lyoadsorption*.

The **hardness** of the crystals is over 5 and may attain a value from 5·5 to 6·5. J. A. von Deurs and P. E. Raaschou[12] studied the fluidity of slip—water and ferric oxide. A. Reis and L. Zimmermann studied the hardness and mol. vol. W. Voigt gave for the **elastic modulus,** E, in kilograms per sq. mm., $E_0=23{,}000$; $E_{45}=21{,}800$; $E_{45}=18{,}700$; and $E_{90}=23{,}100$; while the cubical coeff. of **compressibility** is $1{\cdot}04\times10^{-6}$. E. Madelung and R. Fuchs found the compressibility between 50 and 200 kgrms. per sq. cm. to be between $0{\cdot}0_658$ and $0{\cdot}0_5106$. According to F. Sauerwald and G. Elsner, briquettes made from the compressed and calcined oxide have a compressive strength dependent on the temp. of calcination. M. C. Lea was unable to detect any signs of the dissociation of ferric into ferrous oxide by mechanical press.

H. Fizeau found the coeff. of **thermal expansion** to be, $a=0{\cdot}0_5829$ and $0{\cdot}0_5836$, respectively parallel and vertical to the principal axis; this gives for the coeff. of cubical expansion, 0·00002501, at 40°. H. Kopp gave 0·00004 for the coeff. of cubical expansion; and 0·000007 for the coeff. of linear expansion. H. Bäckström obtained for the length, l, at $\theta°$, between 4° and 82°, in a direction parallel to the principal axis, $l=l_0(1+0{\cdot}0_576109\theta+0{\cdot}0_84901\theta^2)$, and in a direction perpendicular to the principal axis, $l=l_0(1+0{\cdot}0_5576918\theta+0{\cdot}0_712000\theta^2)$, where l_0 denotes the length at 0°. It follows that the coefficient of expansion in a direction perpendicular to the principal axis is the greater; but the coefficients of expansions in both directions are the same at −5·7°, namely, $0{\cdot}0_57555$; and below that temp., the coeff. of expansion parallel to the principal axis is the greater. H. Forestier and G. Chaudron observed a break in the dilation curve at about 675°.

C. C. Bidwell found the **thermal conductivity** of the compressed powder to be 0·00141 cal. per sec. per sq. cm. per degree at 200°; 0·00189, at 400°; 0·00235, at 600°; 0·00262, at 720°; 0·00294, at 800°; and 0·00390, at 1050°. C. H. Lees gave $k=-0{\cdot}003$ cal. per cm. per sec. per degree; J. Königsberger and J. Weiss gave $k=0{\cdot}035$; and J. Kruckenberg, $k=0{\cdot}006$. C. C. Bidwell gave the following results:

	159°	258°	415°	658°	854°	1047°
k .	0·00130	0·00154	0·00189	0·00251	0·00317	0·00390

G. G. Brown and C. C. Furnas gave for the thermal conductivity, k cals. per sec. per sq. cm. per degree, of powdered ferric oxide:

	125°	150°	300°	400°	500°	600°	700°	750°
k .	$0{\cdot}0_3918$	$0{\cdot}0_3925$	$0{\cdot}0_3940$	0·00108	0·00113	0·00122	0·00133	0·00138

The results of C. C. Furnas on rods of powder, and those of C. C. Bidwell on prepared rods are summarized in Fig. 520. H. de Sénarmont made some observations on the thermal conductivity of the crystals; and E. Jannetaz observed that the ratio for the conductivities in the direction of the principal axis and at right angles thereto is 1·232; N. Botez and H. Hertenstein gave 1·198; and H. Bäckström, 1·064 to 1·12 at 50°. According to F. M. Jäger, the quotient of the electrical and thermal conductivities of all metals is a constant, independent of their chemical nature, but directly proportional to the absolute temp. This ratio is not constant for the conductivities of hæmatite measured in the directions of the crystal axes.

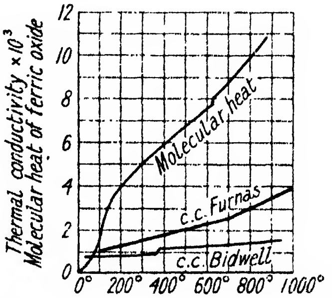

Fig. 520.—The Thermal Conductivity and Molecular Heat of Ferric Oxide.

J. Joly gave 0·1683 for the **specific heat** of hæmatite between 7·8° and 100°; P. E. W. Oeberg, 0·1645 to 0·1647 between 15° and 99°; A. Abt, 0·17425 between 16° and 95°; H. Kopp, 0·154 to 0·159 for the sp. ht. of hæmatite; R. Ulrich, 0·1627 between 19° and 98°; F. E. Neumann, 0·16695 to 0·1692. H. V. Regnault gave 0·16695 for the sp. ht. of hæmatite between 15° and 98°; while for calcined colcothar he gave 0·17167; for strongly calcined colcothar, 0·16921; and for yet more strongly calcined colcothar, 0·16814. G. G. Brown and C. C. Furnas gave for the sp. ht., in cals., of ferric oxide:

	0	40°	80°	120°	200°	300°	400°	500°	650°
Sp. ht. .	0·1550	0·1640	0·1750	0·1845	0·2025	0·2250	0·2645	0·2955	0·3420

The results for the **molecular heats,** C_p, from 298° K to 633° K, can be summarized by $C_p=14{\cdot}13+0{\cdot}0378T$; and between 633° K and 951° K, by $C_p=9{\cdot}16+0{\cdot}0491T$. W. Bertram gave:

	95°	225°	350°	461°	526°	569°	685°	764°	824°
c .	0·1598	0·1746	0·1854	0·1952	0·1995	0·2027	0·2084	0·2106	0·2110

and $c=0{\cdot}1514+0{\cdot}0001239(\theta-20)-0{\cdot}0_7577(\theta-20)^2$. Decomposition sets in at temp. exceeding 700°. G. S. Parks and K. K. Kelley found the sp. ht. at −184·0°, −123·7°, and 17·5° to be respectively 0·0408, 0·0842, and 0·1550, and the mol. ht. respectively 6·5, 13·4, and 24·8. The results of A. S. Russell, G. S. Parks and K. K. Kelley, P. E. W. Oeberg, A. Abt, J. Joly, C. C. Furnas, and H. V. Regnault fall about the mol. ht. curve, Fig. 520. A. S. Russell gave 0·0726 between 191·9° and −81·0°; 0·1318 between −73·7° and 0°; and 0·1600 between 3·5° and 44·0°. The corresponding mol. ht. are respectively 11·59, 21·05, and 25·53. W. A. Roth and W. Bertram gave for the sp. ht., c, between $\theta°$ and 20°, $c=0{\cdot}151+0{\cdot}0_31239(\theta-20)-0{\cdot}0_7577(\theta-20)^2$; and for true mol. heat:

	100°	200°	300°	400°	500°	600°	700°
C .	27·08	30·32	33·01	35·15	36·73	37·75	38·23

I. Maydel studied the mol. ht. F. J. Malaguti and A. Lallemand found the sp. ht. of non-magnetic ferric oxide dried at 300° to be 0·1863, and heated to redness, 0·1743; while the sp. ht. of the magnetic oxide heated to redness is 0·1730; and the sp. ht. of strongly magnetic ferric oxide is 0·1794.

J. J. Berzelius observed that precipitated, hydrated ferric oxide when heated loses water, and when passing from dull redness to bright redness it shows a **calorescence** similar to that described in connection with alumina, chromic oxide, and zirconia. The oxide thus becomes denser, less attacked by acids, and generally less sensitive chemically. L. Wöhler found that ferric oxide is calorescent only when precipitated from boiling soln.; that precipitated from cold soln. becomes calorescent only when well washed with hot water. J. Böhm said that the hydrated oxide caloresces as well when precipitated from cold soln. as it does from hot soln. L. P. de St. Gilles observed no calorescence with aged gels heated with water. F. Muck, and D. Tommasi observed no calorescence with the hydrogel obtained by oxidizing ferrous hydroxide or carbonate. J. J. Berzelius, and L. Wöhler observed no change in weight occurs during the calorescence, although H. Forestier and G. Chaudron obtained a marked shrinkage; J. J. Berzelius found the rate of solution in acids is decreased during the calorescence. The heating curves, obtained by K. Endell and R. Rieke, R. Wallach, and L. Blanc, show a sharp hump during the recalorescence period. K. Endell and R. Rieke observed that the material which showed the phenomenon had 0·5 per cent. of water. The calorescence temp. is 538°. L. Blanc observed the calorescence temp. to be 400° with the oxide precipitated cold, and it is feebler with the oxide precipitated from boiling soln. The temp. depends on the previous history of the hydrated oxide. N. S. Kurnakoff and E. J. Rode gave 325°–400° for the calorescence temp. of bog iron ore. A. A. Baykoff gave 380° for the beginning and 550° for the end; R. Wallach gave 400°; K. Endell and R. Rieke, 450°; H. le Chatelier, 950°; L. Wöhler, 540°; and at first it was assumed that two allotropic modifications exist. L. Wöhler regarded the phenomenon as due to an increase in the grain-size of the oxide. K. Endell and R. Rieke, and R. Ruer, to a change from the amorphous to the crystalline state; and this hypothesis is in agreement with the X-radiograms of J. Böhm of samples before and after calorescence. J. A. Hedvall, however, said that no oxide is amorphous, they are all crystalline or cryptocrystalline, and give identical X-ray spectra before and after heating to 1150°, showing that the calorescence is not caused by a change in structure. W. G. Mixter found that the thermal values of ferric oxide before and after the glow differ by 9·0 Cals. per mol. He calls this difference, the **heat of polymerization.**

E. J. Kohlmeyer said that finely powdered ferric oxide sinters and shrinks in volume on passing through 920° to 950°, and there is a kink in the heating curve in this region. C. C. Furnas observed that just before sintering, powdered ferric oxide becomes very active, and tends to flow like water, assuming an almost zero angle of repose although no liquid is present. The phenomenon may be caused by an evolution of gas, or by an accumulation of electric charges on the particles—*e.g.* the "boiling" of plaster of Paris, and other powders when heated, and the allied phenomenon which occurs in the roasting of some sulphide ores. H. Rose, C. Zenghelis, and L. Elsner observed that there is an appreciable **volatility** of ferric oxide in the porcelain oven $<1600°$; and H. Moissan added that at 2000° ferric oxide can be sublimed in a crystalline form. A. A. Read, and H. Rose, however, showed that at these temp. the ferric oxide is more or less dissociated, forming a magnetic or ferrosic oxide, consequently, not ferric oxide but rather ferrosic oxide would volatilize at these temp. Even magnetite has a dissociation press. approximating an atm. at 2500°. H. von Wartenberg and W. Gurr found that the mixture of oxides formed by the fusion of ferric oxide volatilizes rapidly at 1800°.

In 1848, H. Rose noticed that when ferric oxide is heated in a porcelain oven, at about 1400°, and the cold product dissolved in acid, a blue precipitate is formed when potassium ferricyanide is added to the soln. This was taken to mean that some ferric oxide is transformed by heat into ferrous oxide. C. F. Bucholz, J. J. Berzelius, and E. Mitscherlich showed by weighing that ferric oxide is dissociated at a white-heat, but J. L. Proust, C. L. Berthollet, and J. H. Hassenfratz did not agree. J. A. Hedvall said that the oxide is stable at a red-heat; H. Moissan, that oxygen is lost when ferric oxide is heated in the electric arc furnace; H. Rose, in the porcelain oven; H. Tholander, at a white-heat; and W. Suida, at a bright red-heat. H. Warth added that the association of alumina with the ferric oxide makes it less liable to decompose. E. D. Clarke said that the oxide on charcoal is reduced to metal in the oxyhydrogen flame, and that the metal then burns as a brilliant scintillation.

W. Suida found that at the temp. of a Bunsen burner, ferric oxide is not reduced provided reducing agents be excluded; but at a bright red-heat or white-heat, ferric oxide and ferric silicates do suffer an appreciable reduction in air, or in an atm. of nitrogen. If heated with molten borax, ferric oxide and ferric silicates suffer a little reduction in air, or in an atm. of nitrogen or carbon monoxide, but in an atm. of oxygen, the reduction is *sehr gering*. The observations of C. F. Rammelsberg, C. Bodewig, R. Hermann, and F. L. Hahn and M. Hertrich, N. A. Tananaeff, E. Selch, A. A. Read, and H. Rose also show that very little loss occurs at the temp. of the blast gas-flame. According to E. J. Rode, there is a terrace in the heating curve of ferric oxide at 745°, and this is attributed to the formation of an allotropic oxide; the fluctuations in the curve at 1280° are attributed to the elimination of oxygen. If hydrated ferric oxide is similarly treated, there is an endothermic reaction corresponding with an unstable modification of ferric oxide which is converted into the stable, crystalline oxide at 320° to 340°, with the evolution of heat; the crystalline oxide undergoes another transformation at 450°. J. C. Hostetter and H. S. Roberts stated that the dissociation of ferric oxide into ferrous oxide and oxygen when it is dissolved in molten glasses occurs above 1300°, the exact temp. is dependent on the composition of the glass. The colour of pottery glazes, admixed with ferric oxide, is very markedly altered by variations of temp. much below this. F. Wüst reported that the evolution of oxygen commences at 600°, and at 1050° the residue is $Fe_2O_3.FeO$; at 1100°, $Fe_2O_3.2FeO$; and at 1200°, $Fe_2O_3.3FeO$. W. Biltz found that with the partial press. of oxygen the same as it is in the atmosphere, the equilibrium **dissociation temperature** for the $Fe_2O_3 \rightarrow Fe_3O_4$ is 1970°, and for the dissociation $Fe_2O_3 \rightarrow Fe$, 3025°; while W. D. Treadwell observed that at 1322°, the **dissociation pressure** of the oxygen from ferric oxide is 0·21 atm., and 1 atm. at 1405°. G. P. Baxter and C. R. Hoover observed a constant difference in weight of about 0·004 per cent. in ferric oxide heated in the neighbourhood of 1100° in a current of air, and in a current of oxygen. The oxygen value was higher, and they gave for the dissociation press., p mm.:

	1150°	1200°	1260°	1280°	1290°
p . . .	0·5	1·0	2·0	4·0	10·0 mm.

G. Charpy and S. Bonnerot gave 0·18 mm. at 800°, and 0·36 mm. at 900°. R. B. Sosman and J. C. Hostetter showed that there is a measurable dissociation of ferric oxide heated in air at all temp. between 100° and 1300°, and that the amount of dissociation increases with temp. P. T. Walden reported for the dissociation press., p mm., of ferric oxide:

	1100°	1150°	1200°	1250°	1300°	1350°	1400°
p . .	5·0	7·0	9·0	20·0	59·5	166·0	454·0

so that the press. at 1350° is approximately equal to the partial press. of the oxygen of the atmosphere. W. Hempel and C. Schubert, and C. Schubert said that the reaction: $6Fe_2O_3=4Fe_3O_4+O_2$ sets in slowly at 1250°, and is complete at 1500°. R. Ruer and M. Nakamoto found that ferric oxide in dry nitrogen loses no weight when heated up to 1125°; at 1150°, oxygen is lost until ferrosic oxide with 2 per cent. of dissolved ferric oxide is formed; and above 1200° up to 1550°, oxygen is lost continuously when the substance melts, and when cold, the product is ferrosic oxide with 4 per cent. ferrous oxide in solid soln. They found the dissociation press. of ferric oxide in oxygen at 1150° is scarcely measurable; at 1383° it is 0·20 atm.; and at 1455°, it is 1 atm. This agrees with the observations of E. Greulich, H. O. Hofman and W. Mostowitsch, A. Girard and G. Chaudron, and E. J. Kohlmeyer. With a constant press. of 10 mm., the isobar of ferric oxide was found, by A. Simon and T. Schmidt, to show a sharp break at 1300° corresponding with complete conversion of ferric to ferrosic oxide without the formation of any solid soln., or intermediate oxide—*vide supra*, ferrosic oxide. H. von Jüptner calculated for the dissociation press. at equilibrium for $2Fe_2O_3=4Fe+3O_2$, $\log p=28884T^{-1}+1·75 \log T+2·8$; for $2Fe_2O_3=4FeO+O_2$, $\log p=-29146T^{-1}+1·75 \log T+2·8$;

and for $3Fe_2O_3=2F_3O_4+O$, $\log p=-11466T^{-1}+1{\cdot}75 \log T+2{\cdot}8$. The values of p atm., calculated from these equations, are respectively:

Products	600°	1000°	1400°
Fe	$0{\cdot}0_{40}3326$	$0{\cdot}0_{20}1466$	$0{\cdot}0_{12}4724$
FeO	$0{\cdot}0_{20}1217$	$0{\cdot}0_{21}8017$	$0{\cdot}0_{12}3070$
Fe_3O_4	$0{\cdot}0_{11}3564$	$0{\cdot}0_{3}3837$	1·394

Products	1600°	2000°	2400°
Fe	$0{\cdot}0_{9}2263$	$0{\cdot}0_{5}1364$	$0{\cdot}0_{3}3791$
FeO	$0{\cdot}0_{9}1552$	$0{\cdot}0_{5}1009$	$0{\cdot}0_{3}3726$
Fe_3O_4	17·41	617·9	8668·0

Calculations were also made by G. G. Brown and C. C. Furnas, L. Wöhler and O. Balz, W. Biltz, H. O. Hofman and W. Mostowitsch, and F. Wüst and P. Rütten. S. Hilpert could not verify P. T. Walden's observations because the results varied considerably with the method of preparation, and the previous treatment of the ferric oxide, for the velocity at which equilibrium is attained, is extremely slow. The amount of ferrous oxide formed in air at 1300° did not exceed 5 per cent. He also said that the application of the thermodynamic formula to calculate the dissociation is untrustworthy. According to R. B. Sosman and J. C. Hostetter, the solid phase produced by the dissociation, $3Fe_2O_3=2Fe_3O_4+O$, is a series of solid soln. ranging from Fe_2O_3 to a point very near, if not at, Fe_3O_4. This hypothesis is confirmed by the optical properties of the residues with over 18 per cent. FeO, and by the pressure-composition isotherms at 1100° and 1200°. If FeO denotes the percentage of ferrous oxide in the solid soln., and p mm., the press. of the oxygen in the solid soln., Fig. 522:

Fe_3O_4	2·90	5·80	8·73	14·57	29·30	44·15	59·2	74·4	89·7	100·00
FeO	0·90	1·80	2·71	4·52	9·09	13·70	18·37	23·07	27·83	31·03
p 1100°	0·37	0·22	0·17	0·13	0·10	0·092	0·085	0·069	0·052	$<0{\cdot}005$
p 1200°	5·0	3·6	3·0	2·6	2·15	1·80	1·55	1·27	0·85	$<0{\cdot}04$

Magnetite dissolved in ferric oxide lowers the dissociation press. The results are plotted in Fig. 521. Since the composition of the solid phase depends on the relation between the weight of the charge and the vol. of the space in which the oxygen collects, the results in which these facts have not been taken into consideration are untrustworthy. M. Tigerschiöld wrote the dissociation equation: $6Fe_2O_3=4Fe_3O_4+O_2$, and using R. B. Sosman and J. C. Hostetter's data, gave for the equilibrium constant, K, which is here also the oxygen press., $\log K=\log p=-20{,}946T^{-1}+3{\cdot}5\log T+0{\cdot}0011577T-0{\cdot}6332$. O. C. Ralston, combining these data, and also those of P. T. Walden, gave $\log p=-23{,}550T^{-1}+13{\cdot}83$. Ferric oxide at 1348° has an oxygen press. of 0·207 atm., so that it is stable in air up to this temp., and beyond that temp. it will lose oxygen. Ferric oxide would exert 1 atm. press. at 1430°, and it could be heated in an atm. of oxygen up to this temp. without losing oxygen. Magnetite dissolved in ferric oxide would lower the dissociation press. No evidence was obtained of the existence of compounds of the two oxides above 1000°. The shapes of the curves are taken to show that there is a continuous series of solid soln. from Fe_2O_3 to 90 per cent. Fe_3O_4. The steeper ends of the curves, and the flatness of the central portion of the curve at 1100° when compared with that of the central portion of the 1200° curve, indicated that it is possible that at a lower temp. the central portion will be horizontal. In that case, two immiscible solid soln. will be in equilibrium with one another—one soln. will

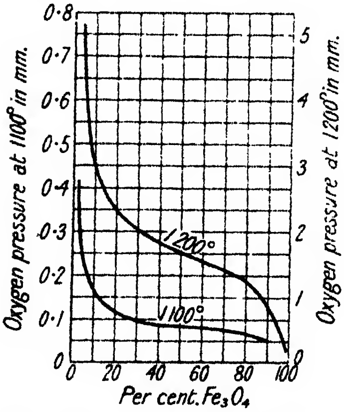

FIG. 521.—Dissociation Pressures in the System: Fe_2O_3–Fe_3O_4.

be Fe_2O_3 with some dissolved Fe_3O_4, and the other conjugate soln., Fe_3O_4 with some dissolved Fe_2O_3. The sloping ends of the curves would apply to unsaturated soln. M. Tigerschiöld deduced for the oxygen press., p, of solid soln. with 97·1 per cent. of Fe_2O_3, $\log p = -20{,}946T^{-1} + 3{\cdot}5 \log T + 0{\cdot}001157(T-600) + 0{\cdot}061$; and for solid soln. with 10·31 per cent. of Fe_2O_3, $\log p = -22{,}080T^{-1} + 3{\cdot}5 \log T + 0{\cdot}001157 (T-600) + 0{\cdot}061$. These are the approximate boundaries of the solid soln. of the system with ferric and ferrosic oxides. The results, plotted in Fig. 522, show the fields of stability of these two oxides—*vide infra*, ferric oxide. E. R. Wagner discussed the decomposition of the oxide in vacuum tubes.

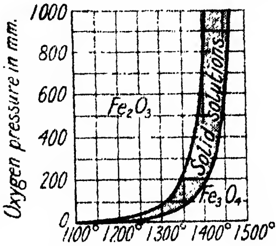

Fig. 522.—Oxygen Pressures in the System Fe_2O_3–Fe_3O_4 at Different Temperatures.

A. Smits and J. M. Bijvoet said that the two oxides are not isomorphous, and that it is very improbable that there is a continuous series of solid soln. of ferric and ferrosic oxides; and A. Simon and T. Schmidt explained the limited solubility of ferrosic in ferric oxide as an example of G. F. Hüttig's theory of vagabond atoms within the crystal lattice. P. P. Fedotéeff and T. N. Petrenko obtained solid soln. of the two oxides by oxidizing iron with a mixture of steam and air between 100° and 1100°, but not in the oxidation of iron by air alone. J. Huggett and co-workers said that their magnetic measurements indicate that 20 per cent. of ferrosic oxide can be dissolved in ferric oxide at 650°. The subject was also discussed by S. Hilpert and J. Beyer, H. S. Roberts and H. E. Merwin, P. Ramdohr, C. Benedicks and H. Löfquist, and E. D. Eastman. R. Ruer and M. Nakamoto obtained the composition curve of ferric oxide after heating it in nitrogen at different temp. No appreciable loss in weight occurred until about 1150°, when an abrupt loss occurred and the product contained about 98 per cent. of ferrosic oxide and 2 per cent. of ferric oxide. Further losses occurred as the temp. was raised. It is assumed that no solid soln. are formed until the product with 98 per cent. Fe_3O_4 is attained. The results contradict those of previous observers, unless some other interpretation is possible. The equilibrium conditions of ferric oxide in the presence of carbon monoxide and hydrogen were studied by A. Matsubara, and others—*vide supra*, Figs. 500 and 501. W. von W. Scholten titrated electrometrically a soln. of ferrous sulphate with a soln. of hypochlorite, and observed that in an acidic soln., the values of the potential furnished a smooth curve from ferrous to ferric sulphate, but in alkaline soln., there was an irregularity corresponding with the presence of a solid soln. of ferrous and ferric hydroxides.

E. J. Kohlmeyer observed that ferric oxide begins to sinter at about 950°, and it is very marked at 1360°; F. Sauerwald and G. Elsner studied the subject; H. O. Hofman and W. Mostowitsch observed a marked sintering after heating for half an hour at 1460°. The subject was also examined by J. A. Hedvall, and J. A. Hedvall and E. Helin. A. Brun gave 1300° for the **melting-point**; C. Schubert, 1500°; H. von Wartenberg and W. Gurr, 1570°; B. Garre, 1560°; and C. Doelter, 1350° to 1400°. These data do not represent true m.p., because R. Ruer and M. Nakamoto found that the product which melts in nitrogen at 1550° is ferrosic oxide with about 4 per cent. of dissolved ferrous oxide in solid soln. The m.p. of ferric oxide in the presence of enough oxygen to prevent dissociation has not been determined. W. Wicht observed that when ferric oxide is fused in the electric furnace, below 2000°, the product has the mol. proportion $FeO : Fe_2O_3 = 10 : 1$; H. Rose also noticed the partial reduction of ferric oxide during fusion —*vide supra*. S. Hilpert and E. Kohlmeyer found 1565° for a sample which, after melting, contained 10 per cent. of Fe_3O_4. C. G. Fink and C. L. Mantell observed that a sample at 1492° showed signs of softening, and it became fluid at 1503°. Observations were also made by O. Ruff and O. Goecke. The possible **allotropic changes** have been discussed elsewhere. There is a definite transformation point at about 700°, and the best representative value of this **transformation point** is taken to be 678°. H. Forestier and G. Chaudron found that mixtures of ferric oxide with ferrosic oxide, alumina, or chromic oxide, lower the transition temp.; and H. Warth found that alumina makes ferric oxide more stable at high temp.

E. J. Kohlmeyer found that red ferric oxide becomes black at 920° to 950°; it sinters strongly at 1370° and the evolution of oxygen begins; the product (solid soln.) melts at 1470°, and becomes quite liquid between 1525°, and 1600°. The m.p. of ferric oxide in oxygen gas is 1562° to 1565°. There is a break in the cooling curve between 1250° and 1350°, and a second between 1028° and 1035°. E. J. Kohlmeyer interprets his observations by assuming that near 1525°, when re-melting occurs, the material has the composition $3FeO.4Fe_2O_3$; that the melt which gave the longest pause at 1470° had the composition $3FeO.5Fe_2O_3$; and that which gave the longest pause at 1370° had the composition $FeO.3Fe_2O_3$. From these results, he set up a temperature-constitution ferric oxide. R. B. Sosman and J. C. Hostetter regard the alleged compounds as solid soln.—*vide supra*.

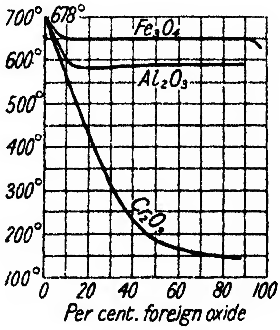

FIG. 523.—The Effect of Foreign Oxides on the Transition Temperature of Ferric Oxide.

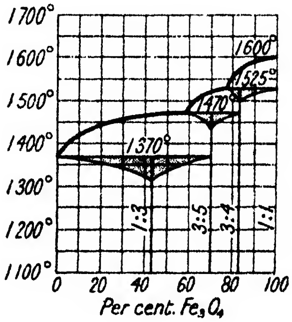

FIG. 524.—Equilibrium Diagram of the Binary System: Fe_2O_3–Fe_3O_4.

H. le Chatelier gave for the **heat of formation** (2Fe,3O)=194·4 Cals., and (2FeO,O)=65·2 Cals.; and for the conversion of ordinary to calcined ferric oxide, he gave 2·14 Cals. G. H. Brodie and co-workers gave (2Fe,3O)=267·4 Cals. per mol.; W. A. Roth, 198·5 Cals; W. G. Mixter gave (2Fe,3O)=192·2 Cals., (2FeO,O)=63·7 Cals., and $2Fe_3O_4+O=3Fe_2O_3+54{\cdot}5$ Cals.; and A. Simon and T. Schmidt calculated for $2Fe_3O_4 \rightarrow 3Fe_2O_3+36{\cdot}815$ Cals. W. A. Roth and co-workers gave $Fe_2O_3+3Cl_2=2FeCl_3+3O+7{\cdot}4$ Cals.; and $FeO+Fe_2O_3=Fe_3O_4+7{\cdot}0$ Cals. M. Tigerschiöld gave (2Fe,3O)=197·1 Cals. W. D. Treadwell gave $2Fe_3O_4+\frac{1}{2}O_2=3Fe_2O_3+49{\cdot}5$ Cals. O. Döpke gave (2Fe,3O)=197·4 Cals. H. von Jüptner estimated $4Fe+3O_2=2Fe_2O_3+132$ Cals.; $4FeO+O_2=2Fe_2O_3+133{\cdot}2$ Cals.; and $2Fe_3O_4+O=3Fe_2O_3+52{\cdot}4$ Cals. Observations were made by T. Andrews. G. S. Parks and K. K. Kelley calculated 197·5 Cals. for the heat of formation, —63·9 for the **entropy,** and —178·4 for the **free energy** at 25°. A. C. Halferstein gave $-107{,}748+63{\cdot}551T$ cals. for the free energy of the reaction $6Fe_2O_3=4Fe_3O_4+O_2$, and for the free energy of ferric oxide, $-194{\cdot}666+63{\cdot}514T$, so that the free energy at 25° is —175,780 cals. J. Chipman and D. W. Murphy studied the subject. R. Dallwitz-Wegener discussed the free energy of the compound, and K. K. Kelley, the entropy.

E. A. Wülfing observed that the **indices of refraction** of hæmatite for the *A*-, *a*-, *B*-, and *C*-lines are respectively $\omega=2{\cdot}904$, 2·949, 2·988, and 3·042, and $\epsilon=2{\cdot}690$, 2·725, 2·759, and 2·797; while C. Försterling gave for red, yellow, green, and blue light respectively $\omega=3{\cdot}05$, 3·11, 3·17. and 2·7; and $\epsilon=2{\cdot}87$, 2·88, 2·92, and 2·84. U. R. Evans, and F. H. Constable studied the optical properties of thin films of the oxide. Observations were also made by A. Kundt. G. Kalb, and L. Michel observed that the **birefringence** is strong; and the **optical character** is negative. According to R. B. Sosman and J. C. Hostetter, the observable optical properties of crystals of completely oxidized magnetite, and of hæmatite are not distinguished; they are uniaxial, and negative; $\epsilon=2\cdot74$ for $\lambda=700\mu\mu$; the birefringence is greater than 0·21; and the ω-absorption is greater than the ϵ-absorption. For samples of ferric oxide heated at 1200°, and containing FeO per cent. of ferrous oxide:

FeO .	0·58	5·60	12·99	16·11	17·79
ϵ . .	2·74	2·73	2·72	2·71	2·71

and $\omega-\epsilon$ in the first case exceeds 0·21, and in the penultimate case exceeds 0·16. The refractive index of magnetite is 2·42 for $\lambda=700\mu\mu$, and that of hæmatite is 2·74, so that the refractive index is lowered by dissolved magnetite, but the lowering is not proportional to the amount of ferrosic oxide in soln. All this agrees with the assumption that solid soln. of ferric and ferrosic oxides are formed when ferric oxide is heated to the temp. at which oxygen is given off. T. M. Broderick stated that some of the specimens of hæmatite assumed by R. B. Sosman and J. C. Hostetter to be solid soln., contained residual free magnetite which was visible on polished surfaces under the microscope. He added that before assuming the presence of solid soln. in natural hæmatite, the effect of free magnetite must be accounted for, and optical homogeneity must be shown in materials containing both Fe_2O_3 and Fe_3O_4. The variation in the colour of reflected light from adjacent grains similarly oriented; the apparent lack of enough magnetite to account for the magnetic properties; and the differences in the behaviour of the grains on etching, all support the hypothesis that solid soln. are present.

C. Försterling found the **absorption coefficients** for red, yellow, green, and blue light to be respectively 0·0875, 0·135, 0·173, and 0·377 for the ordinary ray, and 0·0670, 0·111, 0·126, and 0·305 for the extraordinary ray. M. Kimura and M. Takewaki studied the subject. Ferric oxide colours glass a yellowish-brown, and ferrous oxide a bluish-green. The tinctorial effect of the latter is greater than that of the former. S. English and co-workers investigated the effect of these oxide on the transmission of light of short wave-length by glass. The limits of transmission with the smaller proportions of oxide are:

Oxide . .	0·005	0·010	0·030	0·060 per cent.
Fe_2O_3-glass .	2600	2670	2840	2960 A.
FeO-glass . .	2600	2600	2780	2870 A.

Observations were also made by G. Jaeckel, and D. Starkie and W. E. S. Turner. The effect changes on exposure to light, owing to the transformation of ferrous into ferric oxide. The converse effect was noticed by W. W. Coblentz and R. Stair when the glass is heated in a gas-flame, owing to the presumed reduction of some ferric to ferrous oxide. The subject was studied by A. Rüttenauer, and A. Salmony. The scattering of light by suspended particles was measured by G. I. Pokrowsky. W. W. Coblentz observed that the ultra-red **reflecting power** was about 12 per cent. from 1μ to 13μ; whilst J. Königsberger found for light vibrating perpendicular to the principal axis, 25·71 per cent., or for light vibrating parallel to the chief axis, 22·86 per cent. J. Hofmann found the emission spectrum in the blue is greater than in the red. R. Eisenschitz and A. Reis, and E. Domek made observations on this subject. M. Kahanowicz found that the energy, E, emitted between 300° and 1100° follows the fourth power law, $E=1\cdot30\times10^{-10}T^4e^{-380\cdot5/T}$. The radiation energy was also discussed by E. Schmidt, V. Polak, C. P. Randolph and M. J. Overholser, I. Langmuir, F. Wamsler, M. Kahanowicz, and F. Paschen. According to J. Königsberger, the absorption coeff., a, for the long heat waves are $a=26$ for $\lambda=0\cdot5$ to $4\cdot0\mu$; $a=24$ for $\lambda=1\cdot6$ to $4\cdot0\mu$; $a=17$ for $\lambda=4\cdot0$ to 40μ; and $a=47$ for $\lambda=15$ to 40μ. F. Rinne found that the **pleochroism** of samples from Tvedestrand and Strassfurt is ω brownish-red, and ϵ yellowish-red; and H. Tertsch, with a sample from Vesuvian ash, ω=dark blood-red, and ϵ yellowish-red. The **spark spectrum** of hæmatite was observed by A. de Gramont, and W. N. Hartley and H. Ramage. M. Kimura and M. Takewaki found that the oxide is opaque for ultra-violet light. G. K. Burgess and P. D. Foote found that the **ultra-red emissivity** of ferric oxide for radiation of wave-length $\lambda=0{\cdot}65\mu$ varies from 0·98 to 0·92 over the interval 800° to 1200°; and the total emissivity increases from 0·85 at 500° to 0·89 at 1200°. K. Hild studied the total radiation of the oxide at 800° to 1400°. H. A. Barton and co-workers studied the emission of **positive ions** by the ferric oxide catalyst for ammonia. J. Ewles, and A. Pochettino found that the mineral exhibits a green **cathodoluminescence,** but W. Crookes observed none. M. Ishibashi studied the effect of **cathode rays.** C. B. Thwing found the **dielectric constant** of ferric oxide to be 14·20. According to J. A. Fleming and J. Dewar, the dielectric constant of water at −185° is very greatly increased in the presence of ferric oxide, but, from the slope of the curve, at lower temp., the effect would probably become less. A. Dufour showed that the spectral line 5789·7 A. shows the Zeeman effect when in a magnetic field of 28,000 gauss parallel to the lines of force. C. Doelter, and W. Ackroyd and H. B. Knowles measured the **absorption of X-rays** by ferric oxide; and C. H. Kunsman, the emission of **positive ions.** P. Martin observed the **Kerr effect** parallel to the chief axis evidenced by a positive rotation of 0·2″ and it increases towards the violet; and H. E. J. G. du Bois observed no Kerr effect vertical to the chief axis of hæmatite. S. Loria observed a smaller rotation than 0·2″ when taken parallel to the base. G. A. Dima found that the **photoelectric effect** of ferric oxide is smaller than that of ferrous oxide. H. A. Barton and co-workers, and E. Badareu observed the liberation of positive ions by heated ferric oxide. A. Wehnelt observed no emission of electrons at 1600°, but F. Jentzsch observed the effect. The thermionic emission of electrons between 2000° and 2500° was studied by G. P. Thomson, G. W. C. Kaye and W. F. Higgins, and A. K. Brewer; the surface electrons, by J. E. Nyrop; and the reflection of electrons from a film of ferric oxide, by E. Rupp and E. Schmidt. R. Whytlaw-Gray and co-workers, and E. Thomson found that the particles which exhibit the Brownian movement form straight chains under the influence of an electrostatic field.

R. J. Haüy observed that hæmatite is electrified like glass when it is rubbed with a handkerchief. The **electrical conductivity** of ferric oxide is good compared with that of many other metal oxides. G. Cesaro reported that the electrical conductivity of hæmatite is negligibly small; and F. Beijerinck obtained a similar result, but added that martite is a good conductor, and that the conductivity increases with rise of temp. Observations were made by P. J. Pelletier, S. P. Thompson, J. F. L. Hausmann and F. C. Henrici, E. Wartmann, W. Skey, F. von Kobell, and T. du Moncel. A. Abt found the **electrical resistance** of hæmatite to vary from 1430·52 to 6500 ohms. R. D. Harvey studied the subject. H. Bäckström found that the mineral is a good conductor, and that the conductivity of the crystal is different in different directions. Thus, the conductivity in the direction of the principal axis (0001) is nearly double what it is when perpendicular to that axis. If R_c denotes the electrical resistance in the direction of the principal axis, and R_a, the electrical resistance in a direction inclined to that axis, then, at 0°, R_c=80·8, and R_a=40·8; at 17°, R_c=68·7, and R_a=35·1; and at 100°, R_c=33·1 reduced to a length of 1 sq. mm. section; and R_a=18·3. The ratios R_c/R_a are respectively 1·98, 1·96, and 1·81, while at 236·7°, the ratio is 1·55. For a temp. θ°,

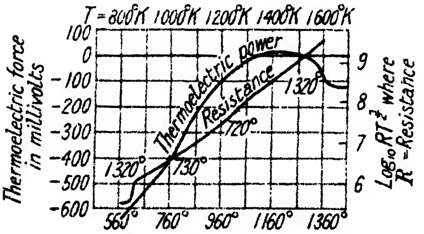

FIG. 525.—Electrical Resistance and Thermoelectric Power of Ferrous Oxide.

between 0° and 80°, the resistance, R, in a direction parallel to the chief axis, is $R=R_0(1+0{\cdot}014178\theta+0{\cdot}0_312533\theta^2-0{\cdot}0_651621\theta^3)$; and the resistance in a direction perpendicular to the chief axis, $R=R_0(1-0{\cdot}012796\theta+0{\cdot}0_31108\theta^2-0{\cdot}0_646464\theta^3)$. The resistance of hæmatite was 38·4 ohms at 19·9° when 3·01 per cent. of moisture was present. Heating a specimen to 1000° and cooling rapidly gave a specimen which was a poor conductor, but with slow cooling the conductivity was greater. J. Königsberger and co-workers, O. Reichenheim, and K. Baedeker obtained results in agreement with these values. J. Rosenthal observed that the conductivity of compressed ferric oxide is perceptible at 300°, and increases as the temp. rises. A. A. Somerville found the resistance of a rod at 252° was 10^7 ohms, and only 80 ohms at 1100°. Observations were made by S. Hilpert and E. Kohlmeyer, J. A. Osteen, J. Königsberger, S. Veil, C. C. Bidwell, G. Reboul and E. Bodin, G. Reboul, and E. Bodin. C. C. Bidwell's results for ferric oxide are summarized in Fig. 525. The electrical resistance is represented in terms of $\log_{10} R/T^{3/2}$, where T denotes the absolute temp., and R the resistance. There are breaks in the curve at 1320° and at 730°. T. W. Case observed no change in the electrical resistance of hæmatite on exposure to light. E. Diepschlag and F. Wulfestieg studied the high temp. electrical conductivity of ferrosic oxide mixed with silica, magnesia, or alumina. T. Frey observed no unipolarity in the compressed powder of ferric oxide.

Observations on the **thermoelectric force** of ferric oxide were made by T. J. Seebeck, and W. G. Hankel. According to H. Bäckström, the thermoelectric force between copper and hæmatite is such that a current flows from the base of the crystal through the hot junction to the copper with an e.m.f. of 0·0002879 volt per degree rise of temp., but if the hot junction is parallel to the chief axis, the e.m.f. is 0·0003138 volt per degree. J. Königsberger and J. Weiss obtained 0·0005 volt per degree at about 50°. C. C. Bidwell's results for ferric oxide against platinum are summarized in Fig. 525. There is a transformation point between 710° and 730°, and one at 1320°. There is a reversal in sign at 1125°. J. Königsberger discussed the theory of the thermoelectric force of ferric oxide against the metals.

W. D. Treadwell measured the press. of the oxygen in the transformation $Fe_2O_3 \rightarrow Fe_3O_4$ from the **electromotive force** of the oxide against an electrode of molten silver sat. with oxygen in the cell Fe_3O_4,Fe_2O | molten borax or glass | O_2,Ag between 800° and 1193°. The result is 0·262 volt, from which it is calculated that $2Fe_3O_4+\frac{1}{2}O_2=3Fe_2O_3+61{\cdot}3$ Cals. ; 0·897 volt was obtained for the cell Fe,FeO | electrolyte | O_2,Ag, from which it follows that $3FeO+\frac{1}{2}O_2=Fe_3O_4+74{\cdot}2$ Cals. ; and 1·040 volt for the cell Fe,FeO | electrolyte | O_2,Ag, from which it follows : $Fe+\frac{1}{2}O_2=FeO+66{\cdot}6$ Cals. W. D. Treadwell gave for the e.m.f. of the cell Fe_3O_4,Fe_2O_3 | electrolyte | O_2, in volts :

	980°	1000°	1010°	1018°	1050°	1080°	1080°	1100°
E.m.f. .	0·285	0·262	0·285	0·251	0·229	0·213	0·225	0·200

and the value at 1100° is in good agreement with the value calculated from the dissociation press. E. Liebreich, and E. Liebreich and F. Spitzer gave for the e.m.f., E volt, at 20°, of the cell Fe_2O_3 | KCl,H_2SO_4 | Fe, $E=0{\cdot}090$; Fe_2O_3|KCl,H_2SO_4|KCl,$HgCl_2$|Hg, $E=-0{\cdot}526$; and Fe_2O_3|KCl,NaOH|KCl,$HgCl_2$| Hg, $E=-0{\cdot}520$. For single crystals in the cell : $Fe_2O_{3\,\text{natural}}$ | Conc. feebly acidified soln. $ZnSO_4$ | Zn, G. Szivessy gave $E=1{\cdot}3335$ volt at 18°. V. H. Gottschalk and H. A. Buehler found that the electromotive force of hæmatite against copper in distilled water is 0·08 to 0·26 volt. S. B. Christy, and A. von Oettingen measured the potential of ferric oxide in soln. of potassium cyanide. K. Fischbeck and E. Einecke observed only 1 per cent. reduction of ferric oxide used as cathode, and this was attributed to the effect of impurities, or of occluded hydrogen. F. Peters, when comparing the capacities of accumulators with negative plates of natural and artificial ferric oxide, obtained no evidence of the electrolytic inactivity of ferric oxide indicated by T. A. Edison, and P. de Beaux. The subject was discussed by O. Pattenhausen. K. Fischbeck and E. Einecke studied the electrolytic reduction of solid ferric oxide; K. R. Dixit, the potential; and S. Borowik, the electrolytic valve action of ferric oxide.

Ferric oxide is usually paramagnetic, but it also exists in a ferromagnetic form both in nature and as a synthetic product; and this even in the absence of magnetite. Hæmatite may not only have a feeble **magnetic power,** but it may also exhibit polar magnetism. J. Plücker said that the relative magnetic powers of iron and hæmatite are as 100,000 : 759. The magnetic power of hæmatite was also noted by M. Faraday, L. F. Nilson and O. Pettersson, T. J. Seebeck, A. C. Becquerel, E. Colardeau, C. B. Greiss, C. F. Rammelsberg, A. Streng, H. A. J. Wilkens and H. B. C. Nitze, F. Bitter, R. Forrer, and T. L. Phipson. W. M. Mordey said that an alternating current magnet with hæmatite powder does not form radical lines of force about the poles as with ordinary ferromagnetic substances, but the powder arranges itself in rings. According to J. L. Smith, ferric oxide is magnetic when it contains small proportions of cobalt or nickel oxide. The magnetic properties of ferric oxide have been attributed by F. J. Malaguti, S. de Luca, J. L. Smith, S. H. Emmens, G. Gilbert, A. Collon, O. Mügge, T. T. Smith, W. H. Newhouse and W. H. Callahan, L. Duparc and co-workers, S. Hilpert and co-workers, R. Chevallier, R. B. Sosman and J. C. Hostetter, P. A. Wagner, G. Frebold and J. Hesemann, D. P. R. Chaudhuri, V. Daniloff and co-workers, O. Baudisch, A. Quartaroli, G. Jouravsky and co-workers, H. Sachse, G. E. Allan, and G. E. Allan and J. Brown to the presence of ferrous oxide, ferrosic oxide, or a ferrite. H. A. J. Wilkens and H. B. C. Nitze, and S. Veil discussed the magnetic separation of hæmatite.

According to S. Hilpert, since ferrosic oxide (*q.v.*) is constituted $FeO.Fe_2O_3$, *i.e.* ferrous ferrite, $Fe(FeO_2)_2$, or $(FeO)^{+}(Fe_2O_3)^{\cdot\cdot}$, the magnetic property is attributed to the acidic radicle. When ferrosic oxide is oxidized to red, ferromagnetic oxide, only the base ferrous oxide is oxidized to form ferromagnetic ferric oxide constituted $(Fe_2O_3)^{+}(2Fe_2O_3)^{-}$. Consequently, S. Hilpert assumes that metastable, magnetic ferric oxide is constituted $Fe^{\cdot\cdot\cdot}(FeO_3)'''$, ferric orthoferrite, whilst the non-magnetic ferric oxide is constituted $Fe_2^{\cdot\cdot\cdot}O_3''$. R. B. Sosman referred the magnetic qualities to the spacing and orientation of the iron atoms, without reference to the other atoms of the molecule. E. V. Shannon said that terrestrial ferromagnetic ferric oxide is not the same as the product of the oxidation of meteorites.

G. E. Allan and J. Brown found that both hæmatite and artificial ferric oxide become magnetic when heated in a magnetic field, and on cooling from 1000°, both oxides become permanently magnetized, presumably owing to the formation of ferrosic oxide. In hydrogen, the temp. at which the magnetic power is acquired is higher (300°), and is more sharply defined than it is in air. The curve showing the relation between the magnetic power and temp., in hydrogen, has maxima at 425°, 575°, and 750°, and these breaks are supposed to indicate the optimum temp. for the various stages in the reduction of ferric oxide by hydrogen. H. Moissan observed that ferric oxide becomes magnetic when heated in the electric furnace, and A. A. Read, when it is heated in the oxyhydrogen flame. The phenomenon is here attributed to the formation of magnetic ferrosic oxide, and not to the formation of ferromagnetic ferric oxide. V. Rodt obtained the ferromagnetic oxide by heating the product of the oxidation of hydrated ferrous or ferric oxide to 210°. W. H. Albrecht and E. Wedekind found that the magnetic susceptibility, χ mass units, of the hydroxide prepared by R. Willstätter and co-workers' process had a susceptibility:

Age . . .	0	1	1·5	4	6	25	30
Mols. H_2O . .	2·01	1·6	1·31	1·27	1·22	1·08	1·0
$\chi \times 10^6$ . . .	116	191	192	192	155	99	60

When prepared by precipitation from ferric nitrate soln., by ammonia at different temp.:

	Hot-washed				Cold-washed			
Temp. .	0°	25°	50°	100°	0°	25°	50°	100°
Mols. H_2O	1·43	1·52	1·45	1·12	2·37	2·11	2·09	1·38
$\chi\times10^6$.	285	321	323	255	203	261	257	230

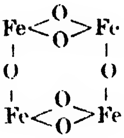
For the different hydrates:

H_2O . .	4·0	3·5	2·1	1·2	0·5
$\chi\times10^6$ . .	85	140	158	159	210

and for ferric oxide prepared, at different temp., from iron pentacarbonyl:

	815°	725°	575°	450°
$\chi\times10^6$ . .	2600	1100	1600	1200

According to E. Wilson, if the magnetic susceptibility of magnetite is 10, that of red hæmatite is 0·00020. P. Hausknecht, T. T. Smith, G. Dupouy, J. R. Ashworth, G. F. Hüttig and H. Kittel, L. Blanc and G. Chaudron, H. Sachse, A. Serres, M. Faraday, J. Königsberger, S. Meyer, E. Feytis, P. Weiss and R. Forrer, J. Plücker, G. Wiedmann, F. J. Malaguti, L. Külp, S. Henrichsen, A. Ditte, F. Rinne, C. F. Rammelsberg, A. Delesse, G. A. Kenngott, A. Liversidge, T. L. Phipson, G. B. Hogenraad, A. Abt, F. Schalch, F. Stutzer and co-workers, J. Kunz, B. Bavink, and E. Wilson and E. F. Herroun made comparative measurements of the magnetic susceptibility of ferric oxide. W. Hagen compared the susceptibilities of ferric oxide and chloride. R. Wallach measured the relative susceptibilities of ferric oxide prepared (i) by ammonia precipitation from a cold dil. soln. of ferric chloride; (ii) from hydrated ferric hydroxide obtained as just indicated, but heated in boiling water; and (iii) by the action of water on sodium ferrite. The first oxide gave a marked break in the heating curve at about 350°, and the third gave a break at about 750°. W. H. Albrecht found that ferric oxide obtained by calcining ferrosic oxide at 650°, 700°, and 1000°, in oxygen, had a magnetic susceptibility ranging from $3·4\times10^{-6}$ to 88×10^{-6} mass unit; and samples prepared by heating hydrated ferric oxide had values ranging from 22×10^{-6} to 34×10^{-6} mass unit. G. Wistrand gave $60·7\times10^{-6}$; E. Wedekind and W. H. Albrecht gave $\chi=220\times10^{-6}$ to 2600×10^{-6} for ferric oxide obtained by the combustion of iron pentacarbonyl; L. A. Welo and O. Baudisch, $144,000\times10^{-6}$ for the oxide obtained from ferrosic oxide at 300°, and 2700×10^{-6} for the oxide obtained from ferrosic oxide at 550°. E. F. Herroun and E. Wilson, $22,800\times10^{-6}$ to $55,000\times10^{-6}$ for the oxide obtained by dehydrating lepidocrocite, γ-$Fe_2O_3.H_2O$; $128,000\times10^{-6}$ for the oxide obtained from ferric oxide; $34,700\times10^{-6}$ for the oxide obtained from ferrous oxalate; 63×10^{-6} for the oxide obtained from basic ferric acetate; and 4400×10^{-6} for powdered iron-rust free from ferrous oxide; K. Honda and T. Sone obtained for commercial ferric oxide, $20·6\times10^{-6}$ at 10·5° to 17·5°; G. Berndt, 262×10^{-6} for $H=27$ gauss, and 354×10^{-6} for $H=201·7$ gauss; and R. Chevallier, $122,000\times10^{-6}$ for the oxide obtained from ferrosic oxide at 400°; and $12,700\times10^{-6}$ for the oxide obtained from ferrous sulphate soln., soda-lye, and hydrogen dioxide. The effect of impurities on the susceptibility was examined by E. F. Herroun and E. Wilson, J. Huggett and G. Chaudron, and S. Veil. J. Königsberger, S. Meyer, and G. Berndt found that the susceptibility, χ, decreases with an increase in the strength of the magnetic field; but L. A. Welo and O. Baudisch found that the susceptibility of ferric oxide obtained by oxidizing ferrosic oxide increases as the field-strength increases up to 65 gauss. G. F. Hüttig and H. Kittel found that the values varied with the mode of preparation; for a specimen of Fe_2O_3, the magnetic susceptibility was $22·8\times10^{-6}$ mass unit; and after heating in oxygen 4 hrs. at 600°, $57·6\times10^{-6}$ mass unit. The dissolved oxygen thus raises the susceptibility. The oxygen is adsorbed on the surface, or it is diffused in the lattice. A. Krause and co-workers attributed the magnetic properties to the $—Fe=O_2=Fe—$ group, and represented the constitution of ferromagnetic γ-Fe_2O_3, by



According to E. F. Herroun and E. Wilson, for a maximum field-strength, $H=180$ gauss, the permeability is a maximum, $\mu=3·68$; the coercive force, $H_c=64·7$ gauss: and the remanent induction, $B_r=252$ gauss. The remanence was studied by E. Holm, C. B. Greiss, A. Delesse, A. Abt, and R. B. Sosman and J. C. Hostetter. T. T. Smith observed that the normal magnetization curve of hæmatite has a sharp rise followed by a slow increase which is proportional to the field-strength. The loss of energy by hysteresis increases with an increase in the maximum field until it attains a constant value, about 150 gauss. H. Forestier and G. Chaudron found that the coeff. of magnetization of ferric oxide varies with the thermal and magnetic treatment to which the sample is subjected. Starting with an oxide devoid of all magnetization, the magnetization-temperature curve shows an increase in the coefficient of magnetization up to 600°; this is followed by a sharp decrease, which ends at 675°. The magnetization-temperature curve obtained on cooling is separated from that obtained on heating below 600°, and the coefficient of magnetization increases on cooling down to the ordinary temp. On repeating the experiment with the same sample, a curve is obtained which is rigorously reversible and superposable on the cooling curve of the first experiment: moreover, the sample is now polarized. Magnetization can be destroyed by heating beyond 675° and cooling in a non-magnetic field. Under the same conditions with magnetite and ferrites, a very sharp increase in the coefficient of magnetization is obtained. The subject was also discussed by J. Huggett and G. Chaudron, R. Chevallier, and G. Berndt. R. B. Sosman and E. Posnjak found that the hysteresis loops of magnetite, and ferromagnetic ferric oxide—natural and artificial—are different, Fig. 526. C. W. Heaps, and C. W. Heaps and J. Taylor observed the Barkhausen effect in the magnetization of crystals of hæmatite. J. Kruckenberg studied the magnetostriction of ferric oxide.

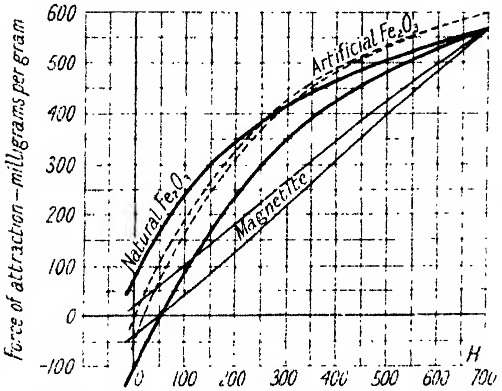


FIG. 526.—Hysteresis Loops of Magnetite and Ferromagnetic Ferric Oxide.

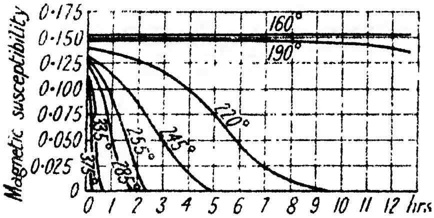

FIG. 527.—The Effect of Time and Temperature on the Magnetic Susceptibility of Ferromagnetic Ferric Oxide.

According to H. Sachse, and H. Sachse and R. Haase, the regular ferromagnetic ferric oxide is unstable at all temp. The susceptibility lost about 60 per cent. of its original value in 4 years, and at the same time, the faculty of transformation is greatly increased. The effect of temp. and time on the susceptibility is illustrated in Fig. 527. The curves show a period of induction. The unstable ferromagnetic oxide is a pseudomorph after magnetite, and this changes to that of ordinary, stable ferric oxide. H. Sachse studied the X-radiograms.

E. F. Herroun and E. Wilson found the magnetic susceptibility of hæmatite to range from $25\cdot0\times10^{-6}$ to $36\cdot8\times10^{-6}$ mass unit, and that of specular iron ore from 107×10^{-6} to 517×10^{-6}. G. Grenet obtained values ranging from 316×10^{-6} to 9×10^{-6} for the coeff. of magnetization. T. D. Yensen studied the magnetization of thin films. J. Tyndall and H. Knoblauch, J. Kunz, O. Mügge, A. Girard and G. Chaudron, B. Bavink, and T. T. Smith studied the relation of the magnetic field and the axes of the crystal on the magnetization. J. Westman found that a crystal of hæmatite is paramagnetic in all directions, but the magnetic susceptibility in the direction of the principal axis, (0001), is only a few hundredths of its value taken perpendicular to the chief axis. Thus, the magnetic susceptibilities in absolute units, with a field-strength, *H*, are :

H	48	60	72	Mean
Perpendicular to chief axis . .	1·780	1·840	1·900	1·840
Parallel to chief axis . . .	0·050	0·073	0·093	0·072

K. Honda and T. Sone found that the magnetic susceptibility, χ mass units, of paramagnetic ferric oxide increases as the temp. rises from −173° somewhat as follows :

	−173°	−52°	−4·5°	104°	371°	596°	696°	817°	1301
$\chi\times10^6$.	13·9	15·4	20·4	21·2	25·1	32·4	14·7	14·7	12·6

The rapid increase in the susceptibility in passing from about 0° to 596° is attributed to the presence of traces of magnetite. The rapid decrease in the susceptibility from about 596° represents the known magnetic transformation on magnetite at 690°. The curve Fig. 527, represents the susceptibility of hæmatite at elevated temp. Hence, it is inferred that the susceptibility of pure hæmatite would suffer a small decrease on raising the temp. from −190° to 1300°. When ordinary paramagnetic ferric oxide is cooled, the susceptibility falls rapidly down to −40°, and thereafter very slowly ; from −40° to −185°, the curve is reversible, but when warmed above −40°, if in a magnetic field, the hæmatite becomes ferromagnetic, so that at room temp., the susceptibility is nearly twice the value of the original sample. With further heating to about 600°, the susceptibility increases irreversibly in the magnetic field, and then rapidly falls to the original value at about 690°. Above this temp., no marked change occurs, and what there is, is reversible. On cooling below 690° in a magnetic field, the susceptibility increases as the temp. drops to room temp. The susceptibility induced by this heat-treatment is much below that of magnetite, but during the change of temp. from −40° to 600°, if carried out in a magnetic field, the material becomes ferromagnetic.

S. Hilpert gave 500° for the Curie point, he also found an irreversible transformation which occupies some days at 400°, a few hours at 500° ; and is almost instantaneous at 700°. J. Huggett and G. Chaudron gave 675° for the Curie point ; and there is an anomaly at 570° which is attributed to the presence of a little magnetite. R. B. Sosman and E. Posnjak found that natural ferromagnetic ferric oxide becomes paramagnetic at 750°. E. F. Herroun and E. Wilson observed that the effect of temp. on the susceptibility is greatly influenced by the mode of preparation of the samples ; and L. Blanc and G. Chaudron, by the grain-size of the material. R. B. Sosman and E. Posnjak also found that ferromagnetic ferric oxide undergoes two types of inversion at high temp. : (1) A reversible inversion, consisting in a relatively sudden change from ferromagnetic to paramagnetic at a temp. not far above 500°. On cooling, the ferromagnetic condition is again assumed. This inversion is similar to those in metallic iron and in magnetite, although at a different temp. (2) An irreversible inversion, consisting in a complete loss of the ferromagnetic property, the oxide becoming like ordinary paramagnetic Fe_2O_3 and perhaps identical with it. This change occurs at an increasing rate as the temp. rises, being slow at 500°, while it is complete in a few minutes at 650° and higher. L. A. Welo and O. Baudisch observed that when magnetite is oxidized to ferric oxide at 220°, there is an increase in the maximum magnetic permeability from 2·93 to 3·39, and when magnetic ferric oxide is heated to 550° in nitrogen, the permeability falls to 1·045, the value for non-magnetic hæmatite. Magnetite can be heated at 800° in an inert atm. without permanent loss of permeability. L. H. Twenhofel observed the transition from ferromagnetic to paramagnetic ferric oxide occurs at 500°, and by heating natural ferrosic oxide, ferromagnetic ferric oxide can be obtained at 800°. J. Huggett and G. Chaudron also found that ferromagnetic ferric oxide is irreversibly transformed, into the non-magnetic variety, when heated to a high enough temp., and heat is at the same time evolved. The reversibility with the ordinary, impure oxide is attributed to the elevation of this temp. above the point of magnetic transformation. The magnetite break occurs at 570° with specular ferric oxide, and martite. The Curie point occurs at 620°. There is a maximum in the curve with the purified oxide at 350°, and this is taken to represent the transformation temp. for the passage of ferromagnetic ferric oxide to the ordinary oxide. R. Yoshimura noted that the presence of chromic oxide lowers the transformation temp. H. Abraham and R. Planiol, L. Blanc, and L. Blanc and G. Chaudron observed that the magnetic form is converted into the non-magnetic from at 600° to 650° ; R. Chevallier said that there is a rapid decrease in the ferromagnetism at 600° to 700°, but is not completely gone at 745° ; R. B. Sosman and E. Posnjak said that the irreversible change is slow but noticeable at 500°, and that it is rapid at 650°. The change at approximately 678°, which may involve a re-crystallization of the oxide, is probably associated with the rearrangement of the atoms in the molecule where the metastable, ferromagnetic molecule forms the stable molecule of paramagnetic hæmatite. The Curie point where there is a reversible loss of ferromagnetism is probably not associated with any molecular rearrangement of the molecule of ferric oxide; at any rate, the X-radiograms of iron, and of magnetite show that no change occurs in the space-lattice of the crystals. The reversible loss of the ferromagnetism of ferric oxide occurs just over 500°, a temp. which is lower than 593·5°, the Curie point of magnetite. It is thought that the magnetic change is associated with the electrons in one of the first three shells of electrons of the atom of iron. K. T. Compton and E. A. Trousdale, and A. H. Compton and O. Rognley could not detect any change in structure when crystals of hæmatite are placed in a strong magnetic field.

J. Beyer found that in a series of solid soln. of ferric and ferrosic oxides, the magnetizability decreases as the proportion of ferric oxide increases, and with over 82 per cent., it becomes zero. J. Huggett and G. Chaudron examined the magnetic properties of mixtures of ferric and ferrosic oxides as they were raised quickly to 800°, and then cooled. The regular magnetic transformation of magnetite at 570° appears in all mixtures with up to 90 per cent. of ferric oxide; there is a magnetic anomaly at 670° with high proportions of ferric oxide, and at 650° with mixtures having from 10·35 to 80·54 per cent. of ferrosic oxide. The anomaly could be faintly traced with mixtures having a little more ferrosic oxide. It is assumed that mixtures with up to 10·35 per cent. of ferrosic oxide are solid soln. of ferrosic oxide in an excess of ferric oxide, and that the transformation point is lowered by increasing proportions of ferrosic oxide until, at 10·35 per cent., the solid soln. is saturated, and any further addition of ferrosic oxide will remain as a new solid soln. of ferric oxide in ferrosic oxide, and the new solid soln. does not mix with the sat. soln. of ferric oxide in ferrosic oxide. The solid soln. of ferrosic oxide in ferric oxide is sat. when 80·54 per cent. of ferric oxide has dissolved, and any further addition of ferrosic oxide produces soln. of magnetite that are not sat. with ferric oxide. The magnetic transformation of ferrosic oxide in the range tested is not altered by the ferrosic oxide being in solid soln. The temp. of the polymorphous change of the ferric oxide is definitely lowered by increasing proportions of ferrosic oxide. R. B. Sosman and J. C. Hostetter found the susceptibility to be proportional to the amount of ferrosic oxide present in soln. No indication of intermediate compounds was observed by R. B. Sosman and J. C. Hostetter or by J. Huggett and G. Chaudron. R. Becker and H. W. F. Freundlich studied the disposition of colloidal particles of ferric oxide on the surface of a magnetized iron plate.

The chemical properties of ferric oxide.—The transformations of hæmatite in nature have been discussed by J. R. Blum,[13] A. H. de Bonnard, E. von Federoff and S. N. Nikitin, A. Frenzel, T. Grandjean, G. Grattarola, R. C. van Hise, H. A. Miers, R. Pumpelly, and G. Tschermak. H. Wedding and T. Fischer found that hæmatite absorbs 0·0002 to 0·0008 mgrm. of **hydrogen** per gram—W. A. Lazier and H. Adkins said that none is absorbed. Ferric oxide is reduced to iron when heated in hydrogen. G. Magnus said that the lowest temp. at which reduction occurs is a little above the b.p. of mercury, namely, 357°. If reduced at the lowest possible temp., the metal is pyrophoric; H. Moissan obtained the pyrophoric metal by reducing the oxide at 440°; if, however, the oxide be reduced at higher temp.—*e.g.* 600°—the product is not pyrophoric. Observations on the action of hydrogen on ferric oxide were made by G. E. Allen and J. Brown, A. Brun, H. Fleissner and F. Duftschmid, A. C. Fieldner and A. L. Feild, C. G. Fink and C. L. Mantel, S. Hauser, P. Sabatier and J. B. Senderens, H. Nishimura, C. Kröger, M. O. Kharmadaryan and G. V. Marchenko, and F. Stromeyer. R. Yoshimura discussed the use of ferric oxide in oxidizing the hydrogen in water gas. W. A. Lazier and H. Adkins discussed the adsorption of hydrogen.

C. R. A. Wright and A. P. Luff said that the reduction occurs at 245°; and F. Gläser said that the reduction occurs at 245°; reduction was observed during 4 hrs.' heating at 283°. E. Vollgold said that hydrogen acts vigorously at 475°. M. Siewert reported that ferric oxide is not reduced at 270° to 280° by hydrogen; at 280° to 300°, ferrous oxide is formed; and above 300°, at about 357°, the metal is produced. H. S. Taylor and R. M. Burns found that even after 26 days, the reduction of ferric oxide by hydrogen is not completed at 450°. G. B. Taylor and H. W. Starkweather said that ferric oxide gel is reduced to ferrosic oxide at 350°, and to metallic iron at 450°; ignited ferric oxide is not appreciably reduced at 350°, but it passed to the metal at 450°; alumina and chromic oxide retard the reduction. The copper (or nickel) first produced during the reduction of copper (or nickel) oxide by hydrogen acts as a catalytic agent on the subsequent course of the reaction, but P. H. Emmett, and A. F. Benton and P. H. Emmett observed no autocatalysis during the reduction of ferric oxide by hydrogen. P. H. Emmett likewise observed no evidence of the autocatalysis of the reaction by the iron as it is reduced from the oxide. For the reduction of the molten oxide, *vide supra*, ferrosic oxide.

F. Wüst and P. Rütten showed that the temp. of the beginning of the reduction as well as the speed of the reduction depends on the previous history of the ferric oxide. Thus, according to W. Müller-Erzbach, moist ferric oxide, obtained by the roasting of iron, begins to be reduced at 293°, and if dry, at 305° to 330°; moist ferric oxide obtained by roasting the oxalate is reduced at 278°, that obtained from the hydrate, at 286°, and hæmatite, or very strongly calcined ferric oxide, at a red-heat. A. F. Benton and P. H. Emmett found that the oxide, obtained by calcining the nitrate at 525°, is reduced less readily at 300° than is the precipitated oxide, dried at 250°, and it is reduced at 285°. S. Hilpert found that ferric oxide obtained from the oxalate at 800°, 1000°, and 1200°, begins to be reduced by hydrogen respectively at 280° to 290°, at 290°, and at 330° to 350°; and ferric oxide obtained by heating the hydrated oxide to 400°, 850°, 950°, and 1200°, begins to be reduced respectively at 280°, 280° to 290°, 300°, and at 330° to 350°. P. H. Emmett and K. S. Love found that the rate of reduction of the cubic ferric oxide is rather quicker than is the case with the rhombohedral oxide. The rate of reduction of either oxide is reduced 50 to 90 per cent. if the oxide has been heated at 550° instead of at 300°. The presence of alumina does not affect appreciably the rate of reduction of Fe_2O_3 to Fe_3O_4, but it markedly retards the speed of reduction of Fe_3O_4 to Fe. K. Hofmann found the speed of reduction of ferric oxide is greatest when the grain-size is between 0·02 and 0·05 mm. diameter; with smaller grains, sintering retards the reactions. J. Percy said that in the reduction by hydrogen, ferrosic oxide appears to be first formed, and if the reduction occurs at a low temp. the product will sometimes be found to consist almost entirely of the magnetic ferrosic oxide and it is then coloured black, not grey. According to E. Berger, the curve representing the quantity of ferric oxide reduced in hydrogen at 209·5° after different intervals of time, has a break corresponding with Fe_3O_4, but not with FeO. A. F. Benton and P. H. Emmett found that at 285° to 300°, the speed of reduction is greatest at the beginning and decreases continuously until the composition has attained Fe_3O_4, or just a little beyond this stage, when it proceeds at a nearly constant rate. K. Hofmann observed that ferrosic oxide is reduced more slowly than ferrous oxide under similar conditions. The speed of reduction of powdered ferric oxide is a maximum at about 550°, and at about 100°; that there are minima in the curve at about 750°, and between 900° and 925°. These minima also occur with ferrosic oxide. K. Hofmann also said that it is unlikely that ferric oxide is reduced in stages: $Fe_2O_3 \rightarrow Fe_3O_4 \rightarrow FeO \rightarrow Fe$, because below 564°, ferrous oxide does not appear in the equilibrium diagram, Fig. 20, and ferrous oxide is formed more readily than ferrosic oxide or iron; whilst above 564°, ferrosic oxide is not formed. F. Gläser, and H. Moissan supposed that the reduction proceeds in the stages just indicated, but S. Hilpert also showed that this assumption is *nicht richtig*. According to E. J. Rode, the time-temp. curve of ferric oxide in hydrogen exhibits two breaks; one at 300° to 325° corresponds with the formation of ferrosic oxide, and the other, at 350° to 370°, corresponds with the reduction of ferrosic oxide to iron. There is no evidence of the intermediate formations of ferrous oxide.

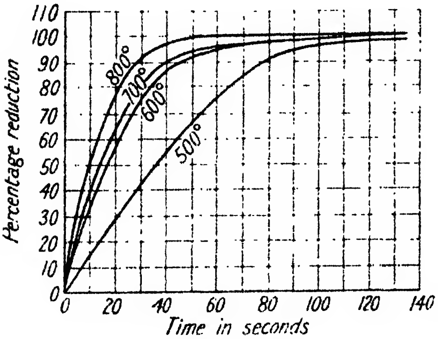

FIG. 528.—The Effect of Temperature on the Speed of Reduction of Hæmatite by Hydrogen.

H. Kamura measured the speed of reduction of hæmatite by hydrogen. Nearly perfect reduction can be effected in about 2 hrs. at 500°. As the temp. rises from 500° to 600°, the higher the temp., the faster the reduction, Fig. 528. Probably the reduction proceeds in stages: $Fe_2O_3 \rightarrow Fe_3O_4 \rightarrow FeO \rightarrow Fe$. He also measured the relation between the temp. and the vol. of hydrogen passed over the heated hæmatite, and the results are in general agreement with the results for the equilibrium constant, $K=[H_2O]/[H_2]$, which increases as the temp. increases. At 600°, the speed of reduction increases rapidly, and the vol. of hydrogen employed decreases suddenly, presumably owing to the appearance of the new phase, FeO, which could not exist below 570°. Above 600°, the speed of the reduction does not increase as it does around this temp., and the vol. of hydrogen used does not make much difference. Hence, H. Kamura inferred that this would be the most economical temp. for the reduction of iron ores by hydrogen. The subject was studied by S. Mita, and H. Saito. G. E. Allan and J. Brown suggested that the breaks observed in the curve representing the magnetic properties of the products obtained by the action of hydrogen on ferric oxide represent various stages in the reduction of ferric oxide. S. Hilpert, and J. Beyer found that at 500°, there is a sharp break in the velocity of the reaction when the composition approximates Fe_3O_4; at higher temp., the products—solid soln.—contain more and more ferrous oxide, until at 1100°, 98·5 per cent. ferrous oxide is present. If water vapour be absent, and hydrogen alone be employed as reducing agent, definite intermediate reduction products cannot be isolated. M. Tigerschiöld said that the reactions $3Fe_2O_3+CO=CO_2+2Fe_3O_4$ and $3Fe_2O_3+H_2=H_2O+2Fe_3O_4$ are practically irreversible.

K. Hofmann emphasized the effects of surface phenomena during the reduction, and did not obtain ferrosic oxide as an intermediate product. A. F. Benton and P. H. Emmett concluded that the reduction of ferric to ferrosic oxide is a "non-interfacial" reaction—*vide* nickel oxide. H. Debray, H. St. C. Deville, E. Baur and A. Glässner, and G. Preuner made observations on the equilibrium conditions, a subject which has been previously discussed. L. Wöhler and O. Balz gave for $K=[H_2O]/[H_2]$, in converting Fe_2O_3 to Fe_3O_4, $K=7{\cdot}5$ at 350° and 17·9 at 950°. For W. Biltz and H. Müller's observations on the equilibrium $Fe_2O_3/Fe_3O_4=p_{H_2O}/p_{H_2}$, *vide supra*, ferrous oxide. The gas phase in the 3-phase equilibria: $FeO+Fe+G$, and $Fe_3O_4+FeO+G$ has been studied both as $[CO]/[CO_2]$ and $[H_2]/[H_2O]$. The systems are univariant at constant press., but the relations are independent of press., so that there is no need to keep the press. constant. F. E. C. Scheffer studied the subject from the point of view of the phase rule. According to A. Bornträger, ferric oxide is reduced by nascent hydrogen so that if ferric oxide be added to hydrochloric acid in which metallic iron is dissolving, it is quickly reduced and dissolved as ferrous chloride. A. F. Benton studied the adsorption of hydrogen by ferric oxide. W. A. Bone and R. V. Wheeler noticed that ferric oxide, like platinum, acts catalytically in the surface combustion of hydrogen in oxygen—*vide infra*.

R. Ruer and J. Kuschmann found that ferric oxide, which has been calcined at 700°, adsorbs **air** to the extent of 0·0025 per cent. at room temp. J. Milbauer observed that if ferric oxide be heated to 480° in **oxygen** under 12 atm. press., no chemical change occurs, and no higher oxide is formed. A. F. Benton studied the adsorption of oxygen by ferric oxide. Several oxides between ferric and ferrosic oxide have been reported. The irregularities in the dissociation press. of ferric oxide led S. Hilpert to suspect the formation of intermediate oxides. E. J. Kohlmeyer's observations on the cooling curves of ferric oxide, which had been heated rapidly to its m.p., showed breaks corresponding with the three oxides, *ferrous triferric oxide*, $FeO.3Fe_2O_3$, *triferrous pentaferric oxide*, $3FeO.5Fe_2O_3$, and *triferrous tetraferric oxide*, $3FeO.4Fe_2O_3$, as well as inversion points at 1028° to 1035° and at 1250° to 1350°; but R. B. Sosman and J. C. Hostetter were unable to detect any evidence of these compounds or these inversion points. They did find a sharp inversion on the cooling curve at 678°, and a barely detectable irregularity between 755° and 785°. O. Hauser, and H. Chandra obtained *tetraferrous ferric oxide*, $4FeO.Fe_2O_3$—*vide supra*; and F. Kaufmann, H. Chandra, and F. Haber also reported *diferrous triferric oxide*, $2FeO.3Fe_2O_3$, to be deposited on heating, in the absence of air, the golden-yellow soln. obtained by electrolyzing at 0° a soln. of ammonium nitrate using a carbon anode and an iron cathode, and a cathode current density of 0·00002 amp. per sq. cm. It is said to be obtained by boiling a soln. of 21 grms. of crystalline ferrous sulphate in 220 grms. of water and 22 grms. of 20 per cent. aqua ammonia; adding 2·5 grms. of potassium nitrate, in small quantities at a time, and continuing the boiling for 15 mins. The product is bluish-black while ferrosic oxide is brownish-black. H. Chandra said that although this product can be dried at 180°, it is unstable at higher temp.—*vide supra*, ferrosic oxide. R. B. Sosman and J. C. Hostetter were unable to find any indication of its existence between 1100° to 1200°, and, as indicated above, they showed that ferric and ferrosic oxides form a continuous series of solid soln. over the ranges represented by these products. A. Simon observed no solid soln. of ferric and ferrosic oxides. R. Ruer and J. Kuschmann found that ferric oxide which had been heated to 700° adsorbs air, but this property is almost completely lost when the oxide is heated to 1000°. E. Reichardt and E. Blumtritt observed that 100 grms. of ignited ferric oxide absorbed 39 grms. of gas from the atmosphere, and that gas contained 83 per cent. of nitrogen, 13 per cent. of oxygen, and 4 per cent. of carbon dioxide. P. H. Emmett and K. S. Love observed that the catalytic decomposition of **ozone** at −74° is equally rapid with the cubic and trigonal forms of oxide, but it is less rapid with varieties of either oxide which have been heated to 550° than those heated to

300°. A. Mailfert stated that ozone does not act on dry ferric oxide, but in the presence of potassium hydroxide, a ferrate is formed.

O. L. Erdmann, L. Brandt, and W. Müller-Erzbach discussed the adsorption of **water** vapour, or the hygroscopic properties of ferric oxide; S. S. Bhatnagar and S. L. Bhatia studied the rate of evaporation of adsorbed water from ferric oxide. B. Aarnio said that if ferric oxide has been completely dehydrated it is not hygroscopic. H. Freundlich and co-workers studied the absorption of water by the oxide; and L. V. Lyutin, suspensions of the oxide in water. P. H. Emmett and K. S. Love found that the adsorption of water is 10 to 60 per cent. less with cubic ferric oxide than it is with the rhombohedral form. In general, the adsorption with both forms of oxide is 75 to 80 per cent. less with oxides which have been heated to 550°, than with those which have been heated only to 300°. The catalytic activities of the two varieties of ferric oxide on the rate of combination of hydrogen and oxygen are approximately the same with samples of both which have been heated to 250°, or to 550°. O. Ruff and A. Riebeth prepared plastic mixtures of ferric oxide with water, *N*-HCl and *N*-KOH. A. Quartaroli, and E. Rosenkranz studied the catalytic action of the oxide on **hydrogen dioxide.**

G. Schikorr discussed the action of hydrated ferric oxide on water—*vide infra*, the corrosion of iron. Ferric oxide is generally considered to be insoluble in water, but C. Doelter found that if hæmatite be heated on a water-bath, at about 80°, with distilled water in a sealed tube, the water dissolves about 0·13 per cent.; a sat. soln. of sodium chloride under similar conditions dissolved 2·74 per cent. in 23 days; while a 10 per cent. soln. of sodium carbonate similarly dissolved 1·987 per cent. in 26 days. J. W. Gruner observed that peat-water dissolved from hæmatite 25 parts of iron per million in 77 days, and 27 parts in 182 days. R. Ruer and J. Kuschmann studied the adsorption of atm. moisture by ferric oxide. According to H. Wölbling, anhydrous hæmatite cannot be hydrated by mixing it with aq. soln. of acids, bases, and salts, for no sign of such a change was observed after two years' contact; but the hydrated forms of hæmatite may form higher hydrates in this way. O. Ruff studied the hydration of the oxide under press.—*vide infra*. P. H. Emmett and K. S. Love found that the catalytic activity of the two forms of ferric oxide on the oxidation of benzidine or guaiacum by **hydrogen dioxide** is nearly the same provided the oxides have been heated to 300°; if heated to 550°, the activities of both forms are almost annulled. For the action of **sodium dioxide,** *vide infra*, ferrates and perferrates.

H. Moissan found that **fluorine** does not act on ferric oxide in the cold, but when warmed ferric fluoride is formed. H. Davy said that at a red-heat, **chlorine** does not act on ferric oxide, but it decomposes ferrosic oxide at a lower temp. According to R. Weber, and H. Schulze, when ferric oxide is heated to a high temp. in a current of chlorine, a small proportion of ferric chloride is formed; but E. Mallet and P. A. Guye observed no action at ordinary temp. W. Kangro and R. Flügge observed that something is wrong with some of these statements, for, with hæmatite at 1000°, 100 per cent. of iron was volatilized as chloride in 210 mins., and at 800°, 88·1 per cent. in 420 mins. In another case, with an hour's heating:

	600°	700°	800°	900°	1000°
Loss in iron	0·9	14·2	29·6	60·2	75·8 per cent.

and at 900°:

Time in hours . . .	1·5	4·5	12·6	20·4
Loss in iron	14·0	29·6	60·2	70·0 per cent.

Hence, the action is quite perceptible at 700°, and it is rapid at 900°. W. A. Roth gave $Fe_2O_3+3Cl_2=2FeCl_3+3O+7{\cdot}4$ Cals. at 97°. R. Wasmuht observed that ferric oxide alone reacts with chlorine at about 525°; if carbon is present, at 500°; and if sulphide or phosphide is present, at 250°. V. Spitzin also observed that chlorine begins to act on ferric oxide at 400°. L. Mathesius observed that **bromine** water does not attack ferric oxide, but a warm soln. of bromine and ammonium acetate dissolves the oxide—a cold soln. does not do so. I. L. Bell found that an aq. soln. of **iodine** does not attack ferric oxide.

As shown by J. J. Berzelius, and H. Rose, ferric oxide is more or less soluble in acids; but H. le Chatelier observed that ferric oxide which has been calcined at 950° is insoluble in acids. G. Gore studied the action of liquid **hydrogen fluoride** on ferric oxide. C. W. Scheele noted that ferric oxide is soluble in **hydrofluoric acid**; and E. Zalinsky said that, unlike magnetite, hæmatite is but sparingly soluble in hydrofluoric acid. K. F. Stahl found that calcined ferric oxide dissolves more readily in hydrofluoric acid than it does in other acids. According to E. Deussen, the rate of solution of ferric oxide in acids is smaller, the higher the temp. at which it has been previously calcined. He found that the following quantities of ferric oxide were dissolved by 10 c.c. of hydrofluoric acid, and **hydrochloric acid,** at 25°:

	Calcined Fe_2O_3			Non-calcined Fe_2O_3		
Time .	4½	43½	139½	4½	21¾	45¾ hrs.
N-HF .	0·0880	0·2035	0·2194	0·1581	0·2235	0·2279 grm.
N-HCl .	0·0224	0·1000	0·1910	0·0409	0·1230	0·2125 grm.

With uncalcined ferric oxide and 10 c.c. of 0·5*N*-acid at 25° acting for 2¾, 23½, and 56½ hrs., the amounts of ferric oxide dissolved by ½*N*-HF were respectively 0·0579, 0·1045, and 0·1162 grm., and with ½*N*-HCl, respectively 0·0126, 0·0382, and 0·0672 grm. Similarly, with 10 c.c. of ¼*N*-acid acting for 2¾, 24¾, and 142½ hrs., the amounts of ferric oxide dissolved by ¼*N*-HF were respectively 0·0180, 0·0475, and 0·0534 grm., and by ¼*N*-HCl, respectively 0·0040, 0·0120, and 0·0306 grm. With a mixture of equal vols. of *N*-HCl and *N*-HF, the amounts of non-calcined ferric oxide dissolved in 2¾, 23¾, 96, and 264 hrs. were respectively 0·1011, 0·1976, 0·2223, and 0·2297 grm.; and by equal vols. of *N*-HCl and *N*-NaF in 2¾, 23¾, 72¼, and 215 hrs., respectively 0·0444, 0·0743, 0·0757, and 0·0766 grm. The subject was studied by P. P. Budnikoff and K. E. Krause, who showed that with 2*N*-HCl:

Calcined at .	450°	650°	750°	850°	950°	1000°
Solubility .	100·00	94·91	91·02	71·44	36·28	29·92 per cent

H. Debray observed that when ferric oxide is heated to redness in a current of **hydrogen chloride,** ferric chloride and water are formed. The reaction was studied by J. L. Gay Lussac, J. B. Moyer, F. A. Gooch and F. S. Havens, V. Spitzin, and F. W. Clarke and E. A. Schneider. Ferric oxide dissolves in conc. hydrochloric acid more quickly than magnetite, and more slowly than ilmenite. F. Leteur said that the oxide is readily dissolved by conc. hydrochloric acid, sat. with hydrogen chloride, when heated in a closed vessel at 65°. E. Weinschenk, and C. R. Fresenius said that the oxide prepared at a high temp. dissolves but slowly in the acid. G. Melczer observed that the basal faces of the rhombohedral crystals are more rapidly attacked than the prismatic faces. According to A. Classen, calcined ferric oxide dissolves quickly in hydrochloric acid if the finely powdered oxide has been digested or boiled with a dil. soln. of potassium oxide. H. Bornträger found that the presence of a little manganese dioxide with the hydrochloric acid enables ignited ferric oxide to be dissolved with great ease. The effect is attributed to the chlorine evolved, since all the halogens hasten the solution of ferric oxide in hydrochloric acid. H. Bornträger also observed that strongly calcined ferric oxide dissolves readily in hydrochloric acid containing a little free chlorine, bromine, iodine, or hydrogen dioxide; and F. P. Dunnington, and N. A. Tananaeff made a similar observation with respect to the hydrogen dioxide. According to H. Bornträger, the dissolution is also facilitated if nascent hydrogen, say from iron wire, is produced in the system; and N. A. Tananaeff found that the presence of a little stannous chloride accelerates the dissolution of calcined ferric oxide in hydrochloric acid. W. R. E. Hodgkinson and F. K. S. Lowndes, E. J. Mills and G. Donald, F. E. Brown and W. C. O. White, and G. J. Fowler and J. Grant observed that the presence of ferric oxide facilitates the decomposition of **potassium chlorate,** and more chlorine is given off when ferric oxide is used as catalytic agent than is the case with manganese dioxide. R. Chenevix found that ferric oxide dissolves in **chloric acid**; and A. J. Balard, that it dissolves in **hydrobromic acid.**

R. Weber observed that when ferric oxide mixed with **sulphur** is heated to redness, sulphur dioxide and iron sulphide are formed. A. C. Halferdahl found that ferric oxide is reduced to ferrosic oxide by sulphur, and that the free energy of the reaction $6Fe_2O_3+\frac{1}{2}S_2=4Fe_3O_4+SO_2$ is $-15,900$ cals. at 600°, and $-52,600$ cals. at 1400°. K. Hilgenstock studied the action of the vapour of sulphur on ferric oxide. A. Gautier found that with **hydrogen sulphide** at a white-heat, the reaction symbolized: $2Fe_2O_3+7H_2S=4FeS+3SO_2+7H_2$, occurs. G. Weyman found that the hydrated or anhydrous ferric oxide, prepared between 100° and 650°, is equally active as regards the absorption of hydrogen sulphide in the cold; this is taken to mean that the activity of the oxide is dependent primarily on the mol. structure, and not on the degree of hydration. P. Nicolardot also explained the behaviour of ferric oxide towards hydrogen sulphide by assuming differences in the mol. state. The reaction was studied by K. Hilgenstock. H. Diecke, R. Cox, and E. Brescius found that in the reaction at about 100°, the product contains more sulphur than corresponds with ferric sulphide, and L. T. Wright regarded the product as a mixture of ferrous and ferric sulphides with free sulphur. L. Gedel said that under alkaline conditions, the product is wholly ferric sulphide, and under acidic conditions, a mixture of mono- and di-sulphides and free sulphur; E. T. Allen and co-workers found it to be a mixture of ferrous sulphide and sulphur—the former being completely soluble in cold, dil. hydrochloric acid, after the free sulphur has been extracted with ammonium polysulphide. In the absence of air, and with the hydrated ferric oxide suspended in water, W. Mecklenberg and V. Rodt obtained ferric sulphide which was pyrophoric when dried; and V. Rodt added that the moist ferric sulphide is readily converted by air into oxide and free sulphur; the ferric sulphide changes into a mixture of ferrous sulphide and iron disulphide on standing, and the formation of colloidal sulphur when ferric sulphide is dissolved in dil. hydrochloric acid makes it appear as if a ferrous salt is a product of the original reaction. L. T. Wright concluded that the action between hydrogen sulphide and hydrated ferric oxide involves: (i) $Fe_2O_3.H_2O\rightarrow Fe_2S_3+4H_2O$, and $Fe_2O_3.H_2O\rightarrow 2FeS+S+4H_2O$—the second reaction applies to 17 to 30 per cent. of the hydrated oxide. T. G. Pearson and P. L. Robinson, and L. A. Sayce found that the reaction varies considerably with temp.; at and below 100°, the primary product is ferric sulphide: $Fe_2O_3+3H_2S=3H_2O+Fe_2S_3$, and the ferric sulphide partially decomposes to ferrous sulphide and iron disulphide: $Fe_2S_3=FeS+FeS_2$; above 100°, these reactions give place more and more to the direct production of ferric disulphide, until, in the region above 300°, the only reaction concerned is: $Fe_2O_3+4H_2S=2FeS_2+3H_2O+H_2$. Between 400° and 500°, the iron disulphide gives place to a product soluble in hydrochloric acid with the liberation of sulphur. This material can be regarded as a mixture of ferrous and ferric sulphides, though some ferrosic sulphide, Fe_3S_4, may be formed. W. A. Damon studied the subject. J. C. Witt found that when ferric oxide is treated with an excess of **sodium sulphide,** a black, amorphous substance is formed. On removing most of the remaining sodium sulphide and adding water, a brilliant green soln. is produced. The results obtained on studying the soln. indicate that the colour is due to a colloid and not to a pure soln. of some iron compound. The exact composition of the disperse phase has not been determined, but apparently it contains neither sulphur nor sodium in chemical combination. The colloid is reversible.

According to F. Wöhler and F. Mahla, when ferric oxide is heated in **sulphur dioxide,** it is reduced to ferrosic oxide, and sulphur trioxide is formed. G. Keppeler represented the reaction with sulphur dioxide, between 500° and 800°, by $3Fe_2O_3+SO_2=2Fe_3O_4+SO_3$. D. L. Hammick could not obtain ferrous oxide by the action of sulphur dioxide at 300°, but a black powder was formed which, at a higher temp., in sulphur dioxide forms sulphur, sulphur trioxide, iron sulphide, and ferric oxide. B. Neumann and E. Goebel studied the adsorption of the gas by ferric oxide. The catalytic activity of ferric oxide in facilitating the oxidation of sulphur dioxide begins at about 400°, and attains a maximum at about 625°. This subject was discussed by G. Lunge and co-workers, C. W. Johnson, K. Hilgenstock, B. Neumann, and G. Keppeler and co-workers *vide* sulphur trioxide, **10**. 57, 27. R. D. Hall noted that **sulphur monochloride** vapour passed over heated ferric oxide forms ferric chloride. According to H. B. North and A. M. Hagemann, **thionyl chloride** does not act on ferric oxide at ordinary temp., but at 150°, the reaction which occurs is symbolized: $Fe_2O_3+3SOCl_2=2FeCl_3+3SO_2$, and the ferric chloride crystallizes from the liquid in green hexagonal plates. The reaction with **sulphuryl chloride** was studied by W. Hesse, and by H. Danneel and W. Hesse. W. L. Ray also observed that whilst liquid **selenium oxydichloride** acts very slowly on ferric oxide at room temp., the vapour at 400° forms ferric chloride and selenium dioxide. J. J. Berzelius, and H. Rose stated that ferric oxide is slowly attacked by **sulphuric acid;** A. Mitscherlich found that dissolution occurs most rapidly in a mixture of 8 parts of the conc. acid, and 3 parts of water; and L. Storch said that the ignited oxide is readily dissolved when warmed with 40 per cent. sulphuric acid. A. and P. Buisine observed that sulphuric acid of sp. gr. 1·530 to 1·712 begins to dissolve calcined ferric oxide in the cold; the action is slow and incomplete; with warm acid, the action is completed in a few hours, and it progresses more rapidly, the higher the temp. It is not necessary to proceed above 300°. J. A. Hedvall attributed the tardy dissolution of the calcined oxide to coagulation of the grains reducing the surface area. The reaction was studied by M. M. P. Muir.

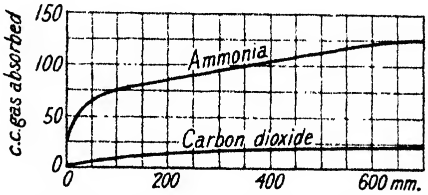

Fig. 529.—The Absorption of Ammonia, and Carbon Dioxide by Ferric Oxide.

E. J. B. Willey said that **nitrogen** is not absorbed when ferric oxide is heated in an atm. of that gas. A. Smits found that heated ferric oxide reacts vigorously with **magnesium nitride;** and likewise with **titanium nitride**—*vide supra*, ferrous oxide. F. Ephraim observed that when heated with an excess of **sodamide,** ferric oxide is reduced spontaneously to iron. Ferric oxide is not dissolved by aq. **ammonia;** but, according to A. W. F. Rogstadius, the Badische Anilin- und Soda-Fabrik, J. J. Berzelius, and H. L. Buff, when ammonia is passed over the red-hot oxide, water and iron nitride are reduced. N. Nikitin's measurements of the absorption of ammonia by ferric oxide at 11·8° and at different pressures are summarized in Fig 529. B. Dirks observed that ferric sulphate is formed when ferric oxide is heated with **ammonium sulphate** at 250°, and at a higher temp., sulphur trioxide is evolved; and H. Arctowsky, that with **ammonium chloride** at 350°, ferric chloride is formed. N Nikitin found that ferric oxide, obtained by igniting the fresh hydrogel at 350°, readily adsorbs ammonia; and by increasing the temp. of ignition of the ferric oxide, the capacity for adsorption is reduced. F. Ephraim observed that no iron nitride is formed when ferric oxide is heated with **sodamide.** For the action of **hydroxylamine,** *vide supra*, ferrous oxide. E. Briner and A. Rivier studied the formation of **nitric oxide** in the ferric oxide arc. P. Sabatier and J. B. Senderens observed that ferric oxide at 500° is not reduced by nitric oxide. C. F. Bucholz found that ferric oxide dissolves very slowly in **nitric acid,** but the ignited oxide is not attacked. U. R. Evans also noted the tardy dissolution of ferric oxide in conc. nitric acid, at room temp.; and H. de Sénarmont observed that the attack of the calcined oxide by nitric acid is slow. E. S. Hedges observed that freshly calcined ferric oxide dissolves perceptibly in conc. nitric acid at the temp., 74·5° to 75·5°, at which iron no longer becomes passive. M. Z. Jovitschitsch found that conc.

nitric acid does not dissolve strongly calcined ferric oxide when heated in a sealed tube at 170° for 10 hrs.; but when warmed on an asbestos plate, at ordinary press., it dissolves in the acid in 8 to 10 hrs. H. Bornträger noted that calcined ferric oxide does not dissolve completely in **aqua regia.** R. Weber found that when **phosphorus pentachloride** is heated with ferric oxide it reacts with incandescence; and H. Bassett and H. S. Taylor observed that **phosphoryl chloride** forms ferric oxide at ordinary temp.; and at 100°, E. Erlenmeyer and O. Heinrich found ferric oxide to be soluble in **phosphoric acid.**

C. J. B. Karsten and others stated that if ferric oxide mixed with **carbon** be gently heated, it is reduced to ferrosic oxide; and if heated strongly, metallic iron is formed. E. Vollgold said that carbon—coke—acts energetically at 875°; and H. Wedding found that the action begins about 700°, and G. Tammann and A. Sworykin, at 625° with sugar-charcoal. G. Charpy and S. Bonnerot added that ferric oxide is not reduced by solid carbon below 950° provided reducing gases are excluded. If no carbon monoxide be present, C. L. Mantell said that carbon does not reduce the oxide at 1000°. Observations were made by C. E. Williams and co-workers, F. Körber and H. H. Meyer, J. Parry, and H. H. Berger. R. Schenck observed that the reduction of ferric oxide by iron tritacarbide in vacuo, begins at about 400°, but with free carbon a reaction is perceptible at 680°. H. H. Meyer found that the reduction of ferric to ferrosic oxide by sugar-charcoal begins at 450°; by wood-charcoal, heated to 1000° in nitrogen, at 500°; and by coke, at 600°. E. J. Rode said that the time-temp. curve of a mixture of ferric oxide and charcoal shows three breaks—(i) at 400° to 650° due to the exothermic reduction of ferrosic oxide; (ii) at 750° to 830°, to the endothermic reduction of ferrosic to ferrous oxide; and (iii) at 875° to 995°, to the reduction of ferrous oxide to iron. W. Baukloh and R. Durrer showed that an intimate mixture of ferric oxide and carbon begins to evolve carbon dioxide in vacuo at 300° to form ferrosic oxide which is further reduced to ferrous oxide (*q.v.*) between 400° and 600°. P. Berthier, F. Margueritte, and J. Percy showed that it is not necessary for the oxide and the carbon to be in contact with one another. Lumps of ferric oxide a few inches in diameter, may be reduced to metallic iron by imbedding them in coarsely powdered charcoal, and heating the containing crucible to bright redness for several hours. At first, the mass is reduced to ferrosic oxide; iron is produced on the surface and then in the interior, and finally reaches the centre. A. F. E. Degen, and A. C. Becquerel assumed that the internal reduction is the result of an electrolysis, but according to F. Leplay and A. Laurent, the reduction in the interior is due to the penetration of carbon monoxide which is formed in the crucible—*vide supra*, hydrogen, and concentration. J. H. Jones and co-workers found that the reactivity of coke, $C+CO_2=2CO$, is increased by admixture with ferric oxide. J. N. Pring observed that at a high temp. ferric oxide is reduced by **aluminium carbide**; likewise with **silicon, chromium, and molybdenum carbides**—*vide supra*, ferrous oxide; R. Schenck showed that **iron tritacarbide** begins to reduce the oxide at 400°. J. Bökmann studied the reaction between iron carbide and oxide.

F. Göbel found that when ferric oxide is heated in **carbon monoxide,** it rapidly forms ferrous oxide, and at a higher temp. it is completely reduced to pyrophoric iron. H. Wedding observed the reduction of ferric to ferrous oxide occurs at about 700°. I. Braithwaite observed that at 700°, the reaction with carbon monoxide is symbolized by $3Fe_2O_3+CO=CO_2+2Fe_3O_4$, and at and below 850° some iron carbide is formed. K. Stammer also noted the formation of some iron carbide. O. Boudouard found that at temp. below 1000°, dry carbon monoxide is a more effective reducing agent than the moist gas, but at 1050°, moist and dry carbon monoxide behave alike. S. Hilpert showed that the temp. of reduction depends, as in the case of hydrogen, upon the previous history of the ferric oxide. The observations of O. Boudouard, R. Schenck and co-workers, and E. Baur and A. Glässner on the equilibrium conditions have been previously discussed—*vide* *supra*, hydrogen. F. Leplay and A. Laurent said that a mixture of equal vols. of carbon monoxide and dioxide merely reduces ferric to ferrosic oxide. The subject was discussed by J. L. Gay Lussac, H. Abraham and R. Planiol, O. Boudouard, F. Brinkmann, M. Decarrière and J. Antheaume, J. Eckell, H. A. Bahr and V. Jessen, A. Gautier and P. Clausmann, F. Hahn, H. Kamura, O. O. Laudig, L. Mathesius, R. Schenck and F. Zimmermann, F. Wüst and P. Rütten, and R. Yoshimura, F. Göbel observed that the formation of ferrosic oxide is an intermediate stage in the reduction of ferric oxide to iron—*vide supra*, hydrogen. J. L. Proust, and W. Naase found that ferric oxide is reduced to metal in a porcelain oven, doubtless by the action of the carbon monoxide. S. Hilpert found that the reduction with carbon monoxide begins at 240°. C. R. A. Wright and A. P. Luff found that the reduction begins at 202° to 220°, dependent on the physical state of the ferric oxide. J. A. Sokoloff said that the reduction of ferric oxide, prepared at 400°, begins at 200° to 230°, and if the ferric oxide has been prepared at a higher temp., a higher temp. is needed to inaugurate the reduction, and is independent of the proportion $CO : CO_2$ in the gaseous phase, but the temp. at which ferrous oxide is formed is lowered by raising the proportion of carbon monoxide. Carbon begins to appear when ferrous oxide is formed. S. Hilpert and T. Dieckmann observed that dry carbon monoxide reduces ferric oxide completely to iron at 950° and very little carbon is formed; iron tritacarbide appears at 850°. H. Tropsch and W. Krönig found that at 720°, the carbon which separates is nearly all free, only a little is combined as carbide. H. Saito showed that ferric oxide, which has been calcined at 800°, begins to be reduced by carbon monoxide at 320°; the separation of carbon begins at 320°, and attains a maximum at 500°. According to W. A. Bone and co-workers, carbon monoxide mixed with nitrogen, but free from hydrogen, begins to reduce hæmatite between 380° and 650°; carbon begins to separate when the oxide is partially reduced. The presence of 2 per cent. of hydrogen favours the reduction and lessens the tendency of carbon to separate. H. Willeke found that the reduction of ferric oxide by carbon monoxide is not influenced by the presence of beryllium oxide, but that the equilibrium is displaced by zinc or manganous oxide; and H. Franz observed that the presence of calcium oxide or alumina hinders the reduction. The reaction was studied by G. Charpy, H. Tropsch and A. von Philippovich, G. Chaudron, etc.—*vide supra*, reaction in the blast-furnace. H. Fleissner and F. Duftschmid studied the reduction of the oxide by water-gas, and by producer-gas. E. F. Armstrong and T. P. Hilditch, and K. Iwase and M. Fukushima found that the presence of ferric oxide favoured the oxidation of carbon monoxide by steam. W. A. Lazier and H. Adkins found 100 grms. of ferric oxide absorbed 65 c.c. of carbon monoxide at n.p.θ. C. J. Engelder and co-workers studied the catalytic activity of ferric oxide with titanic oxide or with cobaltic oxide on the oxidation of carbon monoxide; and R. Yoshimura, and N. A. Yajnik and F. C. Trehana, the catalytic activity of ferric oxide in the photochemical decomposition of carbon dioxide. A. F. Benton studied the adsorption of carbon monoxide, and of **carbon dioxide** by ferric oxide. N. Nikitin found that ferric oxide obtained by igniting the fresh hydrogel, at 350°, readily adsorbs carbon dioxide, and that the capacity for adsorption is reduced by calcining the hydrogel at a higher temp.—*vide supra*, Fig. 529. S. G. Lasky, B. S. Butler, and H. von Eckermann discussed the geological function of carbon dioxide on the $Fe_2O_3 : FeO$-ratio in limestone contact deposits. K. Hilgenstock studied the action of **carbon disulphide.** E. Vollgold said that the activities of carbon monoxide, **methane,** and hydrogen are relatively as 1 : 2 : 5. O. Meyer and W. Eilender studied the reaction. W. Müller-Erzbach found that methane, at the temp. of a Bunsen flame, reduces ferric oxide to ferrosic oxide, at a rather higher temp., to ferrous oxide, and finally, at a still higher temp., to metallic iron. The Gelsenkirchener Bergwerks found that the reduction of iron ores with methane occurs below 700° if a little powdered iron be present to start the reaction. W. P. Yant and C. O. Hawk studied the oxidation of methane with a ferric oxide catalyst. The reduction of ferric oxide earths by methane has been studied by C. E. Williams and co-workers, and by C. M. Bouton. H. W. Walker observed that **ethylene** at a high temp. reduces ferric oxide to ferrosic oxide, and ultimately to iron; the adsorption of ethylene and hydrocarbons, at lower temp., was studied by J. N. Pearce and A. M. Alvarado, H. Hollings and R. H. Griffith, and W. A. Lazier and H. Adkins, and they found 100 grms. absorbed 588 c.c. at n.p.θ. G. Charlot studied the oxidation of **toluene,** with ferric oxide as catalyst. C. M. McDowell and F. L. Usher studied the behaviour of suspensions in toluene, **amyl acetate,** and in chlorinated hydrocarbons.

J. Percy said that ferric oxide is reduced to the metal when heated in a current of **cyanogen.** J. von Liebig, F. Körber and H. H. Meyer, and L. Hackspill and R. Grandadam observed that molten **potassium cyanide** reduces ferric oxide to the metal; but at 570° to 750° with sodium cyanide in vacuo, iron and sodium in nearly equivalent proportions are formed as well as nitrogen, carbon monoxide and dioxide, and finely-divided carbon. It is supposed that sodium carbimide is first produced and that this decomposes to form sodium, nitrogen, carbon, and carbon oxides. J. Tscherniak found that **potassium thiocyanate** at 400° to 500° forms ferrous sulphide and potassium cyanate with the evolution of oxygen: and by a similar reaction, J. Milbauer obtained ferrous sulphide, potassium ferrous sulphide, $KFeS_2$, and potassium cyanide, and H. N. Warren, artificial pyrites, FeS_2. A. Kutzelnigg attributed the oxidizing action of powdered ferric oxide on a soln. of **potassium ferrocyanide** to adsorbed oxygen. J. Aloy and C. Rabaut found that hydrolysis of the benzolated **cyanohydrins** in the presence of acetic acid does not occur in the presence of ferric oxide. E. Deussen showed that 10 c.c. of a normal soln. of **oxalic acid,** at 25°, dissolves 0·0310, 0·0790, 0·1960, and 0·2320 grm. of ferric oxide respectively in 1¾, 6¾, 22, and 94 hrs. N. J. Harrar and co-workers found the solubility of ferric oxide, expressed in milligrams of Fe per 100 c.c. of soln., at 25°, in 40 and 60 days, to be for **formic acid**, respectively, 0·951 and 1·249; **acetic acid,** 0·327 and 0·439; **propionic acid,** 0·344 and 0·374; **oxalic acid,** 97·463 and 36·222; **malonic acid,** 4·159 and 6·260; **succinic acid,** 0·255 and 0·494; **lactic acid,** 2·025 and 2·054; **tartaric acid,** 3·175 and 4·386; **citric acid,** 2·961 and 3·372; **benzoic acid,** 0·428 and 0·428; **salicylic acid,** 4·891 and 5·124; and sulphuric acid, 20·320 and 27·813. N. J. Harrar and F. E. E. Germann studied the solubility of hydrated ferric oxide in various organic acids, and found for the solubilities, S grms. per 250 c.c. of soln., and colours; 1·008N-formic acid, S=1·040 (red to yellow); 1·054N-acetic acid, S=0·958 (red to yellow); 1·008N-propionic acid, S=0·702 (red to yellow); 0·782N-butyric acid, S=0·411 (red to yellow); 0·990N-oxalic acid, S=1·009 (vivid green); 0·991N-malonic acid, S=0·941 (green); 0·968N-succinic acid, S=0·498 (red to orange); 0·985N-glutaric acid, S=0·204 (orange); 0·315N-adipic acid, S=0·081 (orange); 1·020N-tricarballylic acid, S=0·156 (orange); 0·936N-maleïc acid, S=0·923 (red to green); 0·126N-fumaric acid, S=0·004 (colourless); 0·404N-mesaconic acid, S=0·014 (colourless); 1·094N-chloroacetic acid, S=0·985 (red to green); 1·062N-dichloroacetic acid (yellow to green); 1·049N-trichloroacetic acid (pale green); 0·026N-benzoic acid, S=0·006 (colourless): 0·129N-phenylacetic acid, S=0·003 (orange); 0·087N-phthalic acid, S=0·026 (colourless); 0·976N-hydrochloric acid, S=0·917 (green); and 0·962N-sulphuric acid, S=1·014 (pale green). If the acids be arranged in the order of their ionization constants, the strong acids furnish green coloured soln., and the weak acids, red coloured soln. D. Talmud and N. M. Lubman found the floatability of ferric oxide in **oleic acid** and in mixtures of oleic acid and ammonia to be a maximum when p_H=7. L. Kahlenberg and H. W. Hillyer observed no attack by a boiling soln. of **potassium tartrate.** F. W. O. de Coninck and A. Raynaud found that with **calcium oxalate** at a dull red-heat, it forms ferrous oxide, calcium carbonate, and carbon dioxide. W. Müller-Erzbach studied the adsorption of **ether** vapour by ferric oxide.

W. Haller studied the adsorption of ether, acetic acid, **alcohol,** and **acetone** by powdered ferric oxide: and N. A. Yajnik and F. C. Trehana, the photochemical reduction of **sugars.** M. Rakusin observed that egg **albumin** is not adsorbed from its aq. soln. by ferric oxide. E. Ullmann studied the diffusion of ferrum oxydatum saccharatum solubile; and F. H. Rhodes and co-workers, the effect of ferric oxide on the oxidation of **linseed oil.** N. R. Dhar discussed the oxidation of **insulin** with ferric oxide as catalyst.

H. Moissan found that **boron** acts as a reducing agent on ferric oxide at a red-heat. C. H. Burgess and A. Holt noted that ferric oxide is not soluble in molten **boric oxide,** and C. Mazzetti and F. de Carli said that there is a feeble reaction between the ferric and boric oxides at 820°; and the reaction was studied by J. A. Hedvall and N. von Zweigbergk. U. Sborgi and co-workers found that **boron nitride** reduces ferric oxide to ferrous oxide, forming boric oxide and nitric oxide. E. Vigouroux found ferric oxide is reduced when it is heated with **silicon;** and the reaction was studied by L. Kahlenberg and W. J. Trautmann. G. Rauter found **silicon tetrachloride** in a sealed tube with ferric oxide at 180° to 190° forms silica and ferric chloride; no reaction is perceptible at 140° to 150°. H. le Chatelier and B. Bogitsch, J. A. Hedvall and P. Sjöman, and A. Duboin noted that **silica** reacts with ferric oxide at an elevated temp. forming iron silicate. J. Kleffner and E. J. Kohlmeyer observed silica has no effect on the dissociation of ferric oxide. J. A. Hedvall and P. Sjöman observed evidence of reactions at 575° and 900°. G. Tammann and G. Bätz found that whilst quartz begins to react with ferric oxide at 950°, precipitated and calcined silica begins to react at 800°, but that the reaction is not really with ferric oxide but rather with ferrous oxide. When hornblende or basalt is mixed with wood charcoal and a small proportion of lime or sodium carbonate and heated first at 600° and then at 1400°, the iron is reduced almost quantitatively. In the absence of alkali, or when heated directly to 1400°, the reduction is less complete, and it is further diminished by the addition of quartz. When ferric oxide, magnetite, or ferrous oxide is heated with precipitated and ignited silica, each begins to react at 800°, but the reaction with quartz does not begin below 950°. More heat is evolved with the silica than with the quartz. When iron silicates, prepared by heating ferric oxide and silica, are reduced with hydrogen for 1 hr. at 850°, the proportion of the iron reduced falls from 24·4 per cent. when the molecular proportion of silica is 0·375 to 0·600. When the silica content is further increased the proportion of the iron reduced rapidly increases, and is 38·4 per cent. when the molecular proportion of the silica is 0·920. S. Hilpert and E. Kohlmeyer found that with **calcium metasilicate** at about 1220°, ferromagnetic calcium ferrite is formed. F. S. Tritton and D. Hanson found that mixtures with a low proportion of ferric oxide can be fused in **china clay** pots, without serious attack, but some ferric oxide is absorbed by the pot. S. English and co-workers, and V. Dimbleby and W. E. S. Turner studied the action of ferric oxide on **glass;** and J. H. Whiteley and A. F. Hallimond, A. H. Kuechler, and J. W. Mellor, on **firebricks,** and fireclays. P. Ramdohr studied the effect of **titanic oxide** in the system: $FeO–Fe_2O_3–TiO_2$. F. Halla, and G. Tammann and co-workers observed that ferric oxide reacts with titanic oxide at an elevated temp. T. L. Walker applied the term maghemite to the magnetic $(Fe,Ti)_2O_3$ from Bushveld, Transvaal. P. A. Wagner used the same term for magnetic ferric oxide other than martite. P. Ramdohr studied the action of ferric oxide on **ilmenite,**

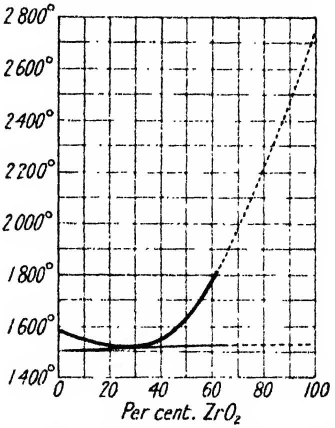

FIG. 530.—Melting-Point Curve for the Binary System: $ZrO_2–Fe_2O_3$.

$FeTiO_3$. H. von Wartenberg and W. Gurr obtained the m.p. curve, Fig. 530, for mixtures of **zirconia** and ferric oxide.

J. L. Gay Lussac and L. J. Thénard found that **potassium** reduces ferric oxide to iron; and similarly with **sodium.** M. Rosenfeld said that when sodium is triturated with ferric oxide, the mixture glows and iron is formed. Ferric oxide is reduced to metal when it is heated with **magnesium;** B. Garre said that the reaction begins at 575° and evolves 239·5 Cals. of heat. E. Donath observed that when the oxide is heated with **zinc** it is easily reduced to the metal. L. Franck observed that iron oxides are also reduced to metal when heated with **aluminium;** and T. W. and W. T. Richards tried to measure the cohesive force between aluminium and ferric oxide. According to J. Percy, when ferric oxide is "strongly" heated in contact with **iron,** it is reduced to ferrosic oxide. M. Billy obtained a similar result. R. B. Sosman and J. C. Hostetter found that when heated to 1200° with **platinum,** in air, ferric oxide is reduced to the metal which forms a solid soln. with the platinum. The loss in weight of platinum heated to 1000° to 1200° is much increased if it be in contact with ferric oxide.

For the reactions of ferric oxide with the **metal oxides,** *vide infra,* the ferrites; and for reactions with ferrous oxide, and ferrosic oxide, *vide supra.* L. Passerini studied the action of ferric oxide on **alumina**; and H. G. Fisk and W. J. McCaughey, on **magnesium oxide.** J. E. Adaduroff and G. K. Boreskoff precipitated a mixture of ferric oxide and **vanadium pentoxide** on broken firebrick for use as a catalyst. P. E. Wretblad found that mixtures of ferric oxide with **chromic oxide** form a continuous series of solid soln. in which the dimensions of the lattice change linearly from those of Fe_2O_3 to those of Cr_2O_3. The rhombohedral angle, α, shows a maximum:

$Fe_2O_3 : Cr_2O_3$	1 : 0	3 : 1	1 : 1	1 : 3	0 : 1
Length of edge	5·419	5·395	5·376	5·362	5·348
α	55·28°	55·37°	55·44°	55·28°	55·11°

L. Passerini, and H. Forestier and G. Chaudron also made observations on this subject, and R. Yoshimura discussed the action of chromic oxide on ferric oxide in the production of hydrogen by the water-gas reaction. Mixtures of ferric oxide and **manganic oxide** with 100 to 75 per cent. Mn_2O_3 give the same X-radiogram; a mixture with 45 per cent. of Mn_2O_3 shows a faint trace of ferric oxide lines; a mixture with 30 per cent. Mn_2O_3 shows the lines of Mn_2O_3 stronger than those of Fe_2O_3; and mixtures with less than 15 per cent. Mn_2O_3 show only the Fe_2O_3 lines. There is, therefore, a break in the series of solid soln. There is no evidence of an intermediate phase. S. L. Penfield and H. W. Foote's mineral *bixbyite,* discussed in connection with the permanganites, was shown by W. Zachariasen to belong to the isomorphous series of sesquioxides, Mn_2O_3, Fe_2O_3, Y_2O_3, etc. Its formula is, therefore, written $(Mn,Fe)_2O_3$, and not $Fe(MnO_3)$, or $FeO.MnO_2$. L. Pauling and M. D. Shappel observed that the body-centred lattice has $a=9·365$ A., and contains $16(Mn,Fe)_2O_3$. W. M. Bradley described a mineral which he called *skemmatite,* $3MnO_2.Fe_2O_3.6H_2O$, as an alteration product of pyroxmangite, $(Fe,Mn)SiO_3$. J. Percy said that ferric oxide is not attacked by soln. of the **alkali hydroxides.** P. Villard, J. d'Ans and J. Löffler, V. S. Yatloff, and S. Matsui and co-workers studied the conversion of **sodium carbonate** into sodium hydroxide by heating it with ferric oxide—*vide infra,* sodium ferrite. P. Rohland found a soln. of **calcium hydrocarbonate** slowly dissolves ferric oxide, and the dissolution is hastened by the presence of alkali or calcium sulphates. E. Mallet and P. A. Guye recommended ferric oxide for use as a diaphragm in the electrolysis of sodium salts in the production of **sodium hydroxide** which does not attack the ferric oxide. T. C. Estelle observed that ferric oxide can be hydrated by boiling it with a 70 per cent. soln. of soda-lye at 100° to 120°. This is of significance in connection with the electrolytic process for iron in which a conc. soln. of sodium hydroxide containing sodium ferrite is electrolyzed. Ferric hydroxide is dissolved from the ferric oxide anode by the conc. soda-lye, and iron is deposited on the cathode. The hydration of ferric oxide by hot conc. soda-lye involves the formation of a ferrite which is subsequently decomposed on cooling and diluting the liquor. During the action 20 parts of ferric oxide are taken up by 80 parts of sodium hydroxide when the heating is continued several hours. R. B. Sosman and J. C. Hostetter said that the best container for ferric oxide at 1100° to 1200° is fused **alumina** (alundum). The alundum vessel remains constant in weight at these temp., but loses weight at higher temp. H. Warth observed that alumina retards the reduction of ferric oxide to ferrosic oxide at elevated temp. L. Passerini observed that mixtures of alumina and ferric oxide form solid soln. and he measured their lattice constants. The subject was studied by H. Forestier and G. Chaudron, T. F. W. Barth and E. Posnjak, and H. von Wartenberg and H. J. Reusch. S. Izawa found that the presence of ferric oxide did not influence the luminescence of alumina in the cathode rays. D. Turner, and F. S. Tritton and D. Hanson found that crucibles of alumina or alundum, **chromite, zirconia,** and **lime,** crack and slag with fused mixtures of iron with a high proportion of oxide ; but bonded crucibles of **magnesia** can be used for the purpose ; magnesia pots absorb the oxide. H. Kittel and G. F. Hüttig studied the magnesia ferric oxide spinels. L. Jacqué observed that with lime, some ferrosic oxide is formed at 1220°—*vide infra,* ferrites. G. B. Taylor and G. A. Hulett found that the presence of ferric oxide favoured the thermal decomposition of **mercuric oxide.** G. Tammann and co-workers observed no reaction when ferric oxide is heated with **molybdenum trioxide;** a slight reaction with **tungsten trioxide ;** and about 15 per cent. reaction with **uranium trioxide.** For solid soln. of ferric oxide and **ferrous oxide** or **ferrosic oxide,** *vide supra.* H. S. Roberts and H. E. Merwin found that in the binary system FeO–Fe_2O_3, the stable phase at temp. below 1386° is a hæmatite solid soln. with less oxygen than Fe_2O_3 ; and just above 1386°, the stable phase is a magnetite solid soln. with considerably more oxygen than Fe_3O_4. E. Diepschlag and E. Horn studied the action of manganous, ferrous, and calcium sulphides on ferric oxide.

J. Krutwig showed that the presence of ferric oxide favours the formation of sodium sulphate from fused mixtures of sodium chloride and iron pyrites in air. G. Tammann studied the action of light on a 0·05*N*-soln. of **silver nitrate** in contact with ferric oxide. K. A. Hofmann and K. Höschele found that if ferric oxide is melted with dry **magnesium chloride,** the iron is almost all volatilized as ferric chloride. H. A. von Vogel observed that ferric oxide is not reduced by a boiling soln. of **stannous chloride,** and W. O. Hickok observed no action with stannous chloride as an etching liquid. C. A. Graumann, and V. Lepiarczyk observed only a slight reaction between **zinc sulphide** and ferric oxide at 1280° ; in a slow current of air at 1280°, sulphur dioxide and zinc vapour are given off, but the reaction soon comes to a standstill ; and in a current of carbon monoxide, iron is formed, and the iron liberates zinc with the production of iron sulphide. For the action on **ferrous sulphide,** *vide infra ;* and for the action on **manganous sulphide,** *vide* manganese sulphide, **12.** 64, 21. E. Diepschlag and E. Horn, and L. Wöhler and co-workers studied the action of **calcium sulphide.** W. H. MacIntyre and W. M. Shaw found that ignited ferric oxide shows no tendency to absorb appreciable amounts of **calcium sulphate** from soln. ; J. E. Adaduroff and V. P. Pligunoff showed that ferric oxide favours the thermal decomposition of calcium sulphate. C. A. Graumann found that with **zinc sulphide** in a reducing atmosphere, ferric oxide is converted into metallic iron and that acts on the sulphide.

§ 31. Hydrated Ferric Oxide—Hydrosol

If a soln. of ferric chloride be treated with hydrated ferric oxide, added in small quantities at a time, or if ammonium carbonate be gradually added to ferric chloride, so long as the precipitated oxide continues to be re-dissolved on stirring, a brownish-red soln. of ferric hydroxide is produced. These soln. were investigated by J. M. Ordway,[1] J. Jeannel, A. Béchamp, and A. Scheurer-Kestner. The rate of dissolution of the hydrated oxide is slow ; and if the digestion in the cold is continued for a long time, the hydrated oxide dissolves until about 18 eq. have passed into soln. in 5 months. Ferric salts of the monobasic acids—*e.g.* hydrochloric and nitric acids—serve for preparing such soln., but salts of the polybasic acids—*e.g.* sulphuric acid—give insoluble basic salts.

According to T. Graham, the red liquid is a **colloidal solution** of hydrated ferric oxide ; and the **hydrosol** can be freed from the excess of the peptizing ferric chloride by dialysis. The dialyzed hydrosol is clear, and deep reddish-brown in colour ; and after 19 days' dialysis, contained 1·5 per cent. of hydrochloric acid, or 1 eq. of acid to 30·3 eq. of ferric oxide. The sol remained liquid for 20 days, and then spontaneously flocculated to form the **hydrogel.** A hydrosol prepared in this way is sometimes called *Graham's solution*, or *dialyzed iron*. There are various pharmaceutical preparations which are essentially hydrosols of hydrated ferric oxide—*e.g. liquor ferri oxychlorati dialysati*, *ferrum oxydatum dialysatum liquidum*, and *solutio ferri hydrati oxydati colloidalis*. E. Henrijean and W. Kopaczewsky discussed the presence of the hydrosol in mineral waters.

The hydrosol of hydrated ferric oxide was also prepared by T. Graham by the dialysis of cold soln. of ferric acetate ; and after 18 days' dialysis, about one half the iron was lost by diffusion and there remained a red liquid in which 1 part of acetic acid was associated with 15 to 16 parts of ferric oxide. R. Fabre and H. Penau found that the speed of hydrolysis is greatly increased by agitating the dialyzing liquid by a current of air or inert gas. L. P. de St. Gilles prepared a colloidal soln. of ferric oxide by the continued boiling of a soln. of ferric acetate ; the reddish-brown colour of the acetate becomes brick-red as the boiling continues, and the peculiar taste of ferric salts gives way to that of acetic acid. The colloid appears turbid or opalescent in reflected light, and clear in transmitted light. The brown ochreous precipitate obtained when the hydrosol is treated with a trace of sulphuric acid or of an alkaline salt, unlike ordinary hydrated ferric oxide, is relatively insoluble in the more conc. acids ; and when the soln. is poured into hydrochloric acid, the finely divided, granular, brick-red precipitate is in many respects unlike ordinary hydrated ferric oxide. It was accordingly called ***meta-ferric oxide***, by analogy with meta-alumina (**5**. 33, 11). To distinguish this colloidal soln. from those soln. with the properties of Graham's hydrosol, it is sometimes called ***St. Gilles' sol.*** The hydrosol was also prepared from soln. of ferric chloride by J. G. Ufer, E. Hatschek, J. M. van Bemmelen, F. W. C. Krecke, H. B. Weiser, and G. H. Ayres and C. H. Sorum. H. Neurath and W. Pauli discussed the conditions to obtain a product of a high degree of purity.

C. F. Schönbein, S. Hausmann, F. Beilstein and R. Luther, and E. A. Schneider observed that when an aq. soln. of ferric nitrate is boiled, a blood-red, colloidal soln. of ferric oxide is formed. A. Scheurer-Kestner obtained it by allowing an aq. soln. of the nitrate to stand for a long time, or by heating in a sealed tube, on a water-bath, a soln. of the basic nitrate. F. W. C. Krecke prepared Graham's sol by the hydrolysis of ferric nitrate soln. without dialysis; A. Scheurer-Kestner, and R. Wintgen obtained it by dialysis of the nitrate soln. T Cohen suggested introducing a metal like copper filings, or zinc dust, to take up the nitric acid liberated during the hydrolysis of the ferric nitrate. R. Wintgen estimated that the dialyzed soln. contains less than 0·002 per cent. of ferric oxide. G. Almkvist found that the solubility of ferric hydroxide is $1·4 \times 10^{-6}$ mol. per litre at 20°.

H. Debray obtained the hydrosol by warming an aq. soln. of ferric chloride to 70°, and then dialyzing the product. F. W. C. Krecke observed that the conc. of the sol so prepared depends on the temp. and duration of the heating, and he recommended slowly dropping one c.c. of a 32 per cent. soln. of ferric chloride into a litre of boiling water. C. H. Sorum dropped 40 c.c. of a molar soln. of ferric chloride into 5 litres of boiling water and dialyzed the hot liquid. The sol so prepared is clear, deep wine-red, almost free from chloride, and it contains 2·07 to 3·60 grms. of iron per litre; only very dil. soln. are stable. The hydrosol was also prepared by J. M. van Bemmelen, A. P. Buntin, E. Deiss and G. Schikorr, A. Janek and B. Jirgensons, B. Kuriloff, M. Neidle, A. W. Thomas and J. D. Garard, and J. G. Ufer. K. Ruegg recommended removing the acid from the aq. soln. of ferric chloride by the addition of hydrated alumina. J. Tribot and H. Chrétien said that the chloride which always persists in the hydrosol prepared by the dialysis of a soln. of hydrated ferric oxide in ferric chloride can be removed by electrodialysis in which the colloidal soln. containing the cathode is placed in the inner cell of the dialyzer, and the anode in the outer vessel containing the water which is frequently renewed.

H. Freundlich and S. Wosnessensky, and H. Freundlich and S. Loebmann obtained the hydrosol by the hydrolysis of iron carbonyl; E. Grimaux, P. A. Thiessen and O. Körner, and O. Körner, by pouring an alcoholic soln. of ferric ethylate, $Fe(OC_2H_5)_3$, in water—*Grimaux's sol;* P. A. Thiessen and O. Körner, by hydrolyzing ferric ethylate; and F. W. O. de Coninck, by adding salicylic acid to a soln. of ferric acetate, and keeping the mixture some months.

N. N. Gavriloff found that the oxidation of a soln. of ferrous hydrocarbonate by air, yields only a precipitate of hydrated ferric oxide which is not peptized by small amounts of hydrochloric acid or of ferric chloride; but with larger proportions of ferric chloride, the hydrosol of ferric oxide is formed solely from the added ferric chloride. Hydrogen dioxide gives a white precipitate with ferrous hydrocarbonate, but in the presence of ferric chloride or hydrochloric acid a colloidal soln. of ferric hydroxide is rapidly formed. G. Stadnikoff and co-workers, and V. Brünig also oxidized ferrous hydrocarbonate by hypochlorites, chlorine, or chlorine water. The minimum amount of ferric chloride necessary for peptization in the oxidation of ferrous hydrocarbonate is about 7 per cent. of the total iron. G. Stadnikoff and N. N. Gavriloff found that the hydrosol of ferric oxide for use as a coagulator in the drying of peat can be prepared by the oxidation of solutions of ferrous hydrocarbonate by means of chlorine water or hypochlorous acid. The necessary conc. (0·04 per cent. of ferrous iron) can be obtained on a commercial scale by the treatment of iron turnings with water and a current of flue gas.

M. Neidle and J. N. Crombie obtained the hydrosol by oxidizing ferrous chloride in the cold with potassium permanganate and dialyzing; M. Neidle, and F. L. Browne, by oxidizing ferrous chloride with hydrogen dioxide and dialyzing the hot soln. The dispersed soln. of iron spluttered from the electric arc with iron electrodes, under water, as indicated by T. Svedberg, A. Schmauss, E. F. Burton, and A. Wander, is probably a hydrosol of hydrated ferric oxide.

A. W. Dumansky and Z. P. Chescheva obtained a mixed ferrous and ferric hydrosol by the electrolysis of a soln. of ferric chloride, using a platinum cathode, and an anode of iron amalgam; and also by shaking iron amalgam with a soln. of potassium hydroxide containing some mannitol, and hydrogen dioxide.

As indicated above, freshly-precipitated and washed hydrated ferric oxide is peptized by a soln. of ferric chloride; and the hydrosol can, therefore, be obtained by (i) partial precipitation of a soln. of ferric chloride by ammonia, etc., and agitating the mixture; or (ii) adding the hydrated oxide directly to a soln. of ferric chloride, as was done by A. Béchamp, F. L. Browne, R. Fabre and H. Penau, B. Szilard, T. Graham, J. Jeannel, A. Müller, J. G. Oberhard, N. Pappada, H. Picton and E. Linder, A. Scheurer-Kestner, O. Schmatolla, and A. W. Thomas and A. Frieden. T. Graham obtained the hydrosol by a process equivalent to the peptization of the hydrogel, for he gradually added ammonium carbonate to a soln. of ferric chloride as long as the precipitate dissolved when the liquid was stirred. The liquid was then dialyzed. The process was also employed by F. L. Browne and J. H. Mathews, A. W. Dumansky, F. L. Browne, and J. G. Ufer. W. Wobbe, H. Schweikert, A. W. Thomas and co-workers, and T. L. Wright obtained the hydrosol by adding aq. ammonia to a soln. of ferric chloride so long as the precipitate re-dissolves on stirring. The clear, dark brown soln. so obtained scarcely tastes of iron. It is evaporated until it contains 3·5 per cent. of iron, and has a sp. gr. 1·05. The last traces of chlorine cannot be removed by dialysis, and the product still contains 0·75 per cent. of ferric chloride, but it is free from ammonium salts. G. D. Kratz added that this process does not give a conc. soln. of the colloid, but it avoids the necessity of washing and dialyzing a gelatinous precipitate. The process is best conducted by pouring a 10 per cent. soln. of ferric chloride into a large excess of conc. ammonia, the colloidal ferric oxide produced is coagulated by the ammonium chloride. On evaporating to dryness and washing with water, the ammonium chloride is first washed out, and then the ferric oxide deflocculates and passes through the filter-paper as a dark or bright red colloidal soln. If the original precipitate is left for some time in contact with its ammoniacal mother-liquor, spontaneous changes occur, so that after evaporation it is found to be insoluble. M. Neidle and J. Barab obtained the hydrosol by the hot dialysis of a soln. of ferric chloride to which was added enough aq. ammonia to react with 60 per cent. of the salt. R. Bradfield recommended removing the excess of precipitating agent by washing the precipitate in a centrifuge making 32,500 revs. per min. The main advantages are (i) the removal of the electrolytes formed on precipitation is more complete; (ii) the addition of a peptizing agent and its consequent incomplete removal by either prolonged boiling or dialysis is unnecessary; (iii) sols of a more uniform degree of dispersion can be prepared, since particles of similar size and of similar degrees of hydration are deposited in the same zone of the centrifuge bowl; (iv) sols of any desired conc., from a semi-gel to the merest trace, can be prepared by the addition of water to the more conc. form, and all conc. are very stable.

A. Müller made the hydrosol by using $0·5N$-KOH as precipitating agent in place of ammonia; and A. W. Dumansky and co-workers employed various carbonates, oxides, or hydroxides. According to H. Picton and E. Linder, when the hydrogel of hydrated ferric oxide is precipitated by univalent anions it is much more readily peptized by washing with water than is the case with polyvalent anions. P. Schmidt used 0·05 per cent. nitric acid, or 0·067 per cent. hydrochloric acid as peptizing agent. A. von Buzagh observed that the quantity of peptizing agent—ferric chloride, hydrochloric acid, or sodium oleate—required for the peptization of the hydrogel of ferric oxide is dependent on the quantity of gel, which is taken to mean that the peptization is dependent on an anterior adsorption. C. H. Sorum, Wo. Ostwald and W. Rödiger discussed the peptization with hydrochloric acid; and A. M. Belousoff and co-workers, by copper and silver salts. A. W. Thomas and A. Freiden, and A. J. Rabinowitsch and V. A. Kargin attributed the stability of the ordinary hydrosol to the presence of adsorbed ferric chloride. The subject was discussed by W. D. Bancroft, W. von Neuenstein, S. Liepatoff, and Wo. Ostwald. The peptization of the hydrogel by glycerol, sugar, and other hydroxylic organic compounds in alkaline soln. was studied by H. J. Babel, N. G. Chatterji and N. R. Dhar, H. W. Fischer, P. Goldschmidt and co-workers, T. Graham, E. Grimaux, C. Mannich and C. A. Rojahn, A. W. Dumansky and L. G. Krapiwina, M. R. Mehrotra and K. C. Sen, A. Müller, J. Puls, H. Rose, C. Gropengiesser, K. C. Sen and N. R. Dhar, and K. C. Sen. The peptization of the hydrogel by acetic acid was studied by A. F. G. Cadenhead and W. H. Vining, and H. B. Weiser; by arsenious acid, by A. Boutaric and G. Perreau, E. Grimaux, M. R. Mehrotra and K. C. Sen, and by K. C. Sen and co-workers; and A. Fodor and A. Reifenberg, by silicic acid. A. J. Rabinowitsch and V. A. Kargin studied the behaviour of the acid soln. on dilution.

Colloidal soln. can also be prepared by the use of **protective colloids.** O. Fisseler obtained colloidal soln. by mixing 3 grms. of sodium protalbinate or lysalbinate, dissolved in lukewarm water, with the calculated quantity of ferric chloride in aq. soln. The precipitated ferric protalbinate or lysalbinate was dissolved in soda-lye, and the dark red soln. dialyzed until salt no longer passed through. The residue on the dialyzer was filtered, and evaporated on a water-bath, and dried over sulphuric acid in vacuo. The dark red plates form a clear, colloidal soln. with water. The colloid is flocculated by adding dil. sulphuric acid; a soln. of sodium chloride in the cold has no visible action, but if heated, yellow flecks separate from the turbid soln. A 10 per cent. soln. of calcium chloride acts similarly; but a 10 per cent. soln. of sodium phosphate does not give a precipitate in hot or cold soln. C. Paal and W. Hartmann, and Kalle and Co. employed an analogous process. F. Sichel used starch xanthogenate as protective colloid; A. W. Dumansky and Z. P. Chescheva, mannitol; H. Freundlich and G. Lindau, hæmoglobin, and globin; W. Bachmann, glycol, glycerol, mannitol, dextrose, sucrose, dextrin, and starch; and J. Müller, cherry gum. J. N. Mukherjee attempted to find a relation between the stability and degree of dilution of the hydrosol. J. W. Bain and W. L. McClatchie studied the ultra-filtration of the hydrosol.

The general idea of H. Debray, L. P. de St. Gilles, T. Graham, and L. M. de la Source was that the hydrosol of hydrated ferric oxide is an allotropic, soluble modification which is associated with some impurities. Numerous observations by A. Béchamp, H. Debray, J. Duclaux, F. Giolitti, A. Hantzsch and C. H. Desch, E. Heymann, H. Picton and E. Linder, M. Neidle, P. Nicolardot, J. M. Ordway, R. Ruer, A. Scheurer-Kastner, L. M. de la Source, J. G. Ufer, H. P. Varma and S. Prakash, and G. N. Wyrouboff —show that some salt must be present, presumably adsorbed, in order that the colloidal soln. be stable. The hydrosol has not the inky or ferruginous taste characteristic of ferric salts, rather does the hydrosol produce a rough sensation on the tongue. H. W. Fischer and E. Kuznitzky also found that in well-dialyzed hydrosols, a ferro-cyanide soln. does not give the prussian blue colour produced by ferric salts. E. Grimaux, and E. A. Schneider found that hydrogen sulphide acts on the cold hydrosol to form ferric and ferrous sulphides. K. Haerting found that the hydrosol reacts with cellulose to form a complex iron-cellulose. C. Doelter observed that when the hydrosol is shaken with a soln. of calcium or magnesium chloride, ferric hydroxide is precipitated. Silver nitrate does not precipitate a chloride from the hydrosol, even though T. Graham, R. Ruer, J. G. Ufer, etc., have demonstrated the presence of chlorides. A. Hantzsch and C. H. Desch said that the failure of silver nitrate to produce the chloride reaction is because of the formation of a complex between the hydrated ferric oxide and the ferric chloride. R. Ruer showed that the phenomenon is more likely to be due to the protective action of the ferric chloride on the colloid. As indicated above, A. W. Thomas and A. Freiden, and A. J. Rabinowitsch and V. A. Kargin considered that the colloidal particles owed their stability as a hydrogel to the adsorbed ferric chloride;

and R. Ruer suggested that in the sol state, the chloride is partially ionized, owing to the invariable presence of, say, ferric chloride in the colloidal ferric oxide produced from that salt.

Many observers—J. Duclaux, A. W. Dumansky, E. Jordis, N. Kühnl and W. Pauli, H. Picton and E. Linder, G. Malfitano and co-workers, L. Michel, M. Neidle, P. Nicolardot, W. Pauli and co-workers, A. W. Thomas and A. Freiden, and G. N. Wyrouboff and A. Verneuil—considered the colloid to be a chloride of a polymerized or condensed ferric hydroxide or an oxychloride of variable composition, $[(FeO_3H_3)_nFe]^{\cdots}(Cl')_3$. N. J. Harrar and F. E. E. Germann studied the effects with salts of organic acids. The work of H. W. Fischer, F. K. Cameron and W. O. Robinson, F. Giolitti, and R. B. Smith and P. M. Giesy furnishes no support for the hypothesis that an oxychloride is formed. P. Nicolardot obtained complexes with eq. ratio of Fe : Cl=125 : 6. A. Béchamp gave 7 : 1 ; J. M. Ordway, 3 : 1 ; G. N. Wyrouboff and A. Verneuil, 8 : 1 ; and J. Duclaux, 300 : 1. The subject was discussed by G. Malfitano, and L. Michel. According to N. Kühnl and W. Pauli, the hydrosols of ferric oxide prepared by peptization of precipitated hydrated oxide with ferric chloride contain on the average ten times as much iron and twenty times as much chlorine as those prepared by hydrolysis. The ratio of active to total chlorine is from 1 : 5 to 1 : 6 in hydrolyzed sols and is little affected by dialysis ; but it decreases from 1 : 3 to 1 : 17 on dialysis of peptized sols, whilst the total oxychloride per colloid eq. increases more than sixfold. The extent to which chlorine is substituted by sulphate and oxalate anions on coagulation is throughout considerably higher for hydrolyzed than for peptized sols. By dialysis, the oxychloride portion of the sol-substance is progressively diminished, more markedly so in hydrolyzed soln. Transport numbers are much the same for both varieties. M. Neidle believed that this particular ratio is more due to chance, but suggested that a complex is formed with the ratio at 21 : 1 ; and A. W. Thomas and A. Freiden considered that it requires a mol. of ferric chloride to keep 21 mols. of ferric oxide in the colloidal state. There is a very wide variation in the Fe : Cl ratio found by different observers. Thus, M. Neidle obtained 84 : 1 ; R. Bradfield, 396 : 1 ; and J. G. Ufer, 2700 : 1. M. Neidle also showed that the maximum degree of purity attainable before coagulation occurs increases with decreasing iron-content of the soln. H. Siebourg studied the effect of dilution on the equilibrium between the hydrosol and the dispersion medium.

E. Heymann observed that with aged soln. of ferric chloride in which the proportion of colloidal hydrated ferric oxide is constant, the quotient of the active masses $[HCl]^3/[FeCl_3]$ is not constant, but undergoes a steady change with a variation of about 30 per cent. This indicates that the active mass of the colloidal ferric hydroxide cannot be regarded as constant. The size of the particles also influences the equilibrium, and the chlorine-content of the colloid particles is greater when they have been formed by hydrolysis than when the system has been prepared by adding hydrochloric acid to colloidal ferric hydroxide—*vide infra*, the hydrolysis of ferric chloride. All this means that, as H. B. Weiser puts it, investigators who assume the existence of definite compounds are unable to agree on their composition. The subject was discussed by E. I. Spitalsky and co-workers. R. Zsigmondy considered the hydrosol to consist of electrically charged mycelial particles with entrained mother-liquor ; and a similar hypothesis was favoured by P. Bary, A. Cotton and H. Mouton, S. I. Diatschkowsky, J. Duclaux and R. Titéica, J. Duclaux, H. Freundlich, G. Malfitano, L. Michel, and R. Wintgen and O. Kühn. J. Duclaux said that there is a state of equilibrium between the chloride ions in soln. and in the mycelia ; although A. W. Dumansky said that the partition of ammonium chloride between the soln. and the mycelia does not follow Henry's law. Wo. Ostwald, H. Freundlich, A. Lottermoser and P. Maffia, and P. Maffia, however, observed that the adsorption agrees with the usual adsorption formula. R. Ruer considered that part of the adsorbed chloride is partially ionized, whilst R. Wintgen and co-workers estimated that 70 to 90 per cent. of the adsorbed chloride is not ionized. The subject was also discussed by W. Pauli, A. W. Dumansky, J. Matula, and R. Zsigmondy. H. Freundlich considered that the mycelia are built up of positively-charged $\mathrm{FeO}^{\cdot}$-ions or $\mathrm{Fe}^{\cdot\cdot\cdot}$-ions associated with the complex. Thus:

$$\begin{bmatrix} n\mathrm{Fe_2O_3} \\ m\mathrm{Cl}.p\mathrm{H_2O} \end{bmatrix}\mathrm{FeO}^{\cdot}+\mathrm{Cl}' \quad \text{or} \quad \begin{bmatrix} n\mathrm{Fe_2O_3} \\ m\mathrm{Cl}.p\mathrm{H_2O} \end{bmatrix}\mathrm{Fe}^{\cdot\cdot\cdot}\mathrm{Cl}'_3$$

where in one case it was estimated that $n=75{\cdot}35$, and $m=7{\cdot}86$. According to J. Böhm, the X-radiograms of fresh hydrosols show that a basic salt is present, but the deposit from old soln. consists of goethite. H. Freundlich and S. Wosnessensky also discussed this subject. G. L. Clark, A. Krause and W. Buczkowsky, P. P. Lazareff, and J. Duclaux and R. Titéica studied the mycellar equilibrium of the hydrosol. G. Schikorr, and A. W. Thomas and E. R. Hamburger studied the hydrosol of the corresponding ferric oxybromide.

The colloidal hydrated ferric oxide as usually prepared is a **positive hydrosol,** but **negative hydrosols** have been obtained. H. Rose found that the presence of glycerol, mannitol, sucrose, and glucose prevent the precipitation of hydrated ferric oxide by the addition of alkali-lye, or a soln. of ammonia to a soln. of a ferric salt. H. W. Fischer dialyzed a soln. obtained by adding a sodium hydroxide soln. to a mixture of ferric chloride and glycerol; and P. Rona and F. Lipmann used a somewhat similar process. E. Riffard said that invert sugar is seven times as effective as cane-sugar in preventing precipitation. There is a converse action, the presence of traces of hydrated ferric oxide hinders the crystallization of cane-sugar, and higher proportions of molasses are formed if raw sugar is kept in iron vessels. E. Grimaux attributed the solubility of the hydrated oxide to the formation of a negative sol stabilized by the preferential adsorption of hydroxylions. A. W. Dumansky and T. P. Tyazhelova obtained the negative hydrosol from ferric chloride in the presence of a soln. of alkaline citrate. F. Hazel and C. H. Sorum obtained the negative hydrosol by the hydrolysis of prussian blue. N. G. Chatterji and N. R. Dhar observed that hydrated ferric oxide can be peptized by adding an alkali hydroxide to a soln. of a ferric salt in the presence of glycerol, or sucrose; and N. R. Dhar and K. C. Sen found that boric, molybdic, malonic, and tartaric acids could be used as peptizing agents; and K. C. Sen and co-workers, sodium arsenite, tartrate, or citrate. A. Schmauss, and J. Billitzer found that the colloid obtained by the spluttering of iron electrodes from an arc under a soln. of gelatin is negatively charged; and the hydrosols obtained by E. Grimaux, D. Vorländer, and P. A. Thiessen and A. Koerner are also negatively charged. A. Boutaric and G. Perreau studied the mutual flocculation of the positive and negative hydrosol.

F. Powis, and A. Boutaric obtained a stable, negative sol without protective colloid; he found that by adding colloidal hydrated ferric oxide to a dil. soln. of sodium hydroxide of suitable conc., it may be changed from positive to negative, coagulation being prevented by mixing in this order. It may also be directly prepared as a negative colloid by allowing the hydrated ferric oxide particles to form in the presence of a dil. soln. of sodium hydroxide. The view is taken that the potential difference at the surface of colloidal particles is due to adsorption of ions from the soln., and that its sign depends on whether the cations or anions are in excess in the layers nearest the particles. The negative sol so prepared is brownish-yellow, and showed no sign of precipitation after standing for three weeks. Sols of ferric oxide prepared by the electrical disintegration of iron electrodes under water are usually charged positively, but, according to T. Malarsky, filtration through filter-paper, fat-free cotton, glass-wool, or sand, may make the charge less positive, neutral, or negative, and he explained the phenomenon as an effect of contact electrification. By successive filtration of the sol of hydrated ferric oxide through filter-paper, the potential difference of the double layer is diminished, and consequently, the velocity in an electrical field is also diminished; repeated filtration will reduce the potential difference to zero and finally change the sign of the charge. H. Freundlich and S. Wosnessensky found that a hydrosol obtained by oxidizing iron pentacarbonyl with hydrogen dioxide and flocculated by boiling, furnishes a negative hydrosol when peptized by sodium or potassium hydroxide; the positively charged hydrosol is also discharged by shaking it with dil. alkali-lye. H. R. Kruyt and J. van der Spek also found that the positively-charged hydrosol is discharged by shaking it with a soln. of sodium hydrophosphate; H. Mayanagi, that potassium ferrocyanide acts similarly; and P. Rona and F. Lipmann, that the positive hydrosol becomes negative when shaken with sodium citrate.

The clear soln. of ferric peptonate prepared by M. Robin by adding ammonium chloride to a mixed soln. of glycerol, peptone, and ferric chloride, was a negative soln. of hydrated ferric oxide peptized by glycerol and peptone. Ordinary positive colloidal soln. of hydrated ferric oxide cannot be used for intravenous injections, since it precipitates the negatively charged serum of the blood, but a negative soln. containing alkali and glycerol does not precipitate serum, and was recommended by H. W. Fischer in arsenical poisoning, and by L. Dozzi, in the treatment of anæmia.

H. B. Weiser and G. L. Mack prepared **alcoholsols** of ferric oxide with methyl and propyl alcohols. P. Rehlinder and E. Wenström studied the stabilizing of suspensions of ferric oxide in benzene, toluene, and heptane.

According to A. Cotton and H. Mouton, the hydrosol of hydrated ferric oxide contains particles of two kinds. The particles in the lower part of the sol are specifically heavier, and have positive birefringence, whilst those in the upper part have a negative birefringence. N. P. Peskoff, and A. Szegvari also found two kinds of particles in the hydrosol, and discussed what is called *barophoresis*. X-radiograms by J. Böhm, J. Böhm and H. Niclassen, H. Freundlich, H. Zocher, H. Zocher and K. Jacobsohn, H. Zocher and W. Heller agree that the lower layers of particles are richer in ferric hydroxide than the upper layers. P. Bary also considered that his experiments on the drying of the hydrosols showed that two kinds of particles are present. G. Quincke also studied this subject. According to H. Freundlich, H. Diesselhorst and H. Freundlich, and B. Lange, the optical properties of the hydrosol show that the aged hydrosol is anisotropic, and contains tabular, and rod-like particles--H. Zocher said disc-shaped. R. Wintgen and M. Biltz, W. Pauli and co-workers, and L. Tieri made estimates of the sizes of the particles; R. Wintgen, A. W. Dumansky, and N. Kühnl and W. Pauli, of their density; and R. Wintgen and O. Kühn, and N. Kühnl and W. Pauli, of the magnitude of the charge. G. Jander and A. Winkel found that in the hydrolysis of the ferric salts, a series of basic states are produced which are stable under definite conditions of equilibrium. The state of equilibrium is very sensitive to the $H^{\cdot}$-ion concentration. The stable states range from the unimolecular ferric salt to the polymolecular ferric hydroxide. Small changes in the $H^{\cdot}$-ion concentration produce large changes in the mol. wt. of the product of hydrolysis.

F. Giolitti showed that the physical character of the precipitated hydrogel of hydrated ferric oxide varies with the nature of the precipitating agent. Thus, the hydrogel produced by the addition of a trace of sulphurous, sulphuric, selenious, iodic, periodic, boric, or phosphoric acid, is gelatinous, and it is not re-peptized by water; while the hydrogel produced by adding traces of hydrochloric, hydrobromic, hydriodic, nitric, perchloric or perbromic acid, is a finely divided, brick-red powder; and the hydrogel produced by the addition of a larger proportion of the monobasic acid is readily peptized by water. H. B. Weiser found that this anomalous behaviour is independent of the valency of the precipitating ion. The most voluminous precipitates are formed when there is a rapid coagulation throughout the entire soln., and when the precipitating agent has no solvent action on the particles. Gelatinous precipitates are formed when the finely divided particles of the hydrate are produced under conditions favouring the formation of a network enmeshing the mother-liquor. Just as large crystals are formed by the slow deposition from a super-saturated soln., and small crystals, by rapid precipitation, a condition which may also form a gelatinous mass, so, in L. P. de St. Gilles' soln., finely-divided particles are present which, if allowed to agglomerate slowly, may form more or less granular masses entangling very little water; but, if allowed to agglomerate rapidly, the particles have not time for orientation and a network may form entangling a relatively large amount of mother-liquor. This produces a relatively voluminous precipitate. Low concentrations of polyvalent ions cause rapid coagulation, and produce gelatinous precipitates. The solvent action of the precipitant also comes into play; thus, potassium chloride has no solvent action, and the stabilizing influence of the potassium ion is slight, hence rapid coagulation and a voluminous precipitate is formed, but with hydrochloric acid, the H'-ion has a stabilizing influence, and the precipitate is slightly soluble in the acid. The smallest particles are most readily attacked, and this will hinder the formation of a network enmeshing the mother-liquor, and restrict the amount of mother-liquor which can be entangled in the precipitate. This reduces the vol. of the precipitate; actually, the precipitate is usually granular. The colour of the precipitate furnished by L. P. de St. Gilles' soln. is not always brick-red; it varies with the conditions of precipitation. H. B. Weiser found that it is possible to make a transition from brown to yellow by increasing the size of the particles. This may be effected by heating water to which ferric chloride has been added. The yellow colloidal hydrated oxide is not readily dehydrated at 100° and probably contains adsorbed ferric salt. A yellow colloidal soln. was prepared by L. P. de St. Gilles' method by allowing the acetate soln. to remain for a few days before diluting and boiling. The slow hydrolysis of the acetate favours the formation of yellow hydroxide stabilized by adsorbed ferric salt. When the soln. is boiled, a stable yellow colloid is formed instead of the usual brick-red one. J. N. Mukherjee studied the effect of dilution on the stability of the hydrosol; A. F. G. Cadenhead and W. H. Vining, the reversibility of the process; and H. Handovsky, the effect of ageing the soln.

According to G. H. Ayres and C. H. Sorum, the **size of the particles** in the hydrosols of ferric oxide, prepared by the hydrolysis of soln. of ferric chloride between 100° and 145°, range from $52\mu\mu$ to $76\mu\mu$—average $60\mu\mu$. The size is not influenced by the temp. of preparation, or by the conc. of its reactants. The **colour** of colloidal hydrated ferric oxide varies from yellow to brick-red and brownish-red. According to E. F. Holden, the colour of colloidal soln. of hydrated ferric oxide when a thickness of 10·5 cms. is viewed against a white background, is pale yellow for soln. with 0·0007 per cent. Fe_2O_3; yellowish-orange, with 0·0034 per cent.; orange, with 0·0059 per cent.; red, with 0·034 per cent.; and dark red, with 0·068 per cent. G. Malfitano, and H. W. Fischer recognized that the variation in colour from yellow to red to brown is associated with an increase in the size of the particles—*vide supra*, ferric oxide. E. A. Schneider observed that the hydrosol becomes brick-red when heated to 200°; and observations were also made by L. P. de St. Gilles. H. B. Weiser's experiments on the hydrolysis of ferric chloride showed that the two factors are co-related. Finely-divided brown particles can be transformed into larger yellow, and still larger brick-red particles by heating them under suitable conditions. J. B. Nichols and co-workers, P. L. du Noüy, R. Audubert, R. Zsigmondy and C. Carius discussed the sizes of the colloidal particles. The observations of U. Antony and G. Giglio, Wo. Ostwald, E. Schaer, T. Svedberg, R. Bradfield, H. M. Goodwin, and C. L. Wagner on the hydrolysis of ferric chloride soln. whereby a colourless, dil. soln. changes spontaneously first to yellow and then to reddish-brown, make it appear that the yellow particles are smaller than the brown. The colour of a dil. colloidal soln. is not necessarily the colour of the particles. R. Bradfield found that a colloidal soln. of hydrated ferric oxide contains varying proportions of small, highly hydrated, reddish-brown particles and also larger, less hydrated yellowish-brown particles which can be separated from one another by the centrifuge. Both forms can be converted into larger, still less hydrated, brick-red particles by heating them to 100°. If the conditions are such that the red particles remain in colloidal soln., then L. P. St. de Gilles' sol is formed.

A yellow St. Gilles' sol does not become red by a prolonged boiling of the soln.; this is attributed by H. B. Weiser to the fact that the yellow particles, formed under certain conditions, lose water at 100° less readily than the reddish-brown particles. W. D. Bancroft pointed out that the yellow colloid is formed under conditions where the adsorption of a ferric salt is possible. H. B. Weiser showed that the adsorption of the ferric salt does not always produce the yellow colloid, but it may be that the yellow colloid, which is not converted to red by heating at 100°, is stabilized by the adsorbed ferric salt. The subject was discussed by G. D. Grane, P. P. Lazareff, H. W. Kohlschütter and H. Siecke, and B. W. Desai and co-workers. M. Annetts discussed the filtration of colloids.

R. Wintgen found that the **specific gravity,** at 25°/4°, of the hydrosol prepared by the dialysis of a soln. of ferric nitrate with the conc. of $Fe(OH)_3$, expressed in grams per 100 grms. of the dispersion medium:

$Fe(OH)_3$	0·23036	0·60683	1·0030	1·0728	2·2759
Sp. gr. . . .	0·99856	1·00095	1·00356	1·00405	1·01199

K. Grossmann expressed the conc. in grams Fe per 100 c.c. of soln., and found:

$Fe(OH)_3$.	0·408	0·815	1·222	1·630	2·445	3·260
Sp. gr. . .	1·0031	1·0084	1·0135	1·0187	1·0291	1·0392

Observations were also made by N. Sahlbom, and G. H. Ayres and C. H. Sorum. A. Gatterer peptized the hydrogel with acetic acid, and evaporated the dil. soln. by warming it under reduced press. The following are the results, Table LXXXIX, reduced to water at 4°, determined in vacuo. Both R. Wintgen, and A. Gatterer observed that the sp. gr. and the **specific volume** of the hydrosol are a linear function of the concentration. H. Picton and E. Linder, and H. R. Kruyt and J. van der Spek observed that a small dilation, just exceeding the errors of observation, occurs when the hydrosol coagulates.

TABLE LXXXIX.—SPECIFIC GRAVITIES OF THE HYDROSOL OF HYDRATED FERRIC OXIDE.

$Fe(OH)_3$ (per cent.)	5°	10°	15°	20°	25°	30°

H. Picton and E. Linder found that the coagulation of the hydrosol is attended by an expansion. They attempted to measure the **osmotic pressure** of colloidal soln. of hydrated ferric oxide prepared in various ways, but consistent results could not be obtained. H. Picton and E. Linder observed no perceptible change of temp. during the coagulation of the hydrosol of ferric oxide by the addition of electrolytes. Observations were also made by F. van der Feen, W. Biltz and A. von Vegesack, and G. Malfitano. J. Duclaux said that the osmotic press. increases with concentration but is not proportional to it; R. Zsigmondy, and J. Duclaux found that the osmotic press. decreases slightly with a rise of temp.; and J. Duclaux, and G. Malfitano found that the osmotic press. of the soln. do not vary directly with the electrical conductivity—the latter decreases with dilution more rapidly than the former. It is assumed that the colloidal soln. contain hypothetical, complex oxy-salts possessing the very properties under investigation! It is not surprising that the colloidal soln. show a slight osmotic press., and f.p. effect, because, generally, some adsorbed soluble salts are present. J. Lindemann showed that the electrolyte content of a sol can determine the osmotic press. The more dil. the hydrosol, the less the relationship between osmotic press. and the conc., and this is attributed to negative osmosis. S. Horiba and co-workers found that the osmotic press. of the hydrosol does not increase in light. T. Yamatori studied the dialysis of the hydrosol, and found that ferric ions dialyze completely when the H'-ion conc. is p_H=3·7 to 3·9. H. Freundlich and co-workers (1932) discussed the action of **sound waves** on the thixotropic gels. R. Wilson and T. C. Poulton found that the hydrosol is immediately coagulated when subjected to a **pressure** of 300 atm., and in 30 mins. when the press. is 100 atm.

H. Picton and E. Linder found that the **surface tension** of water is not affected by the presence of the colloid. N. Sahlbom made some observations on the capillary movements of the hydrosol. W. L. Rolton and R. S. Troop observed no change in the surface tension of the hydrosol in a magnetic field of 16,000 gauss. J. Alexander discussed the relation between surface tension and the kinetic activity. G. Jander and A. Winkel measured the relation between the coeff. of **diffusion** and the H'-ion concentration; and E. Ullmann, the rate of diffusion of ferrum oxydatum saccharatum solubile. K. Grossmann found that with hydrosols of ferric hydroxide having C grms. of Fe per c.c., the **viscosity**, η, at 25°, is:

C . . .	0·408	0·815	1·222	1·630	2·445	3·260
η . . .	0·00914	0·00952	0·00981	0·01030	0·01105	0·01215

Measurements were also made by N. Sahlbom, and A. du Pré Denning. H. Freundlich and E. Schalek, E. Schalek and A. Szegvari, G. H. Ayres and C. H. Sorum, J. H. Yoe and E. B. Freyer, R. N. Mittra and N. R. Dhar, A. Gatterer, N. R. Dhar and V. Gore, H. Meerbrei, and H. W. Woudstra observed the effect of *pressure*, p mm., to be such that with hydrosol, over 4 years of age, containing 9·5 per cent. Fe_2O_3, at 20°, the viscosities in arbitrary units were:

p . . .	10	20	30	40	50
Viscosity .	0·0338	0·0313	0·0299	0·0289	0·0280

A 10 per cent. hydrosol did not change its viscosity, η=0·1368, at 20°, over the range p=10 to 50 mm., and the sol was therefore about 13 times more viscous than water. More dil. hydrosols have perceptibly smaller values. The effect of *temperature* was measured by H. Meerbrei, N. R. Dhar and D. N. Chakravarti, and A. Gatterer. H. W. Woudstra observed:

	20°	25°	30°	35°	40°	45°	50°	55°	60°
η	0·01069	0·00950	0·00849	0·00766	0·00703	0·00639	0·00585	0·00534	0·00490

A. W. Thomas and E. R. Hamburger's results with the hydrosols of ferric oxychloride (Cl) and oxybromide (Br) are summarized in Fig. 531. A. G. Banus and M. Masriera studied the effect of a magnetic field on the viscosity. The effect of ageing is to decrease the viscosities in both cases. The observations of H. W. Woudstra, N. R. Dhar and D. N. Chakravarti, and K. Grossmann show that by reducing the dispersion of the hydrosol by raising the temp., or by the addition of small proportions of an electrolyte, the viscosity decreases until the viscosity curve attains a minimum value. A. Fernau and W. Pauli observed also that the *β-rays* of radium at first depress the viscosity, and then rapidly augment it. J. H. Yoe and E. B. Freyer studied the effect of the H'-ion conc. on the viscosity of the hydrosol, and C. H. Sorum, the diffusion. G. Rossi and A. Marescotti found that the surface tension and stability are not altered by the addition of 0·04 per cent. of gelatin. N. R. Dhar and S. Prakash observed that a mixture of 4 c.c. 0·5M-$FeCl_3$, 1 c.c. M-$(NH_4)_2SO_4$, 2 c.c. 3·5N-$CH_3.COONa$, 12·5 c.c. of water, and 0·5 c.c. of 2·34N-NH_4OH sets to a jelly in 6 hrs. The viscosities of the soln. at 30° were:

Age . .	0	30	60	90	107	132 mins.
Viscosity .	0·009324	0·009324	0·009349	0·1158	0·01731	0·01928

F. Doerinckel found the **specific heat** of the hydrosol and hydrogels of hydrated ferric oxide:

Fe_2O_3	1·6	3·3	6·5	8·6	10·8 per cent.
Sp. ht. Hydrosol	0·982	0·966	0·938	0·915	0·901
Sp. ht. Hydrogel	0·981	0·979	0·967	0·946	0·941

A. Brann, J. H. Walton and A. Brann, and H. Freundlich and F. Oppenheimer observed that under-cooled hydrosols of hydrated ferric oxide freeze more rapidly than is the case with water alone, and the crystals are tabular. Measurements of the lowering of the **freezing-point** were made by F. Krafft, G. Malfitano and L. Michel, H. Picton and E. Linder, A. W. Thomas and A. Frieden, A. Sabanejeff, A. W. Dumansky, A. Gatterer, and G. Bruni and N. Pappada, but the effect, if any, is outside the limits of the experimental errors of observation. F. L. Browne found that the effect of dextrose on the f.p. of the colloidal soln. shows that practically all the water in the sol acts as solvent for the substances dissolved in the sol. J. H. Gladstone and W. Hibbert obtained a lowering of the f.p. corresponding with a mol. wt. of 5000; A. W. Dumansky calculated a mol. wt. of 3120; J. Duclaux, 115,000; and R. Wintgen and co-workers, 32,000. These results, however, have no particular meaning. G. Malfitano discussed the size of the colloidal particles, since the whole basis of the calculation is invalid. G. Bruni and N. Pappada obtained negative results in the attempt to measure the effect of the colloid on the **vapour pressure** of water.

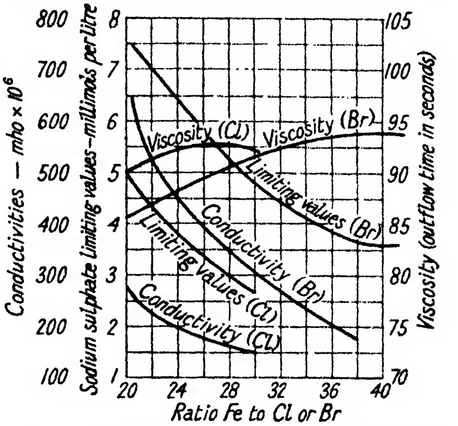

Fig. 531.—Properties of the Hydrosols of Ferric Oxybromide (Br) and Oxychloride (Cl).

M. Berthelot, and H. Picton and E. Linder observed that there is a small evolution of heat during the coagulation of the hydrosol—**heat of coagulation.** F. L. Browne, and F. L. Browne and J. H. Mathews obtained the same value for the heat of coagulation with sols prepared by three different methods, indicating that ferric oxide hydrosols represent an equilibrium which is defined by the temp., press., conc., and purity. The change in the degree of dispersion of ferric oxide during coagulation does not involve a measurable heat effect. The heat effects observed during the coagulation of sols of low purity are due to the dilution of the ferric chloride and hydrochloric acid contained in the sols, to the mixing of these electrolytes with the added coagulating electrolyte, and to changes in the adsorption equilibria. The subject was studied by F. Doerinckel; and H. R. Kruyt and J. van der Spek observed with sodium sulphate coagulation, the heat developed is about 2 cals. per gram of Fe_2O_3, and it increases with the conc. of the chloride in the sol. The heat of coagulation varies greatly with concentration of the hydrosol; and it increases with the proportion of adsorbed salt. The heat of coagulation with potassium oxalate is three times as great as with aluminium sulphate; the heat of coagulation is greater in dil. than in conc. soln., but no heat is developed when the hydrosol is diluted with water. Differences in the results with different preparations of the same hydrosol are due to differences in the proportion of adsorbed salts. F. Doerinckel observed that the **heat of dilution** of an aged 10·8 per cent. hydrosol was zero; but F. L. Browne and J. H. Mathews found that fresh hydrosols have a positive heat of dilution, and that the value decreases during the dialysis, becoming zero, then negative, and finally zero. G. J. Bouyoucos discussed the heat of reaction with soln. of the alkali hydroxides.

H. Picton and E. Linder, and A. Gatterer studied the **dispersion** of the hydrosol as exhibited by the Tyndall effect—1. 13, 7. Ultramicroscopic observations were made by H. Diesselhorst and H. Freundlich, H. Freundlich and co-workers, T. Tevreli, A. Boutaric and C. Tourneur, A. W. Dumansky, N. Kühnl and W. Pauli, B. Kuriloff, R. Wintgen and M. Biltz, and R. Wintgen and O. Kühn. B. Lange found the depolarization of the Tyndall's beam of light by the particles of the hydrosol is much greater with green light than it is with red light. R. Wintgen found that the **index of refraction,** μ, of the hydrosol μ/D is a linear function of the concentration, where D represents the sp. gr. of the soln.; and that with hydrosols having a concentration of C grms. of $Fe(OH)_3$ per 100 grms. of dispersion medium, the indices are:

C . . .	0·23036	0·60683	1·0030	1·0728	2·2759
μ . . .	1·33300	1·33364	1·33443	1·33463	1·33697

S. Prakash studied the extinction coeff. during the coagulation of the hydrosol.

V. Henri and A. Mayer, and C. Doelter observed no coagulation in **radium rays**; but A. Righi, A. Fernau and W. Pauli, and W. P. Jorissen and H. W. Woudstra observed a slow coagulation. J. A. N. Friend made some observations on this subject. P. Lal and P. B. Ganguly studied the action of **ultra-violet light**; S. S. Bhatnagar and co-workers, and J. A. Crowther and J. A. V. Fairbrother, the action of **X-rays**; A. Cotton and H. Mouton, and O. Scarpa, the rotation of the plane of polarization in a magnetic field; and F. Allison and E. J. Murphy, and W. Heller and H. Zocher, the magneto-optic properties. W. Zimmermann observed that the **photoelectric effect** is not perceptible.

O. Majorana observed that hydrosols of hydrated ferric oxide are **birefringent** in a magnetic field, the so-called *Majorana effect*. The hydrosol traversed by a ray of light at right angles to the lines of magnetic force exhibits double refraction sometimes as great as that of quartz. The birefringence disappears when the magnetic field is extinguished. O. Majorana, and A. Cotton and H. Mouton found that the birefringence is accompanied by a perceptible dichroism of the hydrosol. A. Schmauss inferred that the magnetic field caused an orientation of the particles. The phenomenon was discussed by O. Wiener, Lord Rayleigh, J. Kerr, L. Tieri, A. du Pré Denning, R. Gans and H. Isnardi, A. Pontremoli, H. Freundlich, and F. Braun. A. Cotton and H. Mouton observed that after ultra-filtration through collodion, the filtrate remained inactive, while the double refraction of the colloidal residue was increased. While ordinary coagulation gives an inactive gel, coagulation in a magnetic field gives a gel with a permanent double refraction even in the absence of a magnetic field. The turbidity and double refraction depend on the age of the hydrosol; and the ageing is hastened by raising the temp.—thus, 4 hrs.' heating at 100° raised the birefringence forty-fold. The turbidity and viscosity increase during the warming so that the greater the grain-size of the particles, the greater is the birefringence. Some sols prepared by the electric process have particles which are visible under the ordinary microscope, and the long particles become oriented in the magnetic field, and the hydrosol is then birefringent. The double refraction is, therefore, attributed to the orientation of lamellar or rod-like particles in the magnetic field, but the rods or flakes do not form threads. The reason the small particles give a smaller effect is due to the more vigorous brownian movement disturbing the orientation. A. Cotton and H. Mouton inferred that the Majorana effect is due to the nature of the particles themselves as well as to their orientation; and this is in accord with the observations of H. Freundlich, G. Quincke, H. Diesselhorst and co-workers, D. Graffi, A. Pontremoli, and L. Tieri, that the ferric oxide hydrosol exhibits double refraction when stirred mechanically, or when an electric current is passed through the liquid. C. von Nägeli had previously explained the optical and other properties of colloids on the assumption that they consist of anisotropic ultramicrons having a great resemblance to minute crystals. A. W. Ewell, L. Tieri, and O. M. Corbino studied the effect of a variable magnetic field on the Majorana effect.

The colour and dichroism of the hydrosol have been previously discussed. B. Lange studied the absorption of light by the hydrosol of ferric oxide. O. Scarpa found that the **absorption spectra** of the hydrosols are not in accord with Beer's law; with a decreasing concentration, the absorption in the red increases, and decreases in the violet. The absorption spectra observed by B. E. Moore with hydrolyzed soln. of ferric chloride, and hydrosols of hydrated ferric oxide, are summarized in Fig. 532. B. Jirgensons found that when the hydrosol is coagulated, the limit of absorption is at first displaced towards the red, but with complete coagulation, it is displaced towards the violet. A. Boutaric also studied the effect of flocculation on the coeff. of absorption; G. Jander and A. Winkel, the effect of the H'-ion concentration; and V. Petrescu, the depolarization of light by the colloidal soln. M. Matsui and co-workers, B. Kuriloff, and S. Prakash investigated the change in the **extinction coefficient** with the ageing of the hydrosol, and with the hydrosol mixed with different proportions of hydrochloric acid. B. Lange applied Lambert and Beer's law to the hydrosol. T. Ewan observed that when a completely hydrolyzed soln. of ferric chloride is diluted, the extinction coeff., k, has a higher value—wave-length of light constant; and that when the conc. of the hydrosol is C mols. of $Fe(OH)_3$ per litre, and the mean wave-length of the light is λ:

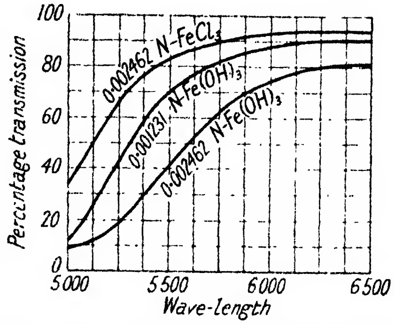

FIG. 532.—The Absorption Spectra of Hydrosols of Hydrated Ferric Oxide.

$C=0·0001254$	λ . .	570·0	513·2	480·2	423·8	442·8
	k . .	22·23	107·2	202·4	263·4	431·6
$C=0·0005680$	λ . .	536·0	497·2	461·2	444·2	434·1
	k . .	53·1	146·8	216·3	263·8	320·7
$C=0·02531$	λ . .	663·8	588·0	550·2	539·2	528·0
	k . .	5·61	14·35	33·04	47·76	61·05
$C=0·09855$	λ . .	665·2	608·0	577·0	552·0	540·5
	k . .	6·12	10·91	17·87	33·1	44·5

S. S. Bhatnagar and co-workers observed no marked change in the velocity of cataphoresis before and after exposing the hydrosol to **X-rays.** The **electrophoresis,** or rather the **cataphoresis,** of the positive colloid was studied by W. Biltz, H. Picton and E. Linder, J. N. Mukherjee and co-workers, S. H. Whang, F. Hazel and G. H. Ayres, W. B. Hardy, A. Reychler, R. Audubert, and W. Spring. The negative form of the colloid was discussed above, likewise also the reversal of the electric sign of colloids by adding varying proportions of positive or negative anions. The speed of migration of the colloidal particles of the positive hydrosol with a potential difference of 1 volt per cm. was found by R. Wintgen and M. Biltz to be 24·1 to 35·1 cms. per sec.; A. J. Rabinowitsch and V. A. Kargin gave 37·1 cms. per sec.; W. Pauli and co-workers—N. Kühnl, L. Engel, F. Rogan, and G. Walter—approximately 4·4; and W. Pauli and J. Matula, 57 to 336. The latter value is considered by R. Wintgen and M. Biltz to be too large, because the conductivity of the intermycellary fluid was ignored. H. Puiggari measured the electrical transport of the colloidal particles for the hydrosol, at 17° using a current of 0·003 amp. and an e.m.f. of 23 volts across the electrodes. The amount of spongy, dark-orange coloured coagulum which separated on the platinum cathode was directly proportional to the current, averaging 304×10^{-5} g. per amp. pet sec. for currents of 0·003 to 0·01 amp., irregularly and progressively smaller for 0·036 to 0·065 amp., and invisible for less than 0·0003 amp. The electrical transport is increased by rise of temp. The subject was discussed by S. S. Bhatnagar and D. C. Bahl, A. Boutaric and G. Perreau, H. Puiggari, F. Hazel and co-workers, A. J. Rabinowitsch and

E. Fodiman, and H. Freundlich and G. Lindau. H. Freundlich and S. Wosnessensky, P. Rona and F. Lipmann, and F. Powis discussed the speed of migration, or rather the **anaphoresis,** of the colloidal particles of the negative hydrosol, and the value works out to be between 15 and 30 cms. per sec. The speed of migration of the cataphoretic particles was found by H. Freundlich and H. P. Zeh to be lowered by the addition of complex cyanides proportionally with the valency; and H. Freundlich and G. V. Slottman found that the lowering of the speed by salts of the sulpho-acids increases as the salts rise in the homologous series. H. Freundlich and P. Rona observed that substances like camphor or thymol lower the speed of migration; and S. W. Young and L. W. Pingree found that light produces a similar result. The subject was discussed by L. Engel and W. Pauli. E. H. Büchner and A. H. H. van Royen found that when a thin stream of the hydrosol of ferric hydroxide flows through the dispersion medium between two vertical electrodes, the stream broadens out in all directions. The effect is not one of cataphoresis, and it is attributed to differences in electrical conductivity of the hydrosol and the dispersion medium. A. Lottermoser and Ta-Yü Chang studied the effect of dilution on the electric charge of the sol.

The sp. **electrical conductivity** of the hydrosol varies within wide limits and it depends on the proportion of chloride associated with the hydrosol. R. Wintgen and M. Biltz found the sp. conductivity in mhos for hydrosols with the following atomic proportions of Cl : Fe to be :

Cl : Fe .	0·1472	0·1354	0·1238	0·1236	0·1132	0·0994	0·0605
Mho × 10^3 .	1·525	1·246	0·8509	0·7544	0·6460	0·5073	0·4622

Observations were also made by W. Kopaczewsky, R. Wintgen and co-workers—M. Vöhl, and O. Kühn—W. Pauli and co-workers—N. Kühnl, G. Walter, J. Matula, F. Rogan, and L. Engel—A. Gatterer, A. Hantzsch and C. H. Desch, N. R. Dhar, and N. R. Dhar and D. N. Chakravarti. The conductivity of the sol increases with ageing, and approaches a constant value. K. C. Sen and co-workers gave 30×10^{-6} to 244×10^{-6} mho for the conductivity of the negative hydrosol. G. Malfitano found that soln. of ferric chloride will pass through a collodion membrane without causing a change in electrical conductivity; but J. Duclaux observed that Graham's sol, with 0·032 gram-atom of iron per litre, gives a colourless liquid by ultra-filtration through a collodion membrane, so as to separate the mycelia from the intermycellary liquid. The original soln. had a conductivity of 113×10^{-8} mho; the filtrate, a conductivity of 82×10^{-6} mho; and the residue, one-tenth the original, had a conductivity of 280×10^{-6} mho. The removal of the mycelia decreased the conductivity; the intermicellary liquid is not changed by its passage through the membrane. The adsorption of the electrolyte by the membrane is negligible. This subject was discussed by R. Wintgen and M. Vöhl, R. Wintgen and M. Biltz, J. Duclaux, E. Heymann, A. Lottermoser, R. Zsigmondy, and Wo. Ostwald. According to H. Handovsky, the longer the hydrosol of ferric oxide is dialyzed, the greater the increase in conductivity with the ageing of the sol; the increase in conductivity is said to take place chiefly in the intermycellary liquid into which the ions move slowly from the mycelia. A. W. Thomas and E. R. Hamburger's results with the hydrosols of ferric oxychloride (Cl), and oxybromide (Br) are summarized in Fig. 532. The effect of ageing is to increase the conductivity in both cases.

R. Wintgen and co-workers attempted to calculate the number of molecules in a single colloidal particle from measurements of the electrical conductivity and the transport numbers, involving a number of very debatable assumptions. It was found that an aged hydrosol, with 1·601 grms. Fe_2O_3 and 0·06014 grm. Cl per 100 grms. of sol, assuming all the particles have the same size, had the average composition of $[75{\cdot}35Fe_2O_3.7{\cdot}86HCl.xH_2O)FeO]^{\cdot}10{\cdot}230+10{\cdot}230Cl'$. A. Lottermoser found that the $H^{\cdot}$-ion conc. of the ultra-filtrates from an aged sol to be the same as that of the sol itself, and the mycelia are supposed to contain neutral chloride and chloride ions. The positive charge of the colloid is attributed to the stronger adsorption of the H·-ion, and he represented the composition of the particles by $[(x\mathrm{Fe_2O_3}.y\mathrm{HCl}.z\mathrm{H_2O})\mathrm{H^{\cdot}}]_n+(n-q)\mathrm{Cl'}$, where $q\mathrm{Cl'}$ represents the chloride ion corresponding to the adsorbed H·-ion. The sp. conductivity of the sol is greater than that of the ultra-filtrates, and A. Lottermoser regarded the difference as the true conductivity of the mycelia. The mobility of the mycelia rises abnormally with increasing dilution in sol containing but a small proportion of chlorine. This is taken to mean that the mycelia are adsorption complexes, and the abnormality is attributed to the displacement of adsorption and hydrolysis equilibria by dilution. H. B. Weiser added that there is no need to assume that the hydrosol is an electrolyte with complex oxychloride to account for the observed fact that only part of the chlorine present appears to be ionic. He argued that an indefinitely large number of hydrated ferric oxides are possible, and differing amongst themselves in the average grain-size, and therefore also in the amount of salt or salt-ions adsorbed at the surface; as shown by F. L. Browne, and P. Maffia, the colloid of Graham's sol adsorbs ferric chloride and hydrochloric acid as well as Fe···-, H·-, and Cl′-ions, in proportions dependent on the nature of the colloid, the sp. adsorption, and the conc. The preferential adsorption is in favour of the ferric and hydrogen ions—the chloride ion is not adsorbed so strongly. There is a state of equilibrium between the proportion adsorbed and the proportion in soln. Prolonged dialysis involves a loss of the adsorbed ions, and this decreases the stability of the sol. The adsorbed chloride is masked or protected by the hydrated ferric oxide, and does not respond to the ordinary tests, and it has a negligible effect on a chlorine electrode and is not detectable by the potentiometer. Hence, continued H. B. Weiser, it is to be expected that the amount of ionic chlorine is less than the total chlorine of the soln. W. L. McClatchie studied the **H·-ion concentration** of sols of ferric hydroxide. H. Puiggari prepared the hydrosol, with the H·-ion conc. eq. to $p_{\mathrm{H}}=3{\cdot}8$, by gradually adding aq. ammonia (90 grms. of 28 per cent. $\mathrm{NH_3}$ and 180 c.c. of water) to 1000 grms. of a soln. of hexahydrated ferric chloride in 2000 c.c. of water, and dialyzing for 264 hrs. The conc. of the H·- and Cl′-ions were determined electrometrically by W. Pauli and J. Matula, N. Kühnl and W. Pauli, A. J. Rabinowitsch and V. A. Kargin, P. Rona and F. Lipmann, R. Wintgen and M. Biltz, F. L. Browne, and A. W. Thomas and A. Frieden. A. J. Rabinowitsch and V. A. Kargin, and H. Pallman studied the H·-ion activity of the dispersed phase. A. Lottermoser and W. Riedel compared the electrolytic and electrokinetic potentials. S. S. Kistler discussed the **dielectric constant.**

A. Turpain and B. de Lavergne observed that a **magnetic field** has no effect on the dispersion of ferric hydroxide, but if some iron, nickel, cobalt, or chromium is present, coagulation occurs. S. Berkman and H. Zocher obtained $\chi=-0{\cdot}03\times10^{-6}$ for the **magnetic susceptibility** of the hydrosol prepared by the dialysis of a soln. of ferric chloride; P. Pascal gave $-0{\cdot}019\times10^{-6}$ for a hydrosol with 4·93 grms. Fe per litre; and O. Scarpa obtained $-0{\cdot}4\times10^{-6}$ to $0{\cdot}7\times10^{-6}$ for hydrosols prepared by electrical spluttering. The magnetic susceptibility was also examined by G. Wiedemann, and A. du Pré Denning. W. Hagen observed that the magnetic susceptibility decreased linearly with the temp.; and R. Gans and H. Isnardi found that it decreased with the temp., and increased with the field-strength.

According to H. Freundlich, the smallest concentrations in mols per litre, required for the precipitation of the hydrogel from the hydrosol of hydrated ferric oxide, are:

$\mathrm{KNO_3}$	$\frac{1}{2}\mathrm{Ba(NO_3)_2}$	NaCl	$\frac{1}{2}\mathrm{BaCl_2}$	$\mathrm{K_2SO_3}$	$\mathrm{MgSO_4}$	$\mathrm{K_2Cr_2O_7}$
0·0119	0·0140	0·00925	0·00964	0·00020	0·00022	0·00019

The negative ion apparently exerts the dominant action, and bivalent ions are more effective than univalent ions. H. Freundlich found the order of the precipitating power of the anions to be: chromate>sulphate>hydroxide>salicylate>benzoate>chloride>nitrate>bromide>iodide; and H. B. Weiser and E. B. Middleton, using L. P. de St. Gilles' sol, found: ferrocyanide>ferricyanide>-dichromate>

tartrate>sulphate>oxalate>chromate>iodate>bromate>thiocyanate>chloride >chlorate>nitrate>bromide>iodide. According to H. B. Weiser, hydrochloric acid has two precipitation values for L. P. de St. Gilles' sol, one above the other with a zone of non-precipitation between, in which the colloid is less stable than the original colloid. The degree of reversibility of the precipitation of hydrous ferric oxide is determined mostly by the specific adsorbability of the precipitating ion, although the physical character of the precipitate has an influence. Non-electrolytes, even in conc. soln., have very little action. A. W. Dumansky found that when the hydrosol is boiled with Fehling's soln., the colloid is precipitated along with cuprous oxide. O. Baudisch and W. H. Albrecht studied the subject. N. R. Dhar and R. N. Mittra discussed the rhythmic coagulation of ferric hydroxide sol.

Observations on the **coagulation** of the hydrosol by electrolytes were made by H. Freundlich and co-workers—H. P. Zeh, K. Jacobsohn, V. Birstein, G. V. Slottman, S. Wosnessensky, A. Brossa, and M. Aschenbrenner—E. Weitz and H. Stamm, H. R. Kruyt and J. van der Spek, J. Traube and E. Rackwitz, A. W. Dumansky and co-workers, E. Schalek and A. Szegvari, W. Knaust, F. Hardy, H. D. Murray, S. I. Dyachkovsky, J. N. Mukherjee and co-workers, B. N. Desai and P. M. Barve, J. Lisiecky, N. R. Dhar and V. Gore, C. H. Sorum, S. Liepatoff, H. Mayanagi, S. G. Chaudhury and A. Ganguli, H. Picton and E. Linder, E. S. Moore and J. E. Maynard, M. N. Chakravarti and co-workers, G. Rossi and A. Marescotti, W. V. Bhagwat and N. R. Dhar, A. J. Rabinowitsch and V. A. Kargin, E. Deiss and G. Schikorr, A. von Buzagh, W. Pauli and co-workers, A. Yanek, K. Jablczynsky and co-workers, A. Ivanitzkaja and L. Orlova, W. P. Jorissen and H. W. Woudstra, W. B. Hardy, A. Boutaric and co-workers—M. Dupin and G. Perreau—N. Pappada, S. Ghosh and N. R. Dhar, N. R. Dhar, D. Deutsch and S. Loebmann, W. W. Taylor, S. S. Joshi and V. L. Narayan, and P. Rona and F. Lipmann. The results show that univalent anions like the Cl′- Br′- and I′-ions are not very different in their action, but the F′-, CyS′-, and OH′-ions have a particularly high coagulating value. Soln. of sodium phosphate act between two limiting concentrations; the coagulating value of the complex cyanides increases with their valency; and the coagulating values of the fatty acids, and of the sodium salts of the sulpho-salts, are greater the higher their position in the homologous series. K. Hakozaki attempted to express the coagulating power of electrolytes by an empirical formula. H. Freundlich, and S. Ghosh and N. R. Dhar found the coagulating values are independent of the age of the hydrosol. A. Boutaric and G. Perreau, H. Freundlich, K. C. Sen and co-workers, H. B. Weiser and H. O. Nicholas, H. R. Kruyt and J. van der Spek, and O. Fodor and R. Riwlin observed that the coagulating power increases with the concentration of the hydrosol, but T. Takamatsu found that whilst the coagulating powers of the OH′-, SO_4''-, CO_3''-, HPO_4''-, $FeCy_6''''$-, and Cr_2O_7''-ions are proportional to the conc. of the hydrosol, that of the I′-, and CH_3COO'-ions is dependent on the conc. of the hydrosol, and that of the Cl′- and NO_3'-ions is independent of the conc. of the hydrosol. E. F. Burton and E. Bishop found that with some colloids: The precipitating power—pp.—of univalent ions increases, that of bivalent ions remains unchanged, and that of tervalent ions decreases with a decreasing concentration of the sol. H. B. Weiser and H. O. Nicholas observed that the rule does not apply for the hydrosol of hydrated ferric oxide; their results, plotted in Fig. 533, were obtained with a hydrosol having 1·7 grms. of the colloid per litre as 100 per cent.:

Conc. of colloid		100	50	25	12·5 per cent.
Pp. value	$KBrO_3$	40·1	34·4	28·0	25·0
	K_2SO_4	0·68	0·41	0·25	0·16
	K_4FeCy_6	0·57	0·30	0·16	0·08

On the other hand, R. C. Judd and C. H. Sorum found that with a hydrosol quite free from chlorides, the coagulation follows E. F. Burton and E. Bishop's rule.

Under these conditions, the amount of coagulating univalent ion decreases as the conc. of the sol increases. N. R. Dhar and co-workers found that the more concentrated the highly purified sols the greater the amount of electrolyte required for coagulation, irrespective of the valency of the coagulating ion.

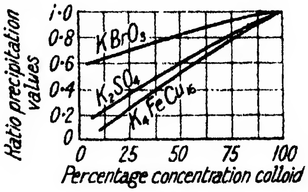

FIG. 533.—The Coagulation of the Hydrosol of Ferric Oxide.

A. W. Thomas and E. R. Hamburger studied the limiting value, or the average of the amounts of sodium sulphate, in millimols per litre, required just to precipitate and just not to precipitate the hydrosols of ferric oxychloride (Cl) and oxybromide (Br), and the results are summarized in Fig. 532. J. Duclaux found that in the coagulation of ferric oxide hydrosol, 10 c.c. of the hydrosol, with 0·0203 gram-atoms of iron and 0·00166 gram-atom of chlorine per litre, required almost eq. quantities of anions for coagulation, regardless of their valency.

SO_4''	$(CH_2)_2C(OH)(COO)_3'''$	CrO_4''	CO_3''	
17×10^{-6}	$16\cdot5\times10^{-6}$	$15\cdot2\times10^{-6}$	17×10^{-6}	
PO_4'''	OH'	$FeCy_6''''$	NO_3'	Cl'
19×10^{-6}	$16\cdot1\times10^{-6}$	13×10^{-6}	1880×10^{-6}	2000×10^{-6}

The nitrate and chloride ions were found to be exceptional. The amount of sulphate or hydroxide ion necessary for precipitation was almost eq. to the chloride-content of the hydrosol. He thus regarded the process of coagulation as a definite stoichiometrical, chemical action, *i.e.* a double decomposition of the ordinary type. F. Hazel and C. H. Sorum, H. Freundlich and G. Lindau, and P. Rona and F. Lipmann found that the coagulating value increases with the H˙-ion conc. of the soln., but the order of the coagulating power of the anions is but little affected by the conc. of the H˙-ion. Graham's sol is stabilized by adsorbed H˙-ions, and probably also by ferric ions. Different concentrations of electrolytes are required to neutralize the adsorbed ions and to precipitate the sol. The conc. of the acids required for precipitation are greater than those of the potassium salts because the stabilizing H˙-ion is more strongly adsorbed than the K˙-ions. W. Pauli and co-workers—J. Matula, G. Walter, F. Rogan, and W. Kühnl—discussed the displacement of the chloride associated with the hydrosol by the coagulating anion; and A. J. Kabinowitsch and V. A. Kargin, the effect of the H˙-ion concentration on the exchange of ions.

H. Freundlich and G. Lindau studied the coagulation value of albumen · egg-albumen, hæmoglobin, paraglobulin, gelatin, globin, and trypsin; and A. Janek and B. Jirgensons, methyl, ethyl, propyl, and isobutyl alcohols. H. M. Stark found that the hydrosol is coagulated by bubbling some gases through the liquid; carbon dioxide caused no coagulation; but the iron precipitated by a litre of gas was 273×10^{-7} grm. with nitrogen; 317×10^{-7} grm. with air; 428×10^{-7} grm. with hydrogen; and 453×10^{-7} grm. with oxygen. A. W. Dumansky found that when a soln. of carbamide is added to a colloidal soln. of hydrated ferric oxide, the time of coagulation increases as the conc. of the carbamide is diminished, but the conc. of the colloid has no effect on the process. Until the occurrence of coagulation, the conc. of the coagulating substance is less than its calculated value, but after coagulation the colloid retains hardly any of the coagulating substance. The process of coagulation is assumed to occur thus: carbamide passes readily through the walls of the bubbles of the colloid suspended in the water, consequently no coagulation appears at first, but the carbamide soln. is concentrated within the cells of the colloid until the strain causes them to burst and coagulation takes place. Under certain conditions, the bubbles of the colloid do not burst, but they stretch, thus occupying a larger vol. and finally cause the formation of a jelly. A. W. Dumansky prepared colloidal soln. of hydrated ferric oxide containing 8·69 grms. of barium nitrate, or 2·152 grms. of potassium chloride, or 4 grms. of potassium nitrate. Conductivity measurements of mixtures, in various proportions, of colloidal hydrated ferric oxide soln. and ammonium chloride soln., show that in these mixed soln. the ammonium chloride distributes itself between two solvents, namely, water and the mols. of the colloid. C. E. Linebarger concluded that it is very unlikely that the coagulation or gelatinization of the hydrosol is comparable with crystallization from supersaturated soln., because the addition of a small amount of a substance having the power to start coagulation in one part of a colloidal soln. does not cause the coagulation to spread at a certain rate throughout the whole soln., such as would occur with crystallization from a supersaturated soln. K. Jablczynsky and M. Soroczynsky studied the kinetics of the process of coagulation of sols of ferric hydroxide by electrolytes; K. Jablczynsky and M. Knaster showed that the speed of coagulation increases with the temp. between 5° and 45°; and K. Jablczynsky and co-workers found that the coagulation velocities with different univalent anions are in the proportions $I' : Br' : NO_3' : Cl' = 1 : 7{\cdot}92 : 72{\cdot}9 : 169$. A. Fordor and R. Riwlin discussed the speed of coagulation of the hydrosol. According to G. H. Ayres and C. H. Sorum, the flocculation of hydrosols showed no regular variation with the temp. of preparation, but samples heated to different temp. were less stable to a flocculating agent the higher the pre-heating temp. Opaque sols of an orange-red colour, produced at a high temp., showed considerable sedimentation on standing. The colour and turbidity of the sols indicate that the oxide is less hydrated the higher the temp. of preparation, and the oxide is then less stable towards electrolytes than sols prepared at a lower temp. The decrease in stability and increase in turbidity are not due to an increase in the grain-size of the particles. W. Knaust discussed the coagulation of the sol peptized by phosphoric acid. E. S. Hedges and R. V. Henley studied the periodic coagulation of the hydrosol.

The coagulation of the negative hydrosol of ferric oxide by electrolytes was studied by H. Freundlich and S. Wosnessensky, P. Rona and F. Lipmann, K. C. Sen and co-workers, and A. Boutaric and G. Perreau.

Mixtures of some electrolytes instead of additively strengthening one another's action, reduce their mutual effect; hence the term **antagonistic electrolytes.** Thus, mixtures of ferric and potassium chlorides, or of aluminium nitrate and potassium sulphate, act as antagonistic colloids in the flocculation of the hydrosol of hydrated ferric oxide. The phenomenon was first observed by H. Picton and E. Linder in connection with the effects of pairs of electrolytes on the coagulation of the hydrosols of arsenic trisulphide. The subject was discussed by K. C. Sen, A. Rabinerson, A. Lottermoser and K. May, and S. Ghosh and N. R. Dhar. It is supposed that the antagonistic effect is due to the interference of the one precipitating ion on the adsorption of the other. A. Boutaric and M. Dupin observed that in the mutual flocculation of the hydrosols of hydrated ferric oxide, and arsenious sulphide, when an insufficient quantity of either sol to cause the flocculation of the other, is added, and the mixture is allowed to stand a few days, the soln. becomes increasingly sensitive to further additions, so that a total quantity of so little as one-twentieth of the quantity required on a first addition is needed to produce flocculation. The phenomenon is analogous with *anaphylaxis*, where an animal, a few weeks after a single injection of protein, becomes extremely sensitive to a second injection which would otherwise be harmless. N. P. Peskoff and V. I. Sokoloff found that when the hydrosol is treated with just sufficient magnesium sulphate to start coagulation, the addition of low concentrations of hydrochloric acid increase the stability of the colloid, whilst high concentrations decrease it, although coagulation is never complete. When sulphuric acid is used as coagulant, the presence of hydrochloric acid increases the instability to a greater extent than in the case of magnesium sulphate.

Protective colloids, or **retarders**, act by hindering the coagulation of hydrosols, and thus make hydrosols more stable—*vide supra*. Some substances, called

sensitizers, increase the sensitiveness of the hydrosol to coagulation by electrolytes —particularly by univalent chlorides, bromides, iodides, or nitrates which have a weak coagulating value. Thus, H. Freundlich and P. Rona observed this to be the case in the presence of urethane, camphor, thymol, amyl alcohol, acetone, phenolthiourea, and tributyrine. Electrolytes which have a stronger coagulating value—like the fluorides, sulphates, and citrates—do not have so marked an effect. H. R. Kruyt and C. F. van Duin observed that the presence of phenol, or, better, of isoamyl alcohol, favours the coagulation power of potassium chloride or sulphate; A. Janek and B. Jirgensons observed that methyl, ethyl, propyl, and isobutyl alcohols have a similar effect on the precipitation value of soln. of sodium chloride; B. N. Ghosh found that thymol, urethane, and amyl alcohol accelerate the coagulation of the hydrosol; H. Freundlich and G. Lindau, egg-albumen, and serum paraglobulin; and S. G. Chaudhury and A. Ganguli found that the hydrosol is more sensitive towards coagulation in the presence of methyl and ethyl alcohols, and pyridine; urea sensitized it towards potassium chloride and sulphate; and glycerol, towards potassium sulphate and ferrocyanide.

According to A. Brossa and H. Freundlich, when the hydrosol is added to a soln. of albumin, free from electrolytes, the particles of albumin and of hydrated ferric oxide are positively charged, but not so strongly as the particles of hydrated ferric oxide when alone. Hence, the hydrosol of hydrated ferric oxide and albumin behaves as a positive suspensoid, which is precipitated by small conc. of electrolytes. In the precipitation by electrolytes the nature of the anion, its valency, and tendency to adsorption are of importance. The quantity of electrolyte necessary to precipitate the complex sol is much less than that required to precipitate the pure hydrated ferric oxide sol; consequently the complex sol has become more sensitive. The sensitiveness can be further increased by adding albumin sol to the albumin-ferric oxide sol. With large conc. of electrolytes, the particles first precipitated are re-dissolved; in this case, as in the peptization of globulin and casein sols, the nature of the anions is determinative, in so far as the high valency anions and organic anions (for example, SO_4'', picrate ion, citrate ion) show their action at much smaller conc. than the others. Albumin is not quantitatively combined with the hydrated ferric oxide sol, but divided between the sol and the soln. The partition does not follow a simple adsorption isotherm, but the quantity adsorbed is proportional to the concentration for small albumin conc.; whilst at high conc., a saturation value is reached. The adsorption does not appear to be reversible. With increasing conc. of hydrated ferric oxide, the sensitiveness of the complex sol decreases, and approaches more nearly to the pure hydrated ferric oxide sol in its properties. The albumin hydrated ferric oxide sol is somewhat more turbid than the hydrated ferric oxide sol, but it cannot be resolved into its constituents in the ultra-microscope. This is easier in the region where no precipitation is possible, and most easy in those sols to which an excess of albumin soln. has been added. The whole of the phenomena of precipitation and re-solution are explained by the adsorption of the anions of the soln., and depend on the discharge and then re-charging of the particles. If instead of adding an electrolyte to a hydrated ferric oxide-albumin sol an albumin sol containing an electrolyte is precipitated with hydrated ferric oxide sol, it is seen that in many respects the relationships are identical, particularly in the amount of hydrated ferric oxide combined with the albumin. Differences noticeable in the nature of the precipitation can be explained by assuming that the changed conditions have affected the rate of coagulation. The action was also studied by W. Pauli and L. Flecker, H. Freundlich and G. Lindau, H. Freundlich and co-workers—G. Lindau, and S. Wosnessensky—and J. Reitstötter. A similar effect was observed with soln. of albumin, paraglobulin, hæmaglobin, and globin; and W. Beck found that lecithin and cholesterin, R. Wintgen and E. Meyer, gelatin, and S. Ghosh and N. R. Dhar, gelatin, albumin, and tannin, act in the same manner. The sensitization effect is attributed to the lowering of the surface charge on the particles as a result of the adsorption of a substance with a lower dielectric constant than water;

but L. Michaelis and P. Rona could not detect any adsorption of these non-electrolytes by the hydrosol of ferric oxide, nor could they detect any effect due to their presence on the adsorption of electrolytes. The subject was discussed by H. Freundlich and co-workers—P. Rona, and G. Lindau—and by W. Pauli and L. Flecker. Y. Matsuno, V. Henri and A. Mayer, and W. P. Jorissen and H. W. Woudstra found also that exposure to the β-rays of radium favours the coagulation of the hydrosol by electrolytes.

H. B. Weiser and E. B. Middleton showed that when a positive colloid like hydrated ferric oxide is coagulated by electrolytes, the negative precipitating ion is adsorbed; but the order of precipitating power and the order of adsorption are not the same. This is because the adsorption measured is ion adsorption plus adsorption of neutral salt, so that one effect may mask the other. H. Freundlich observed that colloids may show a kind of **acclimatization,** for the hydrosol of ferric oxide requires less electrolyte for precipitation when it is added all at once to what is required, than when it is added step-wise with long intervals of time, and particularly when the slow addition produces a fractional precipitation of the sol. This is expressed by saying that the colloid becomes acclimatized to its surroundings when the electrolyte is added slowly, and so more is required to produce a given result. V. N. Krestinskaja and O. S. Moltschanova said that the effect is due to slow chemical changes produced by a reaction of the colloid with the added electrolyte. H. B. Weiser added that the effect of the addition is not necessarily due to the adaptability of the colloid to the electrolyte, because fractional precipitation not only removes ions by adsorption but it alters the stability of the soln. by decreasing its concentration. The factors which determine the excess for slow rates of precipitation are: (i) the extent of the fractional precipitation; (ii) the adsorbing power of the colloid; (iii) the adsorption of the precipitating ions; and (iv) the effect of the dilution of the soln. on the precipitation conc. of electrolytes.

The **mutual coagulation** of hydrosols.—A. Lottermoser, and W. Biltz observed that a positively charged hydrosol like that of hydrated ferric oxide is coagulated by a negatively charged hydrosol. Complete flocculation occurs only within certain limiting proportions of the two hydrosols; with other proportions, the coagulation is incomplete. The phenomenon was observed with silicic acid, by T. Graham, W. M. Simakoff, W. Biltz, A. W. Thomas, and N. Pappada; with the hydrosols of selenium, cadmium sulphide, stannic acid, tungsten-blue, molybdenum-blue, and platinum, by W. Biltz; with humus, by H. Udluft; with mastic, by M. Neisser and U. Friedemann; with arsenic or antimony trisulphides, by W. Biltz, H. Freundlich, A. W. Thomas, J. Billitzer, and M. Neisser and U. Friedemann; manganese dioxide, by E. Deiss, H. Udluft, and W. M. Simakoff; with vanadic acid, by W. Biltz, and H. Freundlich and W. Leonhardt; with ferrous hydroxide, by E. Deiss and G. Schikorr; with gold, by W. Biltz, and A. Galecki and M. S. Kastorskij; and with silver, by A. Rabinerson, and F. Doerinckel, who found that the heat of coagulation reaches a maximum with 60 to 70 per cent. of silver hydrosol, and then falls off rapidly. Optimum coagulation occurs with 70 to 80 per cent. of silver colloid. R. Wintgen and E. Meyer, R. Wintgen and M. Vöhl, D. C. Bahl, H. B. Weiser and co-workers, and H. Freundlich and G. Lindau observed that the hydrosol of gelatin coagulates the hydrosol of hydrated ferric oxide. According to R. Wintgen and E. Meyer, when constant amounts of a sol of hydrated ferric oxide are mixed with increasing amounts of gelatin soln. and water to give constant final vols., two types of flocculation are obtained according as the necessary amount of water is added to the hydrated ferric oxide or the gelatin soln. When the water is added to the gelatin soln., flocculation commences at a well-defined point and the amount of precipitate increases to a maximum. When water is added to the sol of hydrated ferric oxide, for increasing amounts of gelatin, the commencement of the flocculation is well marked, this is followed by an increasing flocculation to a rather indefinite maximum, there is then a sudden fall to a point of no flocculation, and finally, a renewal of increasing flocculation. The amount of gelatin required for the first flocculation decreases with increase in the conc. and the age of the initial gelatin soln. For a series of dilutions of ferric hydroxide sols of different origin, the amount of gelatin required for flocculation decreases in a linear manner with the dilution for typical colloidal sols, but decreases in a linear manner with the conc. of semi-colloidal sols, containing much hydrochloric acid. The first case is regarded as a simple mutual flocculation, and the second as involving, in addition, an increasing dispersion of the gelatin with increasing amounts of hydrochloric acid. H. Udluft found also that coagulation occurs when the hydrosol of hydrated ferric oxide is mixed with humus; A. Rabinerson, with prussian blue, night blue, dextrin, albumin, or silver; M. Neisser and U. Friedemann, with mastic; and R. Ellis, with oil emulsion. E. A. Schneider observed no flocculation of the hydrosol of hydrated ferric oxide by the hydrosol of gold sulphide.

According to W. Biltz, complete coagulation occurs only when a sol of one sign is neutralized by adsorption of an amount of colloid carrying eq. ions of the opposite sign. The amounts required for the purpose vary with their nature. In one case, the positive hydrosol of ferric oxide was more effective than the hydrosol of cerous oxide, and less effective than the hydrosol of thoria in coagulating the hydrosol of gold; while the hydrosols of both thoria and cerous oxide were more effective than positive hydrosols of hydrated ferric oxide in coagulating the hydrosols of antimony and arsenic sulphides. A. W. Thomas and L. Johnson found that there is a chemical equivalence between the peptizing agents of the positive hydrosol of hydrated ferric oxide peptized by ferric chloride and hydrosols of silicic acid peptized by sodium silicate, provided the ratio of the peptizing agent to the disperse phase falls within a certain range; outside this range, the coagulation appeared to be erratic. The precipitations showing chemical equivalence between the peptizing agents at maximum coagulation exhibit little variation in the coagulation ratios with dilution, whilst those showing a divergence from chemical equivalence approach the chemical equivalence on dilution. The mutual coagulation of hydrosols of hydrated ferric oxide and silicic acid is thus assumed to be due to the removal of the peptizing agent by chemical action between them. It is also possible that the mutual coagulation of the hydrosols of arsenic trisulphide and of hydrated ferric oxide is due to the chemical reaction: $\mathrm{S}''+2\mathrm{Fe}^{\cdot\cdot\cdot}=\mathrm{S}+2\mathrm{Fe}^{\cdot\cdot}$. H. B. Weiser added that in order to obtain data supporting the chemical reaction theory, it appears to be necessary to choose the experimental conditions to fit the case. R. Wintgen and H. Löwenthal found the reciprocal coagulation of oppositely charged sols is a maximum when the conc. of the sols expressed in equivalent aggregates are the same, meaning when equal numbers of charges of opposite sign are mixed. J. Billitzer found that gelatin forms a positive sol in acid or neutral soln., and so precipitates negative sols, but not positive ones like the hydrosol of hydrated ferric oxide; on the other hand, gelatin in ammoniacal soln. forms a negative sol, and precipitates the hydrosol of hydrated ferric oxide. If gelatin is first added to the colloidal ferric oxide and afterwards ammonia, a stable mixture of positive sols is changed to a stable mixture of negative sols.

F. Powis observed that the positively charged hydrosol of hydrated ferric oxide is precipitated by the negatively charged hydrosol, and vice versa. The positively charged hydrosol of ferrous hydroxide was found by A. Schmauss to be coagulated by the negatively charged hydrosol of hydrated ferric oxide; but D. Vorländer found that, in general, the negative hydrosol of hydrated ferric oxide is not coagulated by negative hydrosols.

N. Pappada observed that, in general, the **coagulation of the hydrosols by non-electrolytes** does not occur; thus, A. Janek found that the hydrosol of hydrated ferric oxide is not coagulated by benzene, chloroform, and ether, or by mixtures of these liquids, but a partial coagulation was produced by carbon disulphide. Y. Matsuno found that sugar soln. are inactive, but conc. soln. of ethyl alcohol flocculate the hydrosol. A. W. Dumansky found that urea coagulates the hydrosol very slowly; whilst P. P. von Weimarn and A. W. Alexejeff observed that when the hydrosol is shaken with turpentine, a coagulum collects at the boundary surface of the two liquids; and H. Freundlich and S. Loebmann obtained an analogous result with benzene.

A. W. Dumansky observed that the **coagulation of the hydrosol by mechanical agitation** can be produced. For instance, the hydrosol is slowly coagulated when it is treated in a centrifuge having 4000 revolutions per minute. H. Freundlich and H. Kroch observed that the hydrosol obtained from iron pentacarbonyl coagulates readily during 20 hrs.' stirring with 500 revolutions per minute, but not so with the hydrosol produced by the hydrolysis of ferric chloride. H. Freundlich and S. Loebmann compared the result with the coagulation produced with turpentine or benzene—*vide supra*—but here the coagulation occurs at the boundary surface of hydrosol and air. According to E. Schalek and A. Szegvari, if a 5 or 10 per cent. hydrosol of hydrated ferric oxide is mixed with a small proportion of an electrolyte, it gradually forms a pasty hydrogel which easily becomes liquid when it is agitated. Gelatinization again occurs on standing, and the alternate sequence of changes: sol→gel→sol→ . . . can be repeated indefinitely. This isothermal, reversible transformation: Sol⇌Gel, by mechanical agitation, was called by T. Peterfi, **thixotropy**—from *θίξις*, the act of touching; and *νρέπειν*, to change. The phenomenon was studied by H. Freundlich and co-workers—A. Rosenthal, W. Rawitzer, and K. Söllner—N. Marinesco, A. de Waele, A. Paris, E. A. Hauser, S. S. Kistler, W. Heller, D. Deutsch, P. Barry, E. L. McMillen, H. A. Ambrose and A. G. Loomis, and A. Kutzelnigg and W. Wagner. The speed of gelatinization is reduced in the presence of some hydroxylic hydrophiles like the amino-acids, sugar, and increasing conc. of the $H^{\cdot}$-ions; and it is increased by a rise of temp., the addition of sensitizers—like ethyl alcohol, agar-agar, gelatin, and saponin—and by electrolytes with anions of a high valency. R. Wilson and T. C. Poulton found that there is a **coagulation by pressure** of a colloidal soln. of ferric hydroxide—in 30 mins. at 100 atm., and immediately at 300 atm. press.

N. Sahlbom found that **coagulation by capillary action** occurs when long strips of filter-paper are immersed in positive hydrosols, the precipitation takes place at the surface of contact; but negative hydrosols rise through the capillary network without hindrance. The precipitation of the positive colloids is not due to chemical action, but to the setting up of an e.m.f. as a consequence of the streaming of the liquid through the capillaries; this potential difference brings about the discharge of the positively charged colloidal particles. If the capillaries are not sufficiently narrow, the resulting e.m.f. is not large enough to give rise to complete precipitation, and a rise of the positive colloid is observed. According to F. Fichter, when a drop of a dialyzed hydrosol of hydrated ferric oxide is placed on a glass plate, and a second plate is allowed to sink slowly so as to make a pair of parallel plates, the thin layer of soln. between the plates exhibits a sharply defined, circular, opalescent zone in consequence of the precipitation of the positive colloid. The critical distance between the plates necessary for the precipitation is 0·0322 mm. Negative colloids do not show the phenomenon; and A. W. Thomas and J. D. Garard observed the phenomenon only with concentrated, positive hydrosols.

H. Picton and E. Linder observed that in many cases **coagulation by freezing** occurs so that the hydrosol is flocculated by freezing, or by alternate freezing and thawing, but with the hydrosol with much adsorbed chloride, no change occurs. Similar results were obtained by O. Bobertag and co-workers, A. Heiduschka, N. Ljubawin, and A. W. Thomas and A. Frieden. S. I. Dyachkovsky found that the coagulation by freezing is prevented by alcohol. The **coagulation by heat** was examined by N. R. Dhar and S. Prakash. T. Katsurai and T. Watanabe heated the hydrosol between 120° and 180° in an autoclave, and found the products all possessed good quality red colours with X-radiograms like that of hæmatite—*vide infra*, hydrogels. W. Knaust found that the hydrosol of ferric hydroxide coagulated in 45 mins. at 100°; in 150 mins. at 80°; and in 480 mins. at 60°. H. Stintzing, S. Roy and N. R. Dhar, J. R. I. Hepburn, A. Lottermoser and F. Langenscheidt and A. Boutaric and Y. Manière observed no tendency to **coagulation by exposure to light**; but P. Lal and P. B. Ganguly noted the coagulation of the hydrosol in ultra-violet light, and A. Boutaric and J. Bouchard found that if fluorescent substances—eosin, rhodamine, fluorescein or erythrosin—are present in the soln. the flocculation is faster in daylight, and faster still in ultra-violet light. V. Henri and A. Meyer, and W. P. Jorissen and H. W. Woudstra observed no tendency to **coagulation by exposure to the β-rays** of radium, although A. Boutaric and M. Roy, and A. Fernau and W. Pauli said that coagulation does occur with a prolonged exposure to the β-rays. H. Picton and E. Linder, and W. Biltz observed that **coagulation by an electric current** occurs as a flocculation about the cathode—*vide supra*, electrophoresis. H. Puiggari observed that the rate of coagulation is proportional to the current-strength and time; with a current-strength of 0·003 ampère, no coagulation occurs. A rise of temp. favours coagulation. B. N. Ghosh found that the coagulation of the hydrosol, by potassium chloride, sulphate, oxalate, or ferricyanide, by sodium hydroxide, or by aniline sulphate, begins when the electrokinetic potential falls below 32 millivolts.

Adsorption phenomena.—According to H. Udluft, dolomite adsorbs the hydrosol of ferric oxide but not that of manganese dioxide; clay adsorbs both. The two hydrosols exert a protective action on one another, but humus precipitates from the hydrosol hydrated ferric oxide but not hydrated manganese dioxide. Hydrocarbonates precipitate hydrated ferric oxide when unprotected, but not hydrated manganese dioxide and humus soln. M. Geloso also examined the adsorption of the hydrosol by manganese dioxide. N. Carli observed that china clay adsorbs the hydrosol very slightly, if at all. P. Rohland pointed out that the adsorptive powers of clays depends on the colloidal matter present in the clay; and some clays contain virtually none. H. Freundlich and A. Poser, and H. Udluft also observed that china clay adsorbs the hydrosol. A. Fodor and A. Rosenberg found that china clay adsorbs colloidal ferric hydroxide from soln. of ferric chloride, partially hydrolyzed, but colloidal alumina is not adsorbed, so that a separation of the two can be effected. The acid formed by the hydrolysis is not adsorbed by the clay, so that the hydrolysis reaches a state of equilibrium. Talc also adsorbs the colloidal hydroxide and also neutralizes the acid, so that talc causes a complete hydrolysis of the soln. of ferric chloride. Finely-ground sea-sand was also found to adsorb the hydrosol. H. Freundlich and A. Poser observed no adsorption by alumina. E. Wedekind and H. Rheinboldt observed that the hydrosol is decolorized when it is shaken with hydrated zirconium oxide. N. Carli found that the adsorption of the hydrosol by animal charcoal does not follow the usual adsorption law, for the amount of adsorption is independent of the vol. of the hydrosol and the amount of colloid present, but is directly proportional to the weight of the charcoal. On the other hand, A. W. Thomas and T. R. le Compte said that purified charcoal adsorbs no hydrosol. The action of technical charcoal is not due to adsorption, but to a flocculation in consequence of the presence of electrolytes. A. Fodor, and H. Freundlich and A. Poser also observed the flocculation of the hydrosol by charcoal.

According to Y. Matsuno, the hydrosol of ferric oxide readily adsorbs acid-dyes; H. Haber studied the adsorption of potassium ferricyanide, and potassium cuprous cyanide; H. Freundlich and W. Rawitzer, tyrosine; and L. Michaelis and P. Rona, albumen—grape sugar is not adsorbed. A. Boutaric and F. Banès observed that the mycelial liquid adsorbs dyes more readily than does the coagulum. E. Baur and O. Nagel said that the hydrosol can be employed to adsorb the noble metals from sea-water. The adsorption of electrolytes has been previously discussed in explaining some of the phenomena connected with the flocculation of the hydrosol. The subject was discussed by N. Schiloff and A. Iwanitzkaja, and S. Ghosh and N. R. Dhar. A. Lottermoser and P. Maffia, and Wo. Ostwald found that the adsorption of chlorine ions by the mycelia proceeds in accord with the normal isotherm. S. Ghosh and N. R. Dhar found that the H$^{\cdot}$-ions are strongly adsorbed.

H. B. Weiser, and H. B. Weiser and E. B. Middleton noted that the adsorption of the anions proceeds in the following order: phosphates>citrates>tartrates>oxalates>sulphates>iodates>dichromates; and H. B. Weiser and E. E. Porter found that with increasing p_H-values, the oxalates are less and less adsorbed.

The **solubility of gases** in the hydrosol of hydrated ferric oxide.—According to A. Findlay and B. Shen, the solubility of *hydrogen* in the hydrosol of hydrated ferric oxide is not appreciably different from its solubility in water; and G. Geffcken made a similar remark with respect to *oxygen*, for the solubility of that gas in the hydrosol at 25° is 0·03084, and in water, 0·03080. The solubility of *nitrous oxide* in the hydrosol at 25° is less than it is in water, for the respective solubilities in the hydrosol and in water are 0·5793 and 0·5942. A. Findlay and H. J. M. Creighton observed for the solubility, S, at different press., p mm., of soln. with C grm. of $Fe(OH)_3$ per 100 c.c. of sol:

C = 0·625	p .	758	846	934	1010	1121	1383 mm.
	S .	0·590	0·586	0·584	0·588	0·588	0·588
C = 1·49	p .	734	828	935	1078	1215	1432 mm.
	S .	0·586	0·579	0·577	0·581	0·585	0·586
C = 4·061	p .	754	835	883	1093	1208	1358 mm.
	S .	0·578	0·573	0·571	0·574	0·579	0·580

Observations were also made by A. Findlay and O. R. Howell. A. Gatterer found for the solubility of *acetylene* in the hydrosol, expressed in terms of the vol. of gas absorbed by unit vol. of liquid at the given temp. and press.:

		30°	25°	20°	15°	10°
S	0·871N- . .	0·9400	1·018	1·111	1·227	1·364
	0·521N- . .	0·9360	1·016	1·111	1·224	1·364
	0·336N- . .	0·9495	1·029	1·126	1·241	1·383
	0·12N- . .	0·9450	1·026	1·126	1·236	1·379

The solubility of *carbon dioxide* in the hydrosol is greater than it is in water alone; and it does not follow Henry's law. G. Geffcken stated that with carbon dioxide there is a comparatively rapid initial adsorption followed by a slow continuation of the adsorption. A. Findlay and H. J. M. Creighton found that the slow adsorption is barely appreciable even at high press., and, in general, for press. below atmospheric, the increase in solubility is proportional to the conc., C grm. $Fe(OH)_3$ per 100 c.c. of the hydrosol.

C = 0·569	p .	750	846	928	1015	1146	1356 mm.
	S .	0·848	0·843	0·841	0·842	0·845	0·846
C = 0·854	p .	750	847	923	1090	1234	1322 mm.
	S .	0·862	0·858	0·856	0·857	0·860	0·861
C = 1·277	p .	746	841	985	1071	1133	1256 mm.
	S .	0·886	0·881	0·880	0·878	0·878	0·887
C = 1·661	p .	747	831	918	1002	1150	1267
	S .	0·904	0·901	0·896	0·900	0·900	0·902

A. Gatterer found the effect of temp. on the solubility, expressed as the vol. of gas absorbed by unit vol. of solvent, at the given temp. and press., to be:

		30°	20°	15°	10°	5°
S	0·071N- . .	0·8533	0·9610	1·095	1·267	1·471
	0·144N- . .	0·8764	0·9870	1·123	1·297	1·503
	0·293N- . .	0·9063	1·016	1·154	1·326	1·534
	0·513N- . .	0·9526	1·066	1·204	1·379	1·584
	0·967N- . .	1·032	1·149	1·291	1·470	1·680

Observations were also made by A. Findlay and co-workers—W. H. Harby, O. R. Howell, G. King, and T. Williams. The deviations of the solubility of carbon dioxide in the hydrosol were attributed by R. Luther and B. Krsnjavi to the formation of complexes.

H. B. Weiser and G. L. Mack[2] obtained **organosols** with methyl and propyl alcohols. J. Duclaux,[3] and R. J. Kepfer and J. H. Walton studied the catalytic action of the colloid on hydrogen dioxide; and R. Stumper, the effect of the colloid on the rate of evaporation of water.

§ 32. The Hydrated Ferric Oxides—Hydrogels

A highly gelatinous precipitate of **hydrated ferric oxide,** the so-called **ferric hydroxide,** is thrown down when an alkali is added to a soln. of a ferric salt which is not too dil. According to W. Hampe,[1] the precipitates obtained from soln. of ferric chloride at different temp. have the following compositions:

	0°	20°	25°	30°	40°	60°	80°	100°
Fe_2O_3 . . .	54·6	51·4	50·4	46·1	43·9–52·2	66·2	70·1	72·3–92·7
H_2O . . .	45·4	48·6	49·6	53·9	56·1–47·8	33·8	29·9	27·7– 7·3

There is here no evidence of the formation of definite hydrates. After the precipitation of the hydrated oxide by adding aq. ammonia to a cold or hot soln. of a ferric salt, it is washed by decantation with water, and kept in a desiccator over sulphuric acid or potassium hydroxide, and pressed between porous tubes or washed with alcohol and ether. This is the ordinary mode of preparation, and it was used by G. Almkvist, J. M. van Bemmelen, E. Brescius, K. Endell and R. Rieke, O. Hahn and M. Biltz, W. G. Mixter, J. H. Perry, T. W. Richards and G. P. Baxter, O. Ruff, E. Selch, S. Veil, E. Wedekind and W. Albrecht, H. Wolfram, etc.—*vide infra.* L. T. Wright, and A. Simon and T. Schmidt emphasized the tenacity with which the chlorides are retained by the precipitated colloid. G. F. Hüttig and H. Garside washed the precipitate until the wash-water gave no turbidity with silver nitrate, and yet retained 0·12 per cent. of chlorine. J. Jeannel, and C. F. Cross also emphasized the adsorption, or rather the tenacity, with which the hydrogel retains saline and other impurities. R. Willstätter and co-workers prepared the colloid as follows:

A soln. of 100 grms. of ammonium ferric sulphate in 200 c.c. of water at ordinary temp. is powdered into a soln. of 10·8 grms. of ammonia, 27·5 grms. of ammonium sulphate, and 800 c.c. of water, with vigorous stirring. After being stirred for half an hour, the clear liquid is decanted, and the product is washed many times by decantation with ammoniacal water. The gel is mixed with dry acetone, and centrifuged. The last traces of acetone are removed by decantation with ether, and the hydrogel is then exposed to a high vacuum.

L. Schaffner said that if the precipitation is made with aq. ammonia, the precipitate is free from contamination by the precipitant. If alkali-lye be used in place of aq. ammonia, R. Fricke, W. Ramsay, and H. Wolfram found that the precipitate is difficult to wash. The alkali hydroxide may even decompose the nitroprussides (L. Playfair, J. M. van Bemmelen and E. A. Klobbie, O. Pavel, and G. Städeler), and the nitrosyl salts of Z. Roussin as shown by Z. Roussin, J. M. van Bemmelen and E. A. Klobbie, and J. O. Rosenberg. J. J. Berzelius noted that entrained alkali is retained very tenaciously; and according to J. Huggett and G. Chaudron, a small proportion of sodium ferrite may be formed, otherwise the precipitate is considered to be insoluble in an excess of lye. J. Hausmann noted the layer formation of the colloid when a soln. of potassium hydroxide diffuses into gelatine containing some ferric chloride. W. Ramsay found that baryta-water, V. Vincent, lime-water, H. Rose, and A. Mailhe, mercuric oxide, and D. Vitali, silver oxide, precipitate the hydrated oxide from soln. of ferric salts.

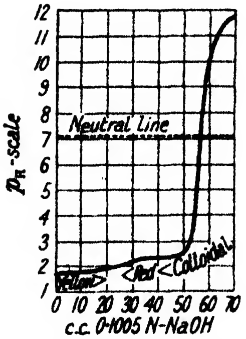

Fig. 534.—Electrometric Titration of an Acidic Solution of Ferric Chloride.

L. J. Curtman and A. D. St. Johns found that the precipitation occurs in the presence of 0·062 mgrm. of iron in soln. H. E. Patten and G. H. Mains said that colloidal hydrated ferric oxide is precipitated from soln. containing 0·03 per cent. Fe, by ammonia or sodium hydroxide, when the H'-ion conc. is $p_H=3{\cdot}3$. H. T. S. Britton found that with 100 c.c. of a soln. containing $0{\cdot}0202N$-HCl and $0{\cdot}0133M$-$FeCl_3$, the electrometric titration with $0{\cdot}1005N$-NaOH furnished the results indicated in Fig. 534. Freshly prepared soln. of ferric chloride, or soln. containing an excess of free acid are only slightly coloured, but the soln. on standing begins to redden, and finally the colour approaches that of hydrated ferric oxide. It was found that the end of the neutralization of the free acid is indicated by an inflexion, at 20·1 c.c. of sodium hydroxide. As the soln. was rendered more basic, the colour gradually changed from yellow to red. It became quite red after addition of 30 c.c. of sodium hydroxide, when the composition of the solute had become $Fe(OH)_{0{\cdot}74}Cl_{2{\cdot}26}$, and with 39 c.c. it began to opalesce. Afterwards the soln. became increasingly colloidal and became opaque at p_H3, which, as will be seen from the curve, occurred just when the sudden change in hydrion concentration had begun. Coagulation set in when the p_H had become 6·6 and 58 c.c. of alkali had been added, the composition of the basic chloride then being $Fe(OH)_{2·85}Cl_{0·15}$. The colloidal soln. persisted until nearly all the chloride had reacted; attempts were made to prevent coagulation during the abrupt fall in H˙-ion concentration. Aq. soln. of ferric chloride more dil. than 0·04*N*-, on boiling, acquired a deep red colour, and often remained colloidal on treatment with 0·10*N*-alkali in slight excess. Small, red, amorphous precipitates separated in some cases, but even then the precipitation was incomplete and the solids did not settle until several hours had elapsed. The presence of a little hydrochloric acid in the soln. before heating had some stabilizing effect on the colloidal soln. which were subsequently produced. In one case the colloidal soln. remained stable for nearly 3 months. This soln. was prepared by adding 55 c.c. of 0·10*N*-sodium hydroxide to 500 c.c. of a boiling soln. containing 100 c.c. of 0·04*N*-ferric chloride and 10 c.c. of 0·10*N*-hydrochloric acid. It seems certain that the red colour of boiled ferric chloride soln. was due to dispersed ferric hydroxide particles, and consequently the increase in the size of the basic chloride particles caused by rendering the soln. alkaline was not so great as that occurring in an unboiled soln., and therefore did not produce coagulation. The increased stability of the colloidal soln. prepared from acidified ferric chloride soln. was probably due to the effect of the acid in suppressing the growth of the colloidal particles on boiling, thereby giving rise to a more highly dispersed and more stable colloidal soln. Prolonged boiling decomposed these alkaline colloidal soln., and they were readily coagulated on addition of electrolytes in sufficient amounts. In accord with the generally accepted theory of the structure of gels (**6**. 40, 21), H. B. Weiser said that when alkali-lye or aq. ammonia is added to the soln. of a ferric salt, there is a relatively large supersaturation before precipitation occurs, and this favours the formation of minute particles; the orientation of these particles into a network of mycelia entraining the mother-liquor, produces the hydrogel. The bulky mass, on standing, gradually loses water and becomes more compact and granular.

Colloidal ferric hydroxide, or hydrated ferric oxide, is a product of numerous reactions. It is formed when iron rusts in the presence of water and oxygen—*vide supra*—as noted by M. Hall, N. J. B. G. Guibourt, D. Tommasi, A. Payen, A. Ackermann, W. R. Dunstan and co-workers, P. Fireman, and L. P. de St. Gilles; by the action of an acidified soln. of hydrogen dioxide on iron, as observed by G. C. Weltzien, and G. T. Moody; by the action of soln. of ammonium salts and air on iron, as found by W. Vaubel, and A. Frickhinger: and by the anodic oxidation of iron in soln. of potassium nitrate, potassium hydroxide, ammonium sulphate, etc., as observed by R. Lorenz, O. Faust, and G. A. le Roy. Colloidal ferric hydroxide is formed during the oxidation of ferrous hydroxide by air or oxidizing agents (E. Deiss and G. Schikorr, A. Krause, and F. Haber), or anodically (H. Becquerel, O. Faust, and V. Paissakowitsch).

The oxidation of chalybeate waters, or water containing ferrous hydrocarbonate in soln., furnishes hydrated ferric oxide as observed by G. Bischof, F. Behrend, and H. Molisch. As shown by H. Klut, O. Kröhnke, and A. Schmidt and K. Bunte, chalybeate waters also deposit iron in the form of hydrated ferric oxide, and, as indicated by D. Ellis, D. D. Jackson, E. M. Mumford, etc.—*vide infra*—the action is favoured by the so-called iron-bacteria. S. de Luca, and A. Krause studied the oxidation of ferrous carbonate by air in the presence of water. The hydrated ferric oxide is formed when many ferrous salt soln. are oxidized by hydrogen dioxide (G. C. Weltzien), sodium dioxide (G. Kassner, and T. Poleck), barium dioxide (W. Kwasnik), potassium hypochlorite (F. Muck), potassium chlorate (R. Phillips, and R. H. Parker), or auric chloride (E. Beutel). F. Behrend, and H. Molisch observed that soln. of ferrous sulphate, acidified with citric acid, give a precipitate of hydrated ferric oxide when exposed to light; O. Baudisch and L. W. Bass, H. W. Fischer, J. Matuschek, and C. F. Schönbein obtained a similar result by exposing a soln. of potassium ferrous cyanide to light; and W. A. Macfadyen observed that the hydrated oxide is formed during the electrolysis of a soln. of ammonium ferrous sulphate.

The hydrogel of ferric oxide is formed during the hydrolysis of some ferric salt soln.—*e.g.* G. Keppeler and J. d'Ans observed that it is deposited during the hydrolysis of basic ferric sulphate—and in the decomposition of aq. soln. of ferrites, perferrites, and ferrates (*q.v.*). O. Hauser observed that the hydrated oxide is deposited during the evaporation of a soln. of ammonium ferric carbonate; G. Kassner, and G. Grube, during the hydrolysis of a soln. of potassium ferricyanide, and, according to C. F. Schönbein, and J. Matuschek, the reaction is favoured by exposure to light; J. H. Paterson, by the electrolysis of soln. of ferric salts with platinum electrodes, a low conc., and a small current density. L. Mond and co-workers, and M. Berthelot found that the hydrolysis of iron pentacarbonyl furnishes the hydrated oxide. S. Kern found that an aq. soln. of ferric chloride in contact with magnesium yields hydrated ferric oxide; H. W. Fischer obtained a similar result with zinc; and G. McP. Smith, by the action of mercury in the presence of alkali hydroxide. If an alkaline soln. of potassium ferricyanide be heated with an excess of ferrous sulphate, H. Bollenbach and E. Luchmann found that hydrated ferric oxide is precipitated.

The **hydrogel** may be also produced by the coagulation of the hydrosol under suitable conditions. The formation of the hydrogel from the hydrosol was observed by L. P. de St. Gilles, N. R. Dhar and D. N. Chakravarti, R. Griessbach and J. Eisele, S. Veil, J. Böhm and H. Niclassen, A. Simon and T. Schmidt, E. Wedekind and W. Albrecht, K. Charitschkoff, etc.—*vide supra.* Slow, uniform precipitation of the hydrosols throughout their entire mass produces the so-called **ferric oxide jellies,** whilst rapid, uneven precipitation results in contraction and the formation of a gelatinous precipitate. E. Grimaux's sol, obtained by the addition of water to an alcoholic soln. of ferric ethylate—*vide supra*—forms a jelly more readily than Graham's sol because, being produced by rapid hydrolysis in the cold, it contains finer, and more hydrated particles; and for a similar reason, Graham's sol is more readily coagulated to a jelly than is the case with St. Gilles' sol. R. Bradfield used the centrifuge for isolating the hydrogel. E. Schalek and A. Szegvary, and H. Freundlich and A. Rosenthal obtained the coagulum from Graham's sol as a jelly by adding electrolytes in amounts below the precipitation values to colloidal soln. containing 6 to 10 per cent. of ferric oxide, and allowed the sols to stand quietly. The mixture set to a clear jelly. The jelly formed a sol on shaking up and this solidified slowly to a hydrogel. The logarithm of the time required for solidification after the shaking of the jelly, was found to be inversely proportional to the temp. and to the conc. of the coagulating electrolyte—*vide supra,* thixotropy. No change in the average distance of the particles and no formation of secondary particles could be detected by the ultramicroscope during the liquefaction. The subject was studied by H. Freundlich and W. Rawitzer, and H. Freundlich and K. Söllner. H. B. Weiser attributed the reversible sol-gel transformation to a breaking up and subsequent re-alignment of the orienting forces amongst the particles.

E. Grimaux's sol coagulates spontaneously to form a transparent jelly when it is allowed to stand without agitation, at room temp., or more rapidly when heated; or when it is treated with electrolytes—carbonic, sulphuric, or tartaric acid; nitrate, chloride, or bromide of potassium; the chloride of sodium, barium, etc. E. Grimaux also prepared a jelly by the dialysis of a negative sol prepared by the peptization of hydrated ferric oxide with alkali-lye and glycerol; if ammonia is used in place of alkali-lye, and the sol be exposed to air, the slow loss of the peptizing agent, ammonia, by evaporation, forms a jelly. H. W. Fischer also produced a firm jelly by the prolonged dialysis of a hydrosol containing 1 per cent. of iron. This preparation formed a gelatinous mass when it was warmed, stirred, or frozen. H. B. Weiser also mentioned the formation of a jelly by the slow evaporation of a conc. Graham's sol of a high degree of purity. S. Prakash and N. R. Dhar studied the formation of the gel. D. H. Ghosh obtained ferric hydroxide as a rhythmic precipitate.

A. W. Bull and J. R. Adams' observations on the adsorption of alkali by hydrated ferric oxide are indicated in connection with sodium ferrite. W. N. Simakoff studied the reciprocal action of sols of ferric hydroxide, aluminium hydroxide, manganese dioxide, and silicic acid. The sparing solubility or insolubility of many hydrated oxides is, according to J. Jeannel, connected with the presence of traces of sulphate, but J. Attfield did not agree with this. According to F. Muck, the hydrated oxide forms a voluminous, gelatinous precipitate which shrinks considerably on drying to form a yellowish-brown, brittle mass. This product loses water when gently heated, and, as the temp. is raised, it becomes calorescent—*vide supra*—without further loss in weight, to form a black, lustrous mass, hard enough to scratch glass. On the other hand, the hydrated ferric oxide, prepared by the oxidation of hydrated ferrous oxide, is pulverulent—particularly if prepared from hot soln.; it does not shrink much on drying, and then forms a friable mass. This product does not exhibit calorescence when heated, and it forms a reddish-brown, friable mass without lustre. This recalls the previous discussion on the St. Gilles' sol, and Graham's sol, and the supposed **allotropic forms** of the hydrated oxide. According to L. T. Wright, recently precipitated, gelatinous ferric hydroxide, when suspended in water and saturated with hydrogen sulphide, is completely soluble in a soln. of potassium cyanide forming potassium ferrocyanide and sulphide: $FeS+6KCy=K_2S+K_4FeCy_6$; but if the ferric hydroxide be kept some time, a certain proportion is converted into an inactive form, not affected by hydrogen sulphide.

According to D. Tommasi, there are two series of hydrated oxides, yellow, and red or brown, which are isomeric or allotropic forms of one another. The members of the red series are produced by precipitating a soln. of a ferric salt with an alkali; the product is voluminous, soluble in dil. acids, and, according to A. E. Davies, is dehydrated by boiling water. The members of the yellow series are obtained by the oxidation of hydrated ferrous oxide or carbonate—say, by potassium chlorate, potassium hypochlorite, or if iron be slowly oxidized under water. R. Phillips found that if the chlorate be added to the ferrous sulphate and sodium carbonate in small portions at a time, black ferrosic oxide is formed, and is not oxidized to red ferric oxide by subsequent addition of the chlorate. The yellow hydrates are denser than the red, they are sparingly soluble in conc. acids, require a higher temp. for dehydration, and retain a mol. of water even when boiled for a long time under water. D. Tommasi thus summarizes the properties of the two series of hydrated ferric oxides:

RED OR α-SERIES.	YELLOW OR β-SERIES.
1. Obtained by precipitating a ferric salt with alkali-lye.	1. Obtained by oxidizing hydrated ferrous or ferrosic oxide, or ferrous carbonate.
2. The dihydrate begins to dehydrate at 50°.	2. The dihydrate begins to dehydrate at 105°.
3. The monohydrate is dehydrated at 92°.	3. The monohydrate is dehydrated at 150°.
4. The anhydride is brown.	4. The anhydride is red or yellowish-red.
5. The sp. gr. of the anhydride is 5·11.	5. The sp. gr. of the anhydride is 3·95.
6. The hydrates are soluble in dil. acids, and in soln. of ferric chloride.	6. The hydrates are sparingly soluble in conc. acids, and in soln. of ferric chloride.
7. The hydrates are dehydrated in boiling water.	7. The hydrates are dehydrated in boiling water.

A. Krause said that the yellow oxide, which he called *meta-ferric oxide* or *β-ferric oxide*, is the more stable form, because the brown oxide, which he called *ortho-ferric oxide* or *α-ferric oxide*, passes into it when kept under water. Contrasting the two oxides, he said that when dried in air, the ortho-oxide breaks up, forming black pieces which furnish a brown powder, which contains some carbon dioxide, and when dried, 70·0 per cent. of Fe_2O_3. The meta-oxide when dried forms a vitreous mass which does not break up, and furnishes a yellow powder with a reddish tinge.

It contains no carbon dioxide, and the dried mass has 82·5 per cent. Fe_2O_3. Both forms are soluble in conc. hydrochloric acid. The ortho-oxide dissolves almost completely in conc. acetic acid forming a brick-red soln. which yields crystals of the acetate; the meta-oxide is almost insoluble in conc. acetic acid, and the soln. does not form crystals of the acetate. The ortho-oxide is peptized by dil. acetic acid, and the hydrosol is yellow, orange, or dark red, according to the proportion of contained ferric oxide; the meta-oxide forms an orange hydrosol, and when very dil., it is greenish-yellow. The ortho-oxide is not peptized by 10 per cent. aq. ammonia, while the meta-oxide is peptized to a greenish-yellow hydrosol. Boiling 76·4 per cent. soda-lye does not dissolve the ortho-oxide completely, but the meta-oxide readily forms a colourless soln. Ammonium sulphate coagulates the hydrosol of the meta-oxide more readily than the ortho-oxide. J. M. van Bemmelen showed that the ratio of oxide to water in the reddish-brown series depends entirely on the method of treatment, and that all the definite hydrates which have been reported are *nur zufällig* being dependent on the accidental conditions used in drying. D. Tommasi represented the reddish-brown hydrate by the formula:

$$\begin{array}{l}\mathrm{Fe{-}O}\diagdown\\ \;\ddot{}\qquad\quad\mathrm{O}\\ \mathrm{Fe{-}O}\diagup\end{array}$$

and the yellow hydrate O=Fe–O–Fe=O each with one, two, or three mols. of H_2O; but, added J. M. van Bemmelen, *alles dies ist nichts als reine phantasie*. The differences between the yellow and red hydrated oxides are determined solely by differences in physical structure. H. B. Weiser added that the later work of E. Posnjak and H. E. Merwin—*vide infra*—has shown that the greater tenacity of the water in the yellow hydrates may be due to the formation of a definite hydrate. P. Nicolardot considered that he had established the existence of six modifications of hydrated ferric oxide. He said that the majority of the crystalline ferric salts are white, and he therefore concluded that the normal hydrated oxide should also be white. He found that the white hydrated oxide is formed when a freshly prepared, conc. soln. of a ferric salt is added to a cooled soln. of ammonia, but it rapidly becomes coloured. He said that the six different forms of the hydrated oxide differ in their physical and chemical properties, and in their water-content. *Toutes sont des polymères de l'hydrate ferrique*, but their degrees of polymerization are different. G. N. Wyrouboff and A. Verneuil suggested that the ferric oxide obtained at the higher temp., and which is very little affected by acids, and forms a red hydrate on salt dialysis, is a hydrate of a polymerized oxide, $(Fe_2O_3)_{44}$, which he calls *para-oxide*. The product obtained by L. P. de St. Gilles was $(Fe_2O_3)_{44}.4HCl$. The product obtained by the dialysis of cold soln. of ferric hydroxide in a neutral ferric salt contains two polymers both of which can unite with acids to form clear, reddish-brown soln. The one oxide, $(Fe_2O_3)_{44}$, called *meta-oxide*, is polymerized during dialysis to form a hydrate or salt of $(Fe_2O_3)_{56}$. T. Graham's product was represented as $(Fe_2O_3)_{56}.4HCl$. This subject has been previously discussed; J. M. van Bemmelen would also have called all this pure phantasy; while H. W. Fischer said that the hypothesis is *experimentell unzureichend gestütz und verfehlt*.

The ferric ferrite obtained by the interaction of hydrated ortho- and meta-ferric oxide was found by A. Krause to be readily peptized by dil. acids after it had been ignited. The resulting sol contains positively charged particles, and its hydrophobic nature is evident from the readiness with which it deposits a ferric oxide mirror on the walls of the containing vessel. Ortho-ferric hydroxide is partly converted into ferric ferrite by ageing under water, or soda-lye yields the same sol after it has been ignited. Neither ortho- nor meta-ferric hydroxide is peptized by acids after ignition, but the meta-oxide, unlike the ortho-oxide and ferric ferrite, is peptized by dil. aq. ammonia after it has been ignited. The hydrosol of meta-ferric acetate has only a slight tendency to produce a mirror, and ortho-ferric acetate has none, and it even exerts a stabilizing influence on the meta-ferric oxide, and ferric ferrite sols. Hence, A. Krause concluded that there are three series of ferric oxides and hydroxides.

Attempts have been made to find how the water is associated with the hydrated ferric oxides, and to establish the chemical individuality of particular hydrates. So long as the earlier workers relied upon analysis alone, there was no limit to the number of possible hydrates, for, as J. M. van Bemmelen has pointed out, the results depended more or less on the actual choice of the method of drying. In only one case does the hydrate exist in a crystalline form, viz., $Fe_2O_3.H_2O$; in all other cases, the products are amorphous, and have the character of hydrogels. The hydrates are usually hygroscopic substances so that the proportions of water they contain at any moment fluctuates with the temp. and humidity of the atmosphere. Nature also furnishes a series of eight minerals which have the character of hydrated ferric oxide, and of these only two occur in the crystalline state—*vide supra*, the hydrosols. Precipitated ferric, and several other hydroxides may be regarded as soln. of water in ferric oxide, etc., or in one of their lower hydroxides. J. M. van Bemmelen called them adsorption compounds, and considered that the moist precipitates contain (i) water mechanically mixed with the precipitate, and (ii) absorbed water. The amount of absorbed water is dependent on the *structure* of the gelatinous mass which in turn is dependent on (i) the method of formation, (2) the time, (3) temp., and (4) the presence of foreign substances. If the adsorbed water be dissolved in the oxide or lower hydroxide, when the water is gradually withdrawn from the system, the vap. press. of the mixture will remain constant so long as free water is present mechanically mixed with the precipitate, and commence to decrease when the free water has disappeared. The composition of the residue at this stage will represent the composition of the sat. soln. of water in the oxide under consideration. Hence, at a constant temp., hydrated ferric oxide, prepared in different ways, should show the same composition at the point where the vap. press. begins to change, provided the system is in equilibrium. H. W. Foote found this to be the case with ferric, aluminium, and zirconium hydroxides. The composition changes with temp., as would be expected if these hydroxides are but soln. of water in the fundamental oxide or in some lower hydrate. At 25°, with hydrated ferric oxide the critical point occurs when the hydrate contains 47·75 per cent. of ferric oxide; with hydrated aluminium oxide, 50·35 per cent. of alumina; and with hydrated zirconium oxide, 32·12 per cent. of zirconia. The difficulties in accepting this hypothesis depend on the facts: (1) If the dissolved water be removed by evaporation, it can never be completely restored; (2) when a moist hydrate is allowed to dry spontaneously there is no sign of an abrupt change in the rate of evaporation.

W. Ramsay, and G. Tschermak tried to find if the existence of definite hydrates could be established by measuring the rate of the drying of the hydrogel at a given temp. J. M. van Bemmelen's hydration and dehydration curves are illustrated in Fig. 535. In drying, the loss of water is continuous with the decrease in the vap. press. of the water. The general result resembles that obtained with silicic acid. At *O*, the drying gel becomes white and opalescent; the re-hydration of the gel does not follow the same track. R. Zsigmondy and coworkers, W. Bachmann, and J. S. Andersen also measured the vap. press. of the hydrated oxide during drying. T. Carnelley and J. Walker, and A. L. Baikoff studied the dehydration of the hydrogel at different temp. At 55°, the composition of the hydrated oxide approximates $Fe_2O_3.3H_2O$; and as the temp. rises, more water is evolved until, at 385°, the product has the composition $10Fe_2O_3.H_2O$, and the weight remains constant

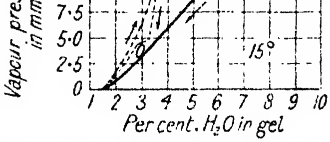

FIG. 535.—Hydration and Dehydration of the Hydrogel of Ferric Oxide.

during several hours' heating between 385° and 415°. At 500°, the dehydration is complete. Observations on the subject have been made by C. F. Cross, A. E. Davies, L. P. de St. Gilles, A. Krieger, L. G. Leroy, F. Limberger, F. Muck, W. Ramsay, G. Rousseau and co-workers, Z. Roussin, L. Schaffner, H. Schiff, W. Spring, D. Tommasi and G. Pellizzari, G. C. Wittstein, D. Balarew and S. Krastew, L. T. Wright, P. A. Thiessen and R. Köppen, and G. F. Hüttig and A. Zörner—*vide infra*. According to the vap. press. curves of J. M. van Bemmelen and co-workers, E. Brescius, T. Carnelley and J. Walker, H. W. Foote and co-workers, W. B. Hardy, W. Ramsay, E. Y. Rode, A. Simon and T. Schmidt, and G. Tschermak, ferric oxide hydrogel does not form a chemical compound. R. Willstätter and co-workers do not consider the results decisive, and the conclusion is not proven. A. V. Rakovsky studied the subject. R. E. Wilson and T. Fuwa investigated the absorbent power of the gel for moisture in air. For the action of heat on the dehydrated gel, *vide supra*, ferric oxide.

E. Wedekind and W. Albrecht found that the magnetic susceptibility of ferric oxide is 4 or 5 times less than that of the hydrated oxide, and they consequently inferred that a compound is formed. R. Willstätter and co-workers treated the gel successively with dry acetone and ether, followed by the preservation of the sample in a high vacuum for some time. This is said to remove all the adherent water. The product treated at 10° to 20° has rather less water than is needed for $Fe(OH)_3$, and the amount decreases slowly when it is kept for a protracted period in contact with water. A preparation dried with acetone at −15° had the approximate composition $Fe(OH)_3.H_2O$. A. Simon and R. Zsigmondy doubted if these products are chemical individuals.

In H. W. Foote and B. Saxton's study of the changes in vol. which occur on freezing the hydrogel, owing to the water expanding when it forms ice, if this amount of water be subtracted from the total loss on ignition, the difference is taken to represent the water chemically combined which cannot be frozen. This corresponded with $Fe_2O_3.4{\cdot}25H_2O$. The water which freezes gradually with a fall of temp. is held in the capillaries—*capillary water*. It was assumed that the loosely attached water freezes at about −5°; and that the capillary water freezes at −30°. The debatable assumption made is that the failure of water to freeze at a given temp. determines whether the water is dissolved or adsorbed. No evidence of the formation of simple ratios between ferric oxide and water was observed during the dehydration of the hydrogels, so that the term chemically combined water was understood to refer to water held in solid soln., in definite proportions, and not adsorbed water. K. Hakozaki discussed the swelling of the hydrogel; P. Barry, and R. E. Liesegang, the structure of the slowly dried gel; and A. and E. Lottermoser, the ageing of the gel.

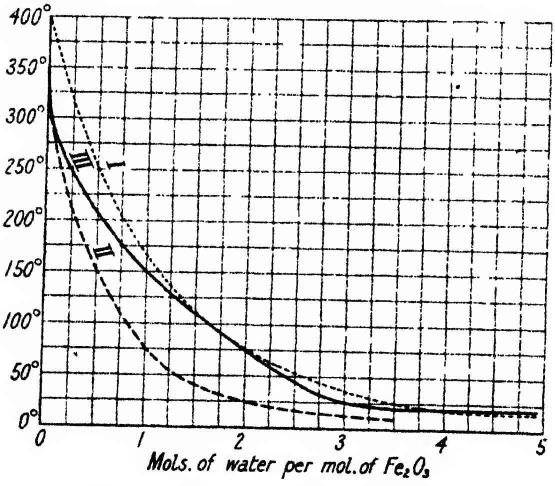

FIG. 536.—Dehydration Curves of the Hydrogel of Ferric Oxide.

A. Simon and T. Schmidt prepared hydrated ferric oxide: I, by precipitation from a soln. of ferric nitrate at 40° by ammonia; II, by precipitation from a cold soln of ferric chloride by ammonia; and III, by the dialysis of a soln. of ferric nitrate until the hydrogel precipitated and the residue was free from nitrate. Sample I was relatively coarse; II, relatively fine; III, was of intermediate fineness. The dehydration curves, Fig. 536, are all continuous, and show no indications whatever of hydrates containing 1, 2, 3, or more mols. of water. X-radiograms showed that I was amorphous when dried in air, but showed amicroscopic crystals of ferric oxide if heated high enough to drive off all the water; while the air-dried oxide III, obtained by slow hydrolysis, showed a weak interference pattern different from that of J. Böhm for anhydrous ferric oxide. This is taken to mean that certain gelatinous substances may contain water in solid soln. between the oriented mols. of the space-lattice, just as E. Posnjak and H. E. Merwin found that water mols. may assume a fixed position in the ferric oxide lattice to form the monohydrate $Fe_2O_3.H_2O$.

J. Böhm showed that the hydrogel, freshly precipitated in the cold, shows no crystalline structure when examined by the X-radiogram process; nor does the hydrogel precipitated from the boiling soln. give any evidence of the formation of a definite hydroxide, but a basic ferric chloride is associated with the precipitate. The main conclusion here indicated agrees with the work of G. F. Hüttig and H. Garside, A. Simon and T. Schmidt, and F. Haber. The subject was also discussed by E. Heymann, E. Wedekind and W. Albrecht, and D. Balarew and S. Krastew. P. A. Thiessen and R. Köppen said that the dehydration curve of the hydrated oxide obtained by exposing a soln. of ferric ethylate, in absolute alcohol, to water vapour, agrees with the assumption that there are eight hydrates $2Fe_2O_3.nH_2O$, with $n=8$, 7, 6, 5, 4, 3, 2, and 1, as well as the more doubtful cases of $n=9$ and 10. W. C. Hansen and L. T. Brownmiller found that no crystalline structure appears when the hydrogel is heated an hour at 200°, but if heated an hour at 300°, the structure of hæmatite appears; aged hydrogels, natural or artificial, were found by J. Böhm and co-workers to show the structure of hæmatite with some distortion which E. Wedekind and W. Albrecht, and A. Simon and T. Schmidt attribute to the introduction of a number of H_2O-molecules in the spaces in the lattice. J. A. Hedvall also found that the dried hydrated hydroxide has a crystalline structure.

According to M. Biltz, the hydrogel has a sponge-like structure in which there are two kinds of capillary canals—primary and secondary. The adsorption of water by the dried gel is due to the fillings of the primary canals followed by the filling of the secondary canals when the vap. press. of the water has attained a high value, so that, according to F. Haber, the gel is built up of aggregates of molecules separated from one another by layers of water. A. Simon and T. Schmidt said that the amount of water associated with the hydrogel depends on the grain-size or degree of dispersion of the molecular aggregates; a preparation with finely dispersed aggregates had $Fe_2O_3 : H_2O = 1 : 36{\cdot}29$; one with medium dispersion, $1 : 30{\cdot}36$; and with a coarser dispersion, $1 : 14{\cdot}58$. The force when the water is retained by the hydrogel is greater the greater is the degree of dispersion. The structure of the hydrogel was also discussed by G. Malfitano and M. Sigaud, and P. P. von Weimarn; W. Kraust found that the X-radiograms of the fresh precipitate showed that the product is amorphous, but on standing, it gradually becomes crystalline.

T. Katsurai observed that when the hydrogel is heated with a slight excess of alkali in an autoclave at 5 to 10 atm. press., a red powder is produced. According to O. Ruff, when red colloidal ferric oxide is heated with water under the enormous press. of 5000 atm., it becomes hydrated. Thus, between about 30° and 42·5°, it yields a yellow hydrate $2Fe_2O_3.3H_2O$, corresponding with natural brown ironstone or limonite; and between 42·5° and 62·5° it yields the yellowish-brown hydrate $Fe_2O_3.H_2O$, corresponding with the mineral goethite; and at a higher temp. it furnishes a hemihydrate $2Fe_2O_3.H_2O$, equivalent in composition to turgite. H. Wölbling said that only the hydrated hæmatites can be hydrated under ordinary conditions of temp. and press.; and added that O. Ruff's products were in all probability mixtures of anhydride and a hydrate. The mol. vols. of brown ironstone, goethite, and turgite are said to be smaller than the mol. vols. of the components, because increasing the press. favours the formation of that compound which is formed with a decrease in vol. The red hydrogel at ordinary temp. gradually passes into a stabler, less hydrated, and denser state, without producing a definite hydrate. It is, therefore, assumed that the hydrogel very slowly loses water and passes into the anhydrous oxide. The dehydration process, however, at ordinary temp. is never complete because another simultaneous reaction occurs so that the hemitrihydrate is formed, and this hydrate, the brown ironstone or limonite of the mineralogist, is the most stable of the hydrates of ferric oxide. O. Ruff represented the successive stages: Colloid→anhydride→hemihydrate→monohydrate→hemitrihydrate. He found that the yellow colloid did not change in the temp. interval 40° to 70°, like the red hydrogel, and he accordingly inferred that the yellow colloid is not really a colloid but a true hydrate, possibly of the character of xanthosiderite; but O. Ruff himself added that limonite at 70° or 75°, and turgite at 40° to 50°, did not behave as they would do if O. Ruff's hypothesis were correct, and form respectively turgite and limonite. H. W. Fischer favoured the hypothesis that many of the colloidal or amorphous ferric oxides are definite compounds. He said that there are three definite hydrates: the yellow hydrates—artificial and natural—of the limonite type; the reddish-black colloid of the hæmatite type; and the reddish-brown colloids studied by J. M. van Bemmelen. He based his opinion regarding limonite on its having a characteristic dehydration curve. This might fit the opinion that the yellow colloids contain a definite hydrate of the goethite type, and C. Hintze regarded limonite as colloidal goethite. H. W. Fischer's remarks on the other colloids are to be regarded more as opinions, since they were not based on experimental work—*cf.* ferrous oxide. J. R. I. Hepburn found that the colloid after a prolonged freezing has some properties usually regarded as characteristic of the crystalline state. G. Graue, and O. Hahn and G. Graue discussed the surface area of the gel.

W. Spring found the **specific gravity** of the hydrogel precipitated by ammonia, and dried in air, to be 2·436 at 15°; G. Berndt gave 1·264 for the impure hydrogel obtained by the slow oxidation of ferrous carbonate in air; A. E. Davies found 4·545 for the sp. gr. of an aged hydrogel, boiled for a long time with water, and containing about 5 per cent. of water; whilst B. Aarnio gave 3·6 for a specimen which had been heated to 200°, and which contained 1·5 per cent. of water. F. Muck emphasized how the freshly-precipitated, voluminous hydrogen shrinks enormously as it dries to a brittle, hard mass; and R. Willstätter and co-workers said that the **drying of the hydrogel** is attended by a marked coagulation of the molecular aggregates. The subject was discussed by E. Brescius, and W. Hampe. B. Aarnio said that the hydrogel precipitated by ammonia, and dried at room temp., retains the following proportions of water on **dehydration** at:

	100°	200°	300°	700°
Retained water . . .	10	1·5	1·0	0·0 per cent.

The subject was discussed by T. Carnelley and J. Walker, W. Ramsay, A. Simon and T. Schmidt, R. Wallach, and R. Willstätter and co-workers—*vide infra*, the special hydrated oxides. T. W. Richards and G. P. Baxter emphasized the difficulty involved in driving off the last traces of moisture from the hydrogel, due in part, said N. A. Tananaeff, to the formation of hard crusts on the surfaces of the grains. H. Freundlich noted the liquefaction of the gel by **ultrasonic waves.** For the **calorescence** when heated, *vide supra*, ferric oxide. The ageing, and possible crystallization of the hydrated oxide when subjected to **freezing,** was discussed by J. M. van Bemmelen and E. A. Klobbie, H. W. Foote and B. Saxton, and F. Limberger and G. C. Wittstein. According to J. R. I. Hepburn, practically no dehydration of hydrated ferric oxide occurs during freezing; the absence of mother-liquor during freezing does not affect the dehydration curve or the composition after desiccation. In general, the products of freezing are colloidal, but they may present some physical characteristics of the crystalline state; thus, optical activity may be detected, but it is rather the result of strains set up by pressure than the effect of a crystalline structure. J. Thomsen obtained for the **heat of formation** $(2Fe,3O,nH_2O)=191\cdot13$ Cals., and M. Berthelot, 191·2 Cals. The subject was discussed by F. Haber. J. Thomsen gave for the **heat of dissolution** of $Fe_2O_3.nH_2O$ in sulphuric acid, 33·75 Cals.; in chloric acid, 32·34 Cals.; and in hydrochloric acid, 33·45 Cals.; M. Berthelot gave for dil. hydrochloric acid, 34·2 Cals.; and in hydrofluoric acid, O. Mulert gave 47·55 Cals.; and E. Petersen, 47·72 Cals.

For F. Doerinckel's observations on the **specific heat** of the hydrogel, *vide supra*, the hydrosol. For the **electrical properties,** *vide supra*, the hydrosol. Some observations on the **magnetic properties** of the hydrogel of ferric oxide were made by J. Plücker, S. H. Emmens, S. de Luca, J. L. Smith, and G. Wiedemann; and numerous observations have been made on the mass magnetic susceptibility of the hydrogel prepared in different ways. Thus, E. Wedekind and W. Albrecht found for a sample precipitated by ammonia from ammonium ferric sulphate, and dried by acetone, $\chi=100\times10^{-6}$; it contained 23·5 per cent. H_2O. A sample similarly treated and obtained from ferric sulphate, contained 22·3 per cent. H_2O, and had $\chi=224\times10^{-6}$. When similar samples were dried below 100° to 14·4 per cent. H_2O, E. F. Herroun and E. Wilson observed that $\chi=102\times10^{-6}$ to 115×10^{-6}, and if dried to 10·1 per cent. H_2O, $\chi=127\times10^{-6}$ to 147×10^{-6}. A sample obtained by ultra-filtration of a dialyzed soln. of ferric chloride, and dried by acetone, gave $\chi=32\cdot5\times10^{-6}$, and it contained 22·3 per cent. H_2O; and a sample obtained by the action of hydrogen dioxide on iron pentacarbonyl, when dried in air, gave $\chi=46\times10^{-6}$, and it contained 31·6 per cent. H_2O; whilst a sample dried by acetone gave $\chi=65\times10^{-6}$, and it contained 22·4 per cent. H_2O. S. Berkman and H. Zocher found that a sample obtained by dialyzing a soln. of ferric chloride gave $\chi=39\times10^{-6}$. A. Quartaroli observed that a sample precipitated by ammonia from a cold soln. of ferric chloride gave $\chi=58\cdot16\times10^{-6}$; 24 hrs. after filtration, $\chi=79\cdot9\times10^{-6}$; and when dried between filter-paper, $\chi=118\cdot4\times10^{-6}$. R. Willstätter and co-workers observed that the susceptibility increased during the progressive dehydration of the hydrogel. Thus, with a precipitated and dried hydrogel:

H_2O . .	22·1	24·3	24·7	25·1	30·0	32·8	40·5	42·8 per cent.
$\chi\times10^6$.	155	117	105	103	88	86	73	71

and with a hydrogel prepared by hydrolysis with water in a sealed tube, and dried by acetone:

H_2O . .	24·7	22·4	19·0	12·8	10·1	9·2	6·9	5·9 per cent.
$\chi\times10^6$.	105	150	208	286	155	114	6·9	5·9

E. Wedekind and W. Albrecht, and G. Wiedemann observed that the ageing of the hydrogel at ordinary temp. is attended by a rise in the susceptibility; and S. Veil studied the change which occurs in the susceptibility when the gels are heated with water. W. Albrecht observed that as the proportion of contained water is reduced, the susceptibility rises to a maximum at $\chi=420\times10^{-6}$, and a minimum at $\chi=280\times10^{-6}$. R. Wallach found that when dehydrated at different temp., there is a maximum at 200°, and a minimum at 650°; these temp. alter a little with different preparations. Treatment of the gels with hydrogen dioxide was found by S. Veil to depress the susceptibility; and S. Hilpert found that treatment with persulphate makes the gel strongly magnetic. O. Hauser found that the hydrate $Fe_6O_7.5H_2O$ furnishes strongly magnetic hydrated ferric oxide—not so, added H. Chandra, if $Fe_6O_7.5H_2O$ be treated with soda-lye and hydrogen dioxide. G. Berndt observed that hydrated ferric oxide, obtained by the oxidation and hydration of ferrous carbonate, has a vol. susceptibility which is dependent on the field-strength, and it also exhibits magnetic hysteresis. S. Veil also studied the magnetic properties of the hydrated oxide.

In general, as C. Whitehead showed, several of the acid-forming elements—phosphorus, arsenic, antimony, tin, selenium, and tellurium—are precipitated as insoluble compounds when an excess of ferric salt is added to ammoniacal soln. The **adsorption** of phosphoric acid by hydrated ferric oxide was examined by E. Angelesen and G. Balanesen; and R. Bunsen and A. A. Berthold studied the adsorption of arsenious acid by freshly precipitated, hydrated ferric oxide so that this reagent can be used as an antidote for arsenical poisoning—a subject discussed by D. Maclagan, R. H. Brett, J. M. Clavera, K. C. Sen, A. Boutaric and G. Perreau, J. H. Orton, T. and H. Smith, J. Zeller, and N. J. B. G. Guibourt. While A. Reychler, T. Oryng, etc., hold that complex, sparingly soluble arsenites are formed; W. Biltz showed that the effect is really an adsorption process, for the proportion of arsenic taken up by the hydrated oxide varies continuously with the conc. of the arsenious acid soln. The isothermal curve varies continuously without a break. G. Lockemann and M. Paucke found that the most complete adsorption occurs when the hydrogel is precipitated with a stoichiometrical proportion of ammonia, an excess of ammonia or precipitation with alkali-lye decreases the adsorptive power. R. Bradfield showed that such a proportion of ammonia gives the most finely divided and most readily peptized particles of hydrate. G. Lockemann and F. Lucius found that the equivalent amount of hydrogel, E mgrms., required to adsorb A mgrms. of arsenic is given by $E=kA^p$, where K and p are constants which vary with the temp. M. C. Boswell and J. V. Dickson, and W. Mecklenburg found that the equation is only approximate. For H. W. Fischer, and H. W. Fischer and E. Kuznitsky on the use of colloidal ferric oxide for intravenous injections in arsenical poisoning, *vide supra*. M. C. Boswell and J. V. Dickson showed that the adsorption of arsenious acid is increased if sodium hydroxide be present, and that the adsorption of sodium hydroxide is increased if arsenious acid be present. The adsorption of arsenious acid by hydrated ferric oxide was studied by K. C. Sen, A. Reychler, L. Herboth, and J. M. Clavera—*vide* arsenic trioxide. J. H. Yoe found that the rate of adsorption of arsenious acid by hydrated ferric oxide is very rapid, for 75 per cent. or more is adsorbed in the first few minutes, although the final state of equilibrium is not attained until after 12 hrs. The adsorption power is lessened, as shown in Fig. 537, the higher the temp. of formation of the hydrogel. Those formed at 0° and at 25° follow the simple adsorption equation: $x/m=kC^{1/n}$—*vide* **5**, 39, 9.

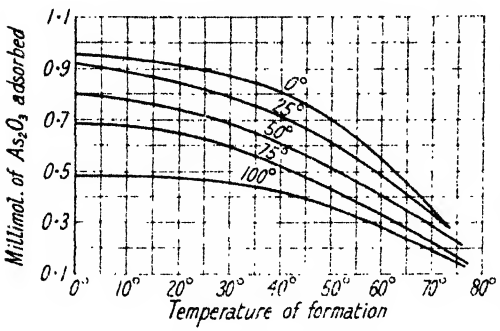

FIG. 537.—The Adsorption of Arsenious Acid by Hydrated Ferric Oxide formed at different Temperatures.

E. Angelesen and G. Balanesen investigated the adsorption of phosphoric acid. H. N. McCoy and C. H. Viol, and J. A. Cranston and co-workers studied the adsorption of the B- and C-members of the radium and thorium series by hydrated ferric oxide. The at. ratio of thorium-B to thorium-C adsorbed is greater than the at. ratio of radium-B to radium-C. O. Erbacher and H. Käding, O. Hahn and M. Biltz, and O. Hahn studied the adsorption of radium emanation by the hydrated oxide; I. Kurbatoff, the effect of the acidity of the soln. on the adsorption of thorium-X by the gel; and D. C. Lichtenwalner and co-workers, the adsorption of salts of magnesium, calcium and potassium by hydrated ferric oxide gels. The order of adsorption of the cations was found to be calcium, magnesium, and potassium; and of the anions, phosphate, sulphate, and nitrate. In the case of nitrates, adsorption was very slight. The time taken to attain equilibrium was considerably greater for phosphates than for other salts. The amount of adsorption of a particular salt increased with increased conc. The adsorption of a cation depended to some extent on the particular anion with which it was associated. Phosphates replaced adsorbed sulphates, but the reverse change did not occur. Sulphates and nitrates adsorbed by hydrogels could be removed by washing, but about two-thirds of the adsorbed phosphate could not be leached out. If hydrated ferric oxide is precipitated by ammonia from soln. containing a copper or a nickel salt, some hydrated copper or nickel oxide is adsorbed, the amount depending on the proportions of the two salts present, and the amount of ammonia added; the hydrated copper and nickel oxides cannot be removed by washing; and A. Charriou observed an analogous result when the precipitation is made in the presence of a calcium salt, and of a magnesium salt. F. Behrend, K. Ruegg, N. R. Dhar and co-workers, E. Toporescu, and A. Charriou studied the adsorption of other hydroxides—Ca, Mg, Cu, Ni, Fe(ous), Zn, Cd; A. C. Chatterji and N. R. Dhar, the adsorption of the hydrosol of ferric oxide; O. Hahn and M. Biltz, thorium emanation; M. Biltz, radiothorium, and radium emanations; and O. Nagel, the effect of adsorption on geochemical processes. M. Geloso observed that precipitated hydrated manganese dioxide likewise adsorbs precipitated hydrated ferric oxide. E. Dittler found that sulphuric acid may be adsorbed by precipitated hydrated ferric oxide; A. Charriou, calcium hydroxide; K. Flerow, potassium nitrate; V. H. Hall, potassium sulphate; F. Ibbotson and H. Brearley, nickel salts; I. M. Levy, copper and nickel salts; H. Busch, manganous, nickel, cobalt, and zinc salts; N. Nikitin, ammonia; W. A. Lazier and H. Adkins, hydrogen and ethylene; A. F. Benton, hydrogen, oxygen, carbon monoxide, and carbon dioxide; Wo. Ostwald and W. Haller, CCl_4, C_6H_{14}, C_6H_6, CH_3Cl, $(C_2H_5)_2O$, $CH_3.COOH$, C_2H_5OH, and $(CH_3)_2CO$; H. N. Holmes and C. J. B. Thor, the adsorption of oleostearine from soln. in volatile organic solvents; H. B. Weiser and E. E. Porter, and C. E. White and N. E. Gordon, P. Rohland, and L. Michaelis and P. Rona, organic dyes; K. C. Sen, citric, racemic, oxalic, sulphuric, malic, succinic, hippuric, and benzoic acids; K. C. Sen's results for the adsorption of some organic acids are summarized in Fig. 538. J. H. Perry found that in the adsorption of vapours from mixtures of vapour and air, (i) the adsorption efficiency is never 100 per cent., and decreases continuously until the saturation value is reached (chloroform, acetone, etc.); (ii) the adsorption is 100 per cent. efficient for some time, and then proceeds to the saturation point, which is reached only after a long time (carbon tetrachloride, ethyl alcohol, benzene); (iii) the curves are almost linear up to saturation, probably indicating chemical reaction (methyl alcohol). The addition of air to sulphur dioxide or ammonia causes a marked lowering of the saturation capacity of the gel. The gel absorbs about 15 per cent. of its weight of water with 100 per cent. efficiency, after which the efficiency falls off up to saturation (18 per cent. of its weight of water). J. C. Philip discussed the reversibility of the adsorptive process as illustrated by the failure of the sorption and desorption curves of ferric oxide gel and benzene to coincide; and B. Lambert and A. G. Foster, the pressure-concentration equilibria

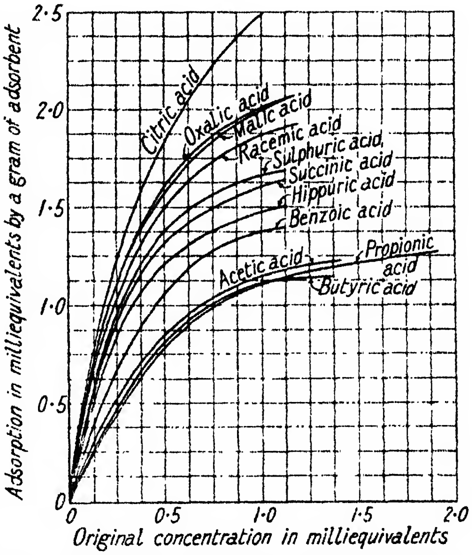

FIG. 538.—The Adsorption of Some Organic Acids by Ferric Hydroxide.

between ferric oxide gels and water, ethyl alcohol, and benzene. J. K. Chowdhury and M. N. Pal, and B. Lambert and A. M. Clark, and A. G. Foster studied the adsorption of benzene; D. P. Grettie and R. J. Williams, piperidine, nicotine, arginine, quinoline, adenine, caffeine, creatine, betaine, acetanilide, urea, acetamide, glucose, succinimide, glycine, vicine, asparagine, glutamic acid, and aspartic acid; G. Malquori, nicotine, caffeine, and quinine; H. Freundlich and G. Lindau, proteins; E. Abderhalden and J. Heumann, trypsin; A. W. Bull and J. R. Adams, sodium alizarin; and A. Boutaric and M. Doladilhe, organic dyes. W. Stollenwerk and M. von Wrangell found that with ferric oxide gels in soln. of sodium hydro-, dihydro-, and normal phosphate, the phosphate is adsorbed in continually increasing amounts until a maximum is attained in about 12 hrs., and after that there is a *retrograde adsorption*, for the adsorbed phosphate is gradually given up again. M. A. Rakuzin observed that neither the anhydrous nor the hydrated ferric oxide exerts a perceptible adsorption when immersed for 24 hrs. in an aq. soln. of egg-albumin. Partly dehydrated or anhydrous ferric oxide has a relatively high adsorptive power for gases at elevated temp. Hence its use in burning hydrogen sulphide for the recovery of sulphur and in a process for making salt cake, discussed by E. Jobling, and E. K. Rideal and H. S. Taylor; and in the contact process for sulphuric acid, discussed by G. Lunge and K. Reinhardt, G. Keppeler and co-workers, J. Krutwig, and L. and P. Wöhler and co-worker; T. Ito studied the action of silver nitrate on hydrazine hydrate, hydroquinone, and sodium hydrosulphite in a medium containing the hydrated ferric oxide.

H. Moissan observed that **hydrogen** at 440° reduces hydrated ferric oxide to ferrosic oxide. The loss of **water,** and the diminution in absorptive power and chemical activity which occur when the hydrogel is kept under water were discussed by J. Lefort, G. A. le Roy, and F. Limberger and G. C. Wittstein. The changes—reduced dispersion, crystallization and loss of water—which occur in the hydrogel when it is heated under water were examined by E. Berl and F. van Taack, J. Böhm, W. Bruhns, A. E. Davies, L. P. de St. Gilles, H. de Sénarmont, E. Wedekind and W. Albrecht, and S. Veil—*vide supra*; and the change which occurs when the hydrogel is heated with water at a high press. was investigated by O. Ruff. For the solubility in water, and for the solubility product, *vide infra*, ferric hydroxide. A. Mailfert observed that the hydrated oxide dissolves in a soln. of potassium hydroxide in the presence of **ozone,** forming potassium ferrate. L. J. Thénard found that hydrated ferric oxide has no action on **hydrogen dioxide.** R. J. Kepfer and J. H. Walton, I. S. Teletoff and E. A. Alekseeva, and G. F. Hüttig and A. Zörner studied the reduction with age in the activity of hydrated ferric oxide as a catalytic agent in the decomposition of hydrogen dioxide. The activity decreased from 18·5 secs. when 14 days old, to 20 secs. when 41 days old, to 22·5 secs. when 55 days old.

According to G. Calcagni, C. E. Janssen, G. A. le Roy, F. Limberger and G. C. Wittstein, B. Reinitzer, O. F. Tower, and G. C. Wittstein, the rate of dissolution of the hydrated oxide in organic and inorganic acids depends on its previous history; the aged hydrogel dissolves in acids slowly. O. Mulert, E. Petersen, and A. Speransky found that the fresh hydrogel dissolves in **hydrofluoric acid,** forming a soln. of ferric fluoride; and for the work of E. Brescius, A. E. Davies, H. R. Ellis and W. H. Collier, F. L. Hahn and M. Hertrich, F. Herrmann, W. G. Mixter, H. Schiff, D. Tommasi and G. Pellizzari, S. Veil, and R. Willstätter and co-workers, *vide supra*. The action of **hydrogen sulphide** is discussed in connection with ferric oxide. P. Berthier, A. Gélis, C. J. Koene, L. Marino, J. Meyer, J. S. Muspratt, K. Seubert and M. Elten, and H. C. H. Carpenter found that with **sulphurous acid** it forms sulphite and dithionate. H. J. Harrar found that 100 c.c. of **sulphuric acid,** at 25°; dissolves during 40 and 60 days' action respectively 12·245 and 14·236 mgrms. of Fe.

F. Ephraim observed that when the hydrogel is rubbed with **sodamide,** much heat is developed and ferric oxide is formed. O. Faust, and A. Guyard found that the hydrogel is not soluble in aq. **ammonia** in the presence of ammonium salts, but if some organic compounds are present, G. P. Baxter and R. A. Hubbard, and others observed that the hydrogel passes into soln. C. F. Cross, and E. Schirm observed that during the washing of the precipitated hydrate, it appears to dissolve —or it may be that the colloid is peptized. According to G. P. Baxter and R. A. Hubbard, " the solubility of hydrated ferric oxide in aq. ammonia is caused by some organic impurity in the ammonia," and they tried, without success, to reproduce the phenomenon by mixing methyl-, ethyl-, diethyl-, and *iso*amyl-amines, ethylenediamine, aniline, and phenyl hydrazine with ammonia. H. von Helmolt said that the hydrogel is soluble in a hot soln. of **ammonium fluoride,** but not in a soln. of **ammonium chloride,** and, according to W. Vaubel, not in a soln. of **ammonium nitrate.** The adsorption of **phosphoric acid** and phosphates has been indicated previously ; E. Erlenmeyer found that it dissolves in a hot, 48 per cent. soln. of phosphoric acid ; and R. M. Caven noticed that the fresh hydrogel reacts with a boiling soln. of **ammonium phosphate** to form ferric phosphate. The adsorption of **arsenious acid** by the hydrogel has just been discussed ; and A. Rosenheim and St. Thon observed that if heated in a sealed tube with a soln. of arsenious acid, basic ferric arsenite is formed—*vide supra*, adsorption. H. N. Hartshorne studied the action of arsenic acid. According to P. de Clérmont and J. Frommel, the fresh hydrogel does not react with **arsenic trisulphide.**

According to J. A. Sokoloff, **carbon monoxide** begins to reduce the hydrogel at about 150°. F. K. Cameron and W. O. Robinson, and P. N. Raikow observed no reaction with **carbon dioxide,** but J. Tillmans and co-workers stated that the hydrated oxide does absorb carbon dioxide. G. MacKinney, N. R. Dhar, G. Rao and A. Ram, G. Rao and N. R. Dahr, and E. Baur and A. Rebmann studied the photo-reduction of carbon dioxide to formaldehyde with colloidal ferric oxide as catalyst. According to E. Wedekind and W. Albrecht, and H. W. Fischer, freshly precipitated ferric hydroxide gradually becomes black in contact with 4 per cent. **hydrocyanic acid,** whilst the liquid acquires an intense reddish-violet colour, the cause of which has not been ascertained. With increasing age of the ferric hydroxide, the colour becomes less intense, and is scarcely perceptible with a preparation 20 days old. With specimens which have been preserved during 5 to 6 weeks, the blackening of the solid or violet colour of the soln. is not observed. The black precipitate consists of a mixture of prussian blue and ferric hydroxide ; it is also formed when freshly prepared ferric hydroxide is brought into contact with prussian blue. The ageing of the hydroxide affects only the first phase of the change, viz., the reduction of ferric to ferrous hydroxide by hydrocyanic acid. G. A. Goyder found that when the hydrogel is treated with a soln. of **potassium cyanide,** potassium ferrocyanide is formed. N. Tarugi, and K. C. Bailey found that the fresh hydrogel dissolves in **thiocyanic acid** to form ferric thiocyanate ; E. Belloni, A. Scheurer-Kestner, and O. F. Tower, that it dissolves in **formic acid.** C. L. Parsons and S. K. Barnes found that the hydrogel is insoluble in a 10 per cent. boiling soln. of **sodium hydrocarbonate.** A. Bette, F. Haber and G. von Oordt, C. E. Janssen, G. Mankiewicz, S. U. Pickering, and B. Reinitzer also found that the hydrogel is soluble in **acetic acid** ; W. G. Bateman and A. B. Hoel, in **chloroacetic acid** ; F. K. Cameron and W. O. Robinson, J. M. Eder and E. Valenta, and A. Rosenheim, in **oxalic acid** ; F. K. Cameron and W. O. Robinson observed that the hydrogel dissolves in oxalic acid to an extent proportional to the conc. of the acid, and no definite basic oxalate was formed at 25°. Soln. of oxalic acid of sp. gr. *S* dissolve the following percentage amounts of hydroxide, estimated as Fe_2O_3 :

S	1·007	1·015	1·031	1·040	1·050	1·064
Fe_2O_3	0·48	0·95	1·86	2·33	2·98	3·62 per cent.

A. Bussy observed that the hydrogel is soluble in **alkali oxalate** soln. ; H. Malfati found that the hydrogel is soluble in **tartaric acid** ; E. Landrin, and S. U. Pickering, in **malonic acid,** tartaric acid, and in **citric acid** ; G. Werther, and E. Soubeiran and H. Capitaine, in **alkali tartrate** soln.; and G. Calcagni, in **glycollic and lactic acids.** According to H. J. Harrer, the solubility of limonite expressed in milligrams of Fe per 100 c.c., at 25°, during 40 and 60 days' action, is for formic acid respectively 4·329 and 4·352; acetic acid, 0·505 and 0·535; **propionic acid,** 0·259 and 0·381; oxalic acid, 6·645 and 3·825; **malonic acid,** 10·520 and 12·125; **succinic acid,** 1·213 and 1·220; **lactic acid,** 8·845 and 10·958; tartaric acid, 10·528 and 16·098; citric acid, 16·159 and 18·582; **benzoic acid,** 5·888 and 6·039; and **salicylic acid,** 21·568 and 21·335. There is a definite relation between the strengths of the acids and the quantities of ferrous and ferric oxides and limonite dissolved. The hydroxy-acids which form complex anions with iron dissolve abnormal proportions, and the soln. undergo striking changes of colour. Some of the supposedly weak organic acids dissolve remarkable quantities of iron, and in natural soln. would be the most effective of all solvents. J. B. Burt found that a 12·5 per cent. excess of citric acid is necessary to dissolve ferric hydroxide. He also examined the reducing action of light on elixir of iron in the presence of quinine and strychnine. J. Wolff observed that the hydrated oxide is soluble in **ammonium salicylate,** and is precipitated from the soln. by hydrogen sulphide. M. Leprince found adsorption products were formed with **methylarsinic acid.** A. Naumann found that the hydrogel is insoluble in **benzonitrile;** and P. Vignon, insoluble in **trimethylamine;** A. Müller observed that the hydrogel is soluble to some extent in **glycerol;** J. M. van Bemmelen and E. A. Klobbie said that it is dehydrated by boiling glycerol; H. Malfatti observed that it is soluble in **polyhydric alcohols,** glycerol, and **sugar** soln.; and G. Buchner, that it is soluble in soln. of **albumen.** C. F. Schönbein found that **tincture of guaiacum** is not oxidized by hydrated ferric oxide.

G. Rousseau and J. Bernheim found that the hydrated oxide dissolves in fused **sodium hydroxide**—*vide infra*, goethite. G. Zirnité observed that if a current of air be passed into hot, conc. soda-lye containing hydrated ferric oxide in suspension, a little ferric oxide dissolves without colouring the liquor, and when the soln. has stood for some days, it becomes turbid owing to the separation of hydrated oxide. The turbid soln. is clarified when it is warmed—*vide infra*, alkali ferrites, and ferrates. The hydrogel dissolves in some soln. of **metallic salts** to form complex salts. C. L. Parsons and S. K. Barnes found that the hydrogel is insoluble in a 10 per cent. boiling soln. of **sodium hydrocarbonate.** H. Ost observed no reaction with soln. of **magnesium chloride,** and O. T. Christensen, that when fused with **potassium hydrofluoride,** potassium ferric fluoride is formed. W. O. Hickok observed that a soln. of **stannous chloride** acts on goethite. J. Jeannel, and P. Nicolardot found that soln. of the hydrated oxide in one of **ferric chloride** have an acidic character, they decompose carbonates, and are said to contain an oxychloride or basic chloride (*q.v.*). According to E. A. Schneider, the hydrated oxide dissolves in a conc. soln. of **aluminium sulphate,** forming a brown liquor which can be evaporated without decomposition, but if water be added, a basic sulphate is precipitated. A. Charriou studied the adsorption of ferric hydroxide by precipitates of **barium sulphate,** and **calcium oxalate.** E. S. Hopkins discussed the use of hydrated ferric oxide as a flocculant in the purification of water.

A red, earthy ore, sometimes mistaken for limonite and called *red ochre*, as well as *hæmatite*, occurs in the Turginsk copper-mine near Bogoslovsk, Urals; in the Kolyvan district, Altai; near Hof, Bavaria, near Siegen and Düsseldorf, Prussia; etc. A. Breithaupt[2] called it *hydrohæmatite*; and H. R. Hermann, **turgite,** or *turite* or *turjite*, according to the spelling adopted for the Russian name. The word turgite is an incorrect German transliteration from the Russian. Analyses were reported by P. A. Schemjatschensky, J. Samojloff, C. F. Rammelsberg, F. M. Heddle, G. J. Brush, E. Manasse, E. Posnjak and H. E. Merwin, J. Eyerman, H. R. Hermann, and G. C. du Bois. Turgite was also described by E. S. von Fedoroff and S. N. Nikitin, and A. Krasnopolsky. The results in some cases approximate to **hemihydrated ferric oxide,** $2Fe_2O_3.H_2O$. With the analyses of N. S. Kurnakoff and E. F. Rode, the percentage water in hydrohæmatite ranges from 5·91 to 7·98, and a sample of red Gloskopf had 0·60 per cent. J. D. Dana regarded turgite as identical with hydrohæmatite. G. Tschermak, F. Zirkel, F. Klockmann, and P. Groth discussed the right of turgite to be regarded as a definite mineral species; L. J. Spencer found that the dehydration curve is different from those of limonite and goethite, and he favoured the hypothesis that the mineral is a distinct mineral species, and M. Bauer represented it by the formula $H_2Fe_4O_7$. H. W. Fischer did not regard it as a definite individual, and E. Posnjak and H. E. Merwin found that the facts fitted the assumption that it is a solid soln. of hæmatite and goethite with enclosed (or capillary) and adsorbed water. O. Ruff obtained a hemihydrate by heating ferric oxide and water under a press. of 5000 atm. above 62·5°. H. Wölbling regarded the product as a mixture of anhydride and hydrate. According to E. Posnjak and H. E. Merwin, turgite is not necessarily a dehydration product of goethite or lepidocrocite; but pseudomorphous turgite may have resulted from the dehydration of fibrous goethite, and from the oxidation and slight hydration of magnetite and the martites. Pseudomorphous turgite is intermediate between hæmatite and primary turgite. A. Pelikan, who observed turgite—which he called limonite—on some fibrous goethite, concluded that turgite could not have been formed by the dehydration of goethite, but was rather deposited there directly. H. Stremme, and F. Cornu considered that the dehydration of the higher hydrates of ferric oxide takes place in nature under the influence of salt soln. or by atmospheric weathering, since it is impossible for several hydrates to be stable under a given set of conditions. E. Posnjak and H. E. Merwin, however, question whether the assumed series of hydrated ferric oxide really exists. The monohydrate is probably stable at any temp. which the earth's surface may normally reach, and it is therefore unlikely that in nature the red ferric oxide is derived by the *direct* dehydration of the yellow. It is probable that both red and yellow substances may be formed at ordinary temp. by somewhat different chemical reactions; both are relatively stable under the conditions usually met with near the earth's surface. According to J. Böhm, the naturally-occurring hydrated ferric oxides, except ruby mica, consist of impure goethite; in the case of turgite, the X-radiograms correspond with the hæmatite structure, so that turgite is partially dehydrated goethite. X-radiograms of the hydrogels give no indication of the presence of any crystalline hydroxide, but if they be heated with 2*N*-KOH, at 150°, the lines of goethite appear. The hydrosols appear to contain a basic salt, but aged sols show the goethite lines. E. Davies prepared what he regarded as the hemihydrate, $2Fe_2O_3.H_2O$, by adding aq. ammonia, or soda-lye, or potash-lye to a soln. of a ferric salt, heating the precipitate with the mother-liquor for 100 hrs. at 100°, or 1000–2000 hrs. at 50°–60°, washing the precipitate, and drying it between 50° and 100°.

L. J. Spencer said that turgite usually occurs as a layer on limonite, and forms hard, lustrous, mamillated or botryoidal masses with a radially-fibrous and concentric-shelly structure. It is black often with a reddish tinge of colour. The streak is dark cherry-red, and very thin fibres transmit a crimson colour. E. Davies' product had a sp. gr. of 4·545. A. Breithaupt gave 4·29 to 4·681 for the sp. gr. of the mineral turgite; H. R. Hermann gave 3·54 to 3·74; J. Samojloff, 4·63; G. J. Brush, 4·14; and C. Bergemann, 4·681. N. S. Kurnakoff and E. J. Rode gave 4·41 to 4·57 for the sp. gr. of hydrohæmatite. E. Posnjak and H. E. Merwin found that the sp. gr. of turgite ranges from 4·607 to 4·978 at 25°/25°; and if corrected for the contained silica and siderite, the sp. gr. ranges from 4·648 to 5·050; with sp. vols. from 0·198 to 0·215. If the water is adsorbed, turgite should have very nearly the sp. vol. of the sum of the sp. vols. of water and ferric oxide (sp. gr. 5·2). The sp. vol. curve would then be that represented by the thin line in Fig. 539. The observed results deviate from this, and lie more nearly on the sp. vol. curve of mixtures of hæmatite and goethite represented by the thick line in Fig. 539. This agrees with the assumption that turgite is a solid soln. of ferric oxide (hæmatite) and monohydrated ferric oxide (goethite). L. J. Spencer found that the hardness of turgite is near 6·5; and that turgite decrepitates violently when heated. The dehydration curve, with a 4 months' heating at each temp., is a continuous line. This was confirmed by E. Posnjak and H. E. Merwin, who found that the curve is different from the corresponding curves of goethite, limonite, lepidocrocite, and xanthosiderite—*vide infra*. The smooth curve shows that the water is given off gradually, as the temp. rises. There is no sudden decomposition anywhere. It is therefore inferred that the water is adsorbed or in solid soln., or both. The rehydration of dehydrated turgite was not successful, so that the dehydration is not a reversible process, and consequently it is doubtful if the water is merely adsorbed. The water is supposed to be held in solid soln. E. Posnjak and H. E. Merwin found the heating curve of turgite shows a slight exothermal break at 110°, and no other singularity occurs between that temp. and 600°. The heating curve is unlike the corresponding curves with the other hydrates. If turgite be a solid soln. of hæmatite and goethite, it might have been expected that the heating curve would resemble that of goethite—*vide infra*.

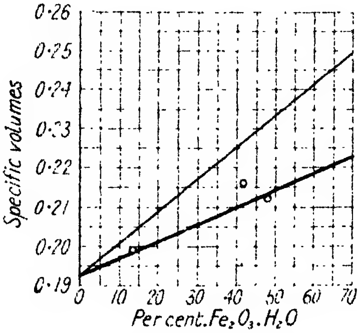

FIG. 539.—Specific Volumes of Mixtures of Goethite and Hæmatite.

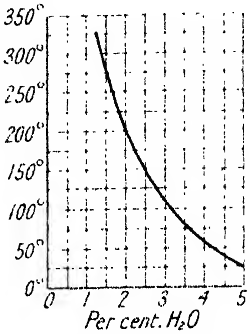

FIG. 540.—Dehydration Curve of Turgite.

N. S. Kurnakoff and E. J. Rode showed that the dehydration curves of the natural hydrated ferric oxides can be subdivided into three groups, and they furnish three phases. The first group, illustrated by curve I, Fig. 541, has a continuous dehydration curve analogous to the dehydration curves of the zeolites. There may be a break at 125° to 130°—*vide infra*. This group includes the turgites and the hydrohæmatites. The sp. gr. is 4·4 to 4·8. The colour is red, and the streak differs from the streaks of the substances in the other classes. The second group, illustrated by curve II, includes goethite, lepidocrocite, and limonite with 8 or more per cent. of water. These substances have 9·9 to 13·2 per cent. of water. Water exceeding $Fe_2O_3.H_2O$—*i.e.* 10·1 per cent.—is probably present in solid soln. The sp. gr. is 3·5 to 4·2; and the streak is pale yellow to dark brown. The dehydration curves have a characteristic terrace—the goethite terrace—in the vicinity of 200°, shown by curves II and III. This terrace corresponds with the beginning of the breaking of the α-phase-solid soln. of water in hæmatite. The hydrates of group I are typically α-solid soln. In substances with the higher proportions of water there is a terrace between 125° and 135°, corresponding with the

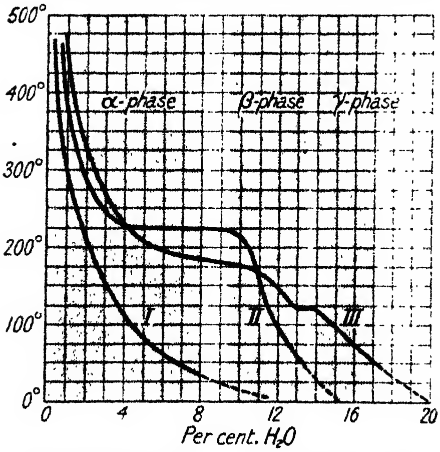

FIG. 541.—Dehydration curves of the Natural Hydrated Ferric Oxides.

beginning of the breaking up of the β-phase or solid soln. of water in goethite. The third group, illustrated by curve III, includes xanthosiderite, bog ores, and limonite. They have 13·8 and more per cent. of water. The dehydration curves show the goethite terrace; and the terrace at 120° to 150° where the β-phase or solid soln. begins to decompose; below that temp. there is the γ-phase, or what N. S. Kurnakoff and E. J. Rode call the xanthosiderite soln., or the γ-solid soln. is present. Curve III represents the decomposition of the bog iron ore, the sp. gr. of which is 2·7 to 3·8, and the streak pale yellow or dark brown. P. A. Thiessen and R. Köppen's study of the dehydration curves of goethite shew that it is a hemihydrate; the vap. press. curves of hydrated ferric oxide, at different temp., had breaks corresponding with the *tetrahydrate*, $Fe_2O_3.4H_2O$; the *hemiheptahydrate*, $2Fe_2O_3.7H_2O$; the *trihydrate*, $Fe_2O_3.3H_2O$; the *hemipentahydrate*, $2Fe_2O_3.5H_2O$: the *dihydrate*, $Fe_2O_3.2H_2O$; the *hemitrihydrate*, $2Fe_2O_3.3H_2O$; the *monohydrate*, $Fe_2O_3.H_2O$: and the *hemihydrate*, $2Fe_2O_3.H_2O$. There are probably also the *pentahydrate*, $Fe_2O_3.5H_2O$; and the *hemienneahydrate*, $2Fe_2O_3.9H_2O$. G. F. Hüttig and A. Zörner, G. F. Hüttig and H. Garside, O. Ruff, and C. Slonim studied this subject.

Turgite is optically negative. E. Manasse found that it is not doubly refracting. According to E. Posnjak and H. E. Merwin, fibrous red oxide of iron containing variable amounts of water—4 to 6 per cent.—cannot be definitely characterized. Detached splinters have parallel extinction, negative elongation, and negative, apparently uniaxial, optical properties. The refractive indices range from α (or ϵ) $=2\cdot3$ to $2\cdot6$, and β (or ω) $=2\cdot5$ to $2\cdot7$. They found $\alpha=2\cdot46$ to $2\cdot58$ for Na-light, and $\beta=\gamma=2\cdot38$ to $2\cdot52$ for Li-light. T. W. Case found that the resistance does not change on exposure to light. E. Davies found the artificial product dissolves readily in hydrochloric acid, and slowly in nitric acid.

In 1789, J. P. Becher[3] described what he called *Rubinrotherz Eisenglimmer*, which occurred at Siegen, in thin scales of a ruby-red colour; and later L. A. Emmerling, an *Eisenglimmer* with a colour, red, steel-grey or black; F. Mohs, a fibrous ironstone, coloured hyacinth-red, or blood-red, and forming four-sided plates; while J. F. L. Hausmann said that *Brauneisenstein* occurs (i) in thin, red, scaly or tabular crystals, in *Rubinglimmer*, a name synonymous with J. C. Ullmann's *pyrrhosiderite*—from *πυρρός*, fiery red; *σίδηρος*, iron—and which D. G. J. Lenz called **goethite**—after J. W. Goethe; (ii) scaly and fibrous, *e.g.* the *lepidocrocite* or *lepidokrokite*—*λεπίς*, scale; and *κροκίς* or *κροκύς*, fibre—of J. C. Ullmann; (iii) acicular, or capillary (not flexible) crystals, or in slender prisms sometimes grouped, *e.g.* the yellowish-red, fibrous *needle-ironstone* or *Nadeleisenerz* of A. Breithaupt. K. Willmann considers rubinglimmer and nadeleisenerz to be definite varieties. A variety occurring at Pribram, has a velvety surface and was called *Sammetblende* or *velvet blende*, and it is the *przibramite* of E. F. Glocker. There is also (iv) a brown or black, fibrous variety called *Glaskopf*; (v) a drossy variety corresponding with J. C. Ullmann's *stilpnosiderite*—*στιλπνός*, shining—which is a form of limonite (*q.v.*); (vi) a compact form; and (vii) an ochreous variety—both the compact and ochreous varieties are probably limonites. The *stainerite* of V. Cuvelier, and A. Schoep and V. Cuvelier approximates $(Co,Fe,Al)_2O_3.H_2O$. The *chileite* of A. Breithaupt is a form of goethite, and the acicular goethite which penetrates the quartz found on an island in Lake Onega, Russia, was called *onegite* by C. C. André, and *fullonite*—after a Mr. Fullon—by A. Breithaupt. F. Cornu called a colloidal variety with the "composition" of goethite, *Ehrenwerthite*—after A. Ehrenwerth. The crystals in some forms of *flèches d'amour*, and in some *aventurine* felspars—*e.g. sunstone*—are supposed to be goethite. F. von Kobell showed that needle-ironstone, goethite, and lepidocrocite have the general formula $Fe_2O_3.H_2O$, while varieties of limonite have the composition $2Fe_2O_3.3H_2O$. Analyses of goethite were also reported by A. Breithaupt, G. J. Brush, I. Domeyko, P. A. Dufrénoy, C. W. von Gümbel, B. J. Harrington, T. Häege, F. M. Heddle, H. R. Hermann, A. Lacroix, E. Manasse, J. J. Nöggerath, W. F. Pfaff, E. Posnjak and H. E. Merwin, C. F. Rammelsberg, G. Rose, J. B. Schober, M. Weibull, K. Willmann, and P. Yorke. N. S. Kurnakoff and E. J. Rode found 9·89 to 11·17 per cent. of H_2O in the samples they analyzed. The analyses of goethite and lepidocrocite are in general agreement with the formula for the **monohydrated ferric oxide,** $Fe_2O_3.H_2O$, or, with less justification, **ferric oxyhydroxide,** FeO(OH). N. S. Kurnakoff and E. J. Rode, however, are not satisfied that this substance is really a chemical individual. The formation of goethite in nature has been discussed by F. Babanek,[4] W. Bornhardt, O. Mügge, and A. E. Reuss, from which it appears that in some cases, limonite represents an intermediate stage in its formation, but in other cases—*e.g.* the inclusions of geothite in quartz, etc.—it is not probable that it was formed from limonite. According to L. P. de St. Gilles, when a soln. of a ferric salt is treated with ammonia, and the precipitate washed until free from ammonia, and then dried at 100°, the colour slowly changes from yellowish-brown to brick-red, and it then contains water eq. to $Fe_2O_3.H_2O$. G. Fownes obtained an analogous product by the action of potassium hydroxide on ammonium potassium ferric sulphate. Observations on this subject were made by C. W. C. Fuchs, H. Schiff, H. de Sénarmont, H. Debray, and F. W. C. Krecke. According to G. Rousseau, this hydrate is obtained in crystals by the action of boiling water on ferric oxychloride. F. Muck obtained the amorphous monohydrate by the action of a mixture of sodium carbonate and hypochlorite on a boiling soln. of ferrous sulphate; and G. Rousseau and J. Bernheim reported violet plates contaminated with a little soda, to be formed at 1100° by the action of dry, hydrated ferric oxide on sodium carbonate. The needle-like crystals produced by the last-named were said to be rhombic and different from ordinary goethite, so that this hydrate was said to be dimorphous. J. D. Dana, however, did not accept these statements; and C. Doelter could not obtain the dimorphous crystals, and said that the synthesis must be regarded as very doubtful. For D. Tommasi's observations on the α- and β-monohydrate, *vide supra*. D. Tommasi oxidized hydrated ferrous carbonate or hydrated manganosic oxide with potassium chlorate, he also oxidized ferrous hydroxide, and oxidized iron under water to form in all cases the yellow hydrogel hydrated ferric oxide. F. Muck said that the oxidation is complete when sodium hypochlorite is employed. O. Ruff, J. M. van Bemmelen, and E. Posnjak and H. E. Merwin regarded the yellow hydrogel as a true monohydrate. H. W. Fischer obtained a yellow hydrogel by the hydrolysis of a hot soln. of ferric chloride; S. Veil, and V. Rodt by the oxidation of ferrous or ferric sulphide suspended in water by means of a current of air; O. Baudisch and co-workers, the action of an azide or organic base on ferric chloride; and A. Krause, by oxidizing ferrous hydroxide.

H. Brunck and C. Gräbe obtained a substance resembling goethite from a molten sodium hydroxide, at 400°, contained in an iron boiler. According to W. L. Dudley, iron is attacked by fused sodium dioxide to form dark red, tabular crystals of the monohydrate. A. Frickhinger, obtained the monohydrate by the action of a soln. of ammonium chloride on iron in a closed vessel; and F. Wibel, by the action of soln. of ferrous salts on copper or on cuprous oxide. Z. Roussin obtained this hydrate by heating iron nitrosylsulphide, or sodium nitroprusside with conc. alkali-lye. J. M. van Bemmelen and E. A. Klobbie found that the hexagonal plates of sodium ferrite, $NaFeO_2$, when treated with water at 15°, furnish a *ferrous acid*, $H.FeO_2$; the crystals lose water at 100°, and consequently this hydrate cannot be the same as goethite, which retains its water at a much higher temp. They also doubted if goethite can be produced under the conditions of temp. which prevailed in G. Rousseau's, and H. Brunck and C. Gräbe's experiments. A. Vesterberg obtained monohydrated ferric oxide, pseudomorphous after ferric sulphate, by drying his dihydrate—*vide infra*—in a desiccator. The product was not very stable, for it began to lose water at 100°; and, unlike some other forms, it is hygroscopic. E. Posnjak and H. E. Merwin found that the yellow hydrated ferric oxide resembling the natural, amorphous oxide was formed below approximately 120°, but only above that temp. was red, hydrated ferric oxide, resembling turgite and hæmatite, produced. O. Ruff obtained the monohydrate, goethite, by heating the hydrated oxide with water between 42·5° and 62·5°; at a higher temp. a less hydrated oxide was formed, and at a lower temp. a more hydrated product was produced—*vide supra*. H. Wölbling regarded O. Ruff's product as a mixture of anhydride and hydrate. C. Doelter found that the precipitate of hydrated ferric oxide becomes crystalline after being shaken for 88 days; and that the gelatinous precipitate gradually forms the crystalline monohydrate when heated on the water-bath. The syntheses of crystalline goethite here reported are not, in general, satisfactory; and those of the monohydrated ferric oxide which yield a colloidal or amorphous product leave it open for debate whether or not the proportion of water observed is only due to an arbitrary selection of the conditions of drying. According to W. H. Albrecht, and E. Wedekind and co-workers, what F. Haber called the *a-hydrate*, a-FeO(OH), identical with goethite, is prepared by oxidation of ferrous hydrogen carbonate soln. by hydrogen dioxide, by a current of air or oxygen, or by a prolonged exposure of the soln. to air at 37°. In the last case, ferrous iron is present as well. The *γ-hydrate*, γ-FeO(OH), identical with lepidocrocite, is obtained by the oxidation of very dil. soln. of a ferrous salt by the eq. amount of sodium iodate in presence of sodium thiosulphate. Both hydrates are crystalline. The temp. of decomposition of the synthetic hydrates is markedly lower than that of the natural substances. The ratio $H_2O : Fe_2O_3$ is not constant, the water-content being usually higher than the theoretical.

H. Freundlich and S. Loebmann, and P. von Mutzenbecher prepared a colloidal soln. of goethite by centrifuging a mixture of perhydrol and iron pentacarbonyl. They found the speed of coagulation to be a quadratic function of the rate of stirring. Coagulation occurs at the interface of sol and air. The speed of coagulation passes through a minimum on adding increasing amounts of electrolytes. Small amounts of propyl alcohol favour coagulation, larger amounts delay it. *Iso*amyl alcohol favours coagulation, methyl alcohol inhibits it. H. Freundlich and B. S. Greensfelder also studied the subject.

Goethite occurs in reniform or stalactitic masses with a concentric and radiated structure; it also occurs fibrous and foliated or in scales, as well as in prismatic crystals which are vertically striated, and often flattened into scales or plates parallel to the (010)-face. The colour is yellowish-, reddish-, and blackish-brown; often blood-red by transmitted light. The streak is brownish-yellow or ochre-yellow. J. L. C. Schröder van der Kolk [5] said that the colour of the powder is like that of a ripe orange; and E. Posnjak and H. E. Merwin added that the fine powder is dull orange-yellow. The thicker grains show a slight pleochroism in orange-yellow and browns; but the thinner grains are not perceptibly pleochroic, and they are clear yellow. K. Willmann said that the mineral is feebly pleochroic—yellowish-orange in the direction of the *c*-axis; and brownish, perpendicular to that axis. O. Mügge said that when thin plates are warmed, between crossed nicols, the colour passes from green to red, but the green colour returns on cooling. According to W. Phillips, the rhombic crystals of needle ironstone have the axial ratios $a : b : c = 0{\cdot}9185 : 1 : 0{\cdot}6068$; and E. Posnjak and H. E. Merwin gave 0·90 (to 0·92) : 1 : 0·600 (to 0·605). The elongation of the prismatic, bladed, and fibrous varieties is parallel to (001). The (010)-cleavage is perfect, and the (100)-cleavage is good. In one sample, the optic axial angle $2E = c.\ 80°$ for 600$\mu\mu$; and in another sample, $2E = 90°$ for 675$\mu\mu$, and 120° for 546$\mu\mu$, or $2V = 35°$ to 40°. E. Palla gave $2E = 50°$; A. Pelikan, $2E = 58° 31'$ for red light, and 67° 42′ for yellow light. O. Mügge found that with the 577$\mu\mu$ and 579$\mu\mu$ yellow mercury double line, the effect of temp. on the optical axial angle is:

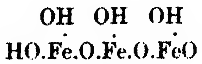
θ .	12·0°	31·0°	55·7°	63°	74·1°	102·5°	116·3°
$2E$.	83° 11′	63° 14′	24° 05′	0°	46° 22′	96° 11′	119° 20′

The optical character is negative. R. Gaubert found that the effect of temp. on the variation of the dispersion of the optic axes of goethite and limonite, and the action of hydrochloric and hydrofluoric acids show that fibrous limonite is impure goethite. K. Willmann regarded the scaly rubinglimmer, and acicular needle-ironstone as two different forms of the monohydrate, so that goethite is considered to be dimorphous, and rubinglimmer is called γ-**goethite,** and needle-ironstone, α-**goethite.** The γ-form is taken to include lepidocrocite—*vide infra*—and pyrrhosiderite. For the coagulation of colloidal soln., *vide* hydrosols of ferric oxide. O. Baudisch and L. A. Welo dehydrated $\gamma\text{-Fe}_2O_3.H_2O$ by friction, forming red $\gamma\text{-F}_2O_3$.

According to J. Böhm, the X-radiograms show that precipitated hydrated ferric oxide is amorphous, but after slow drying it gives hæmatite, and when heated with potash-lye, goethite. The α-monohydrate has a rhombic holohedral lattice with $a=4\cdot60$ A., $b=10\cdot01$ A., and $c=3\cdot04$ A., or $a:b:c=0\cdot459:1:0\cdot303$, and a sp. gr. 4·195; the γ-form has $a=385$ A., $b=12\cdot5$ A., and $c=3\cdot07$ A., or $a:b:c=0\cdot308:1:0\cdot246$, and a sp. gr. 3·97. These values for the *a*- and *c*-axes are about half those generally accepted. J. Böhm gave for the dimensions of the elementary cell, $a=4\cdot60$ A., $b=10\cdot01$ A., and $c=3\cdot04$ A. S. Goldsztaub gave $a=6\cdot64$ A., $b=10\cdot0$ A., and $c=3\cdot03$ A. for goethite; and for lepidocrocite, $a=3\cdot87$ A., $b=12\cdot4$ A., and $c=3\cdot06$ A.; and W. F. de Jong gave for goethite, $a=4\cdot55$ A., $b=9\cdot90$ A., and $c=3\cdot01$ A.; and he said that it is not isomorphous with stainerite—*cf.* ferrous oxide. G. Tunell and E. Posnjak, and P. F. Kerr studied the X-radiograms of goethite. J. Böhm gave for *Nadeleisenerz* the axial ratios $a:b:c=0\cdot918:1:0\cdot606$; and for *Rubinglimmer*, $0\cdot64:1:0\cdot43$. Observations on the crystals were also made by F. Babanek, M. Bauer, A. Breithaupt, K. Busz, J. Cates, G. Cesaro and A. Abraham, J. H. Collins, J. D. Dana, A. P. Dufrénoy, R. P. Greg and W. G. Lettsom, F. M. Heddle, A. Johnsen, G. A. Kenngott, A. Lacroix, A. Michel-Lévy and A. Lacroix, L. Michel, E. Palla, A. Pelikan, F. A. Quenstedt, C. F. Rammelsberg, A. E. Reuss, G. Rose, H. Traube, and D. F. Wiser.

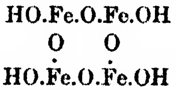
For the sp. gr., G. Rose gave 4·7; D. F. Wiser, 4·111; F. M. Heddle, 3·768 to 4·146; A. Breithaupt, 4·006; J. D. Dana, 4·0 to 4·4; and O. Mügge, 4·193 to 4·481; and after dehydration, the sp. gr. was 4·318 to 4·524. E. Posnjak and H. E. Merwin found the sp. gr. of their samples ranged from 4·091 to 4·263 at 27°/27°; and when corrected from the analyses for the contained siderite, manganite, and silica, they ranged from 4·29 to 4·32 at 27°/27°; N. S. Kurnakoff and E. J. Rode gave 4·20 for the sp. gr. The hardness is between 5 and 5·5.

The α-form is also called **ferric metahydroxide,** and the γ-form **ferric orthohydroxide.** According to A. Krause, and O. Baudisch and L. A. Welo, the metahydroxide has acidic properties, its isoelectric point being $p_H=5\cdot2$. whilst the orthohydroxide is more basic than acidic having an isoelectric point $p_H=7\cdot7$; whilst goethite, J. Böhm's α-Fe.O.OH, has no acidic properties. For the ferrous ferrites from these two hydrated ferric oxides, *vide infra*, ferrous ferrites. Since orthoferric hydroxide furnishes $Ag_3H(FeO_2)_4$, when heated with silver nitrate, A. Krause and K. Pilawsky suggested that not all the OH-groups have the same value, and, in the absence of a knowledge of the mol. wt., suggested that the graphic formulæ of the ortho- and meta-hydroxides are respectively as follows:—



$$\begin{array}{c}\text{OH}\;\;\text{OH}\;\;\text{OH}\\ \text{HO.}\dot{\text{F}}\text{e.O.}\dot{\text{F}}\text{e.O.}\dot{\text{F}}\text{eO}\end{array}$$

Orthohydroxide



$$\begin{array}{c}\text{HO.Fe.O.Fe.OH}\\ \text{O}\;\;\;\;\text{O}\\ \text{HO.}\dot{\text{F}}\text{e.O.}\dot{\text{F}}\text{e.OH}\end{array}$$

Metahydroxide

According to G. Schikorr, the X-radiograms of rust show that both α- and γ-FeO(OH) can be formed in the rusting of iron. The two forms are crystallographically different and they are represented by the minerals goethite—or α-FeO(OH)—and lepidocrocite—or γ-FeO(OH). G. Schikorr observed that when ferrous chloride in aq. soln. is oxidized spontaneously in air, α-FeO(OH) is formed; when ferrous hydroxide is rapidly oxidized in water through which oxygen is passed, α-FeO(OH) is formed; and α-FeO(OH) is produced when the hydroxide is slowly oxidized. When a soln. of ferrous hydroxide in ammonium chloride is rapidly oxidized, α-FeO(OH) is formed, and if slowly oxidized, γ-FeO(OH) is produced; and if a soln. of ferrous hydrocarbonate in saturated carbonic acid is slowly oxidized α-FeO(OH) is formed, but if the carbonic acid is in only slight excess, some γ-FeO(OH) is formed. E. Stirnemann observed the formation of the γ-form in the hydrolysis of ferric oxychloride. According to G. Schikorr, rust which is formed in contact with iron, under water, consists of γ-FeO(OH), presumably because it has been produced by the oxidation of a ferrite; whereas rust formed at some distance from the iron consists of α-FeO(OH), presumably because it has been formed by the direct oxidation of a ferrous salt. R. D. Williams and J. Thewlis prepared crystals of the γ-hydroxide, *i.e.* lepidocrocite, by precipitation from a soln. of ferrous chloride with calcium hydroxide, and subsequent oxidation at room temp. The crystals are of the order 10^{-5} cm. across, and those of the α-oxide, are of the order 10^{-4} cm. across. When heated, the α-hydroxide passes into cubic ferric oxide, and later into the rhombohedral oxide. The transformation from the γ-hydroxide to the γ-oxide (cubic) is roughly between 250° and 300°. R. Kattwinkel, F. Haber, O. Kröhnke, H. Schwiersch, and F. Drexler also studied this subject. The dehydration of the oxyhydroxide was examined by O. Ruff, H. W. Fischer, P. Nicolardot, G. F. Hüttig and co-workers, J. Böhm, and A. Simon and T. Schmidt. G. Schikorr represented by Fig. 542 the dehydration curves of the two forms prepared by slow and rapid oxidation of soln. of ferrous hydroxide in aq. soln. of ammonium chloride. W. H. Albrecht and E. Wedekind thus summarized the relations between the different oxides and hydrates: A. Krause and co-workers concluded from their study of silver ferrite that the ferric hydroxides include:

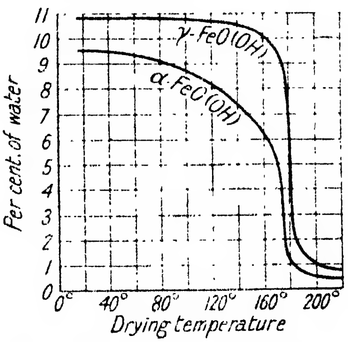


Fig. 542. — The Dehydration Curves of the two Ferric Oxyhydroxides.

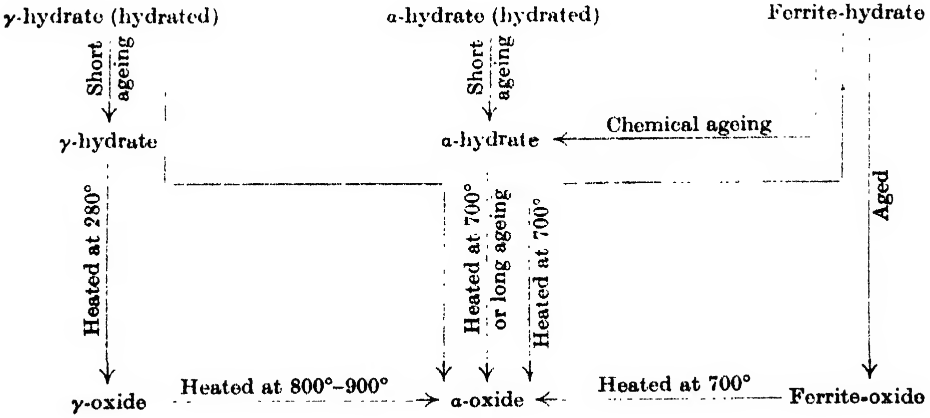
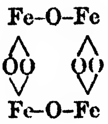
I.—The orthohydroxide and polyorthohydroxide with chain-like molecules.

II.—Yellow hydroxide with ring-like molecules—*e.g.* the metahydroxides—embracing (1) the ferrous acid, $(HFeO_2)_n$ either amorphous, or crystalline γ-FeO(OH); and (2) goethite, $(Fe_2O_3.H_2O)_n$, to which the α-hydroxide and amorphous goethite belong.





J. W. Gruner's limonite was probably goethite, and he found :

> The stability of limonite in the presence of water was tested at 250° and 300° in sealed, thick-walled pyrex tubes. At 250° limonite showed no change. At 300° it was found that limonite in the tube above the water turned a brilliant red, whereas the limonite under water remained unchanged. The time of the experiment was 21 days. On analysis it was found that the whole sample in the tube contained 5·95 per cent. volatile matter after drying at 105°, and the ignition loss of the original material after drying at 105° was 12·13 per cent. This very peculiar behaviour of ferric hydroxide at these temperatures will be investigated further. It is probable, however, that, as J. M. van Bemmelen pointed out long ago, limonite is stable in the presence of water and under corresponding pressures at temperatures which approach 300°.

According to G. Tunell and E. Posnjak, the conversion of goethite to hæmatite probably proceeds at a much lower temp., for with boiling 0·1*N*-HCl, goethite passes into hæmatite ; and in J. W. Gruner's experiments, a product with a slow rate of decomposition was mistaken for a stable state. Variations were observed owing to differences in the rates of heating, and differences in the physical character of the substance—*e.g.* size of grain. Dehydration experiments in which the substance was heated for 4 months at different temp., and the losses of weight determined, showed that the dehydration curve consists of three parts, Fig. 543. The middle portion represents the loss of water attending the decomposition of the goethite, and it is accompanied by a change in colour from yellow to red. The upper and lower portions of the curve represent losses of water not chemically combined, and which is in all probability adsorbed and capillary water held in proportions which vary largely with the structure of the material. The re-hydration curves show that, roughly, the proportion of water taken up by the dehydrated material in a humid atmosphere is the same as the amount lost in the first stage of the heating. Goethite which was crystalline before dehydration, took up very little water ; while the fibrous varieties, and particularly the amorphous varieties, took up larger proportions. L. J. Spencer also found a break in the dehydration curve of goethite just below 250° ; and O. Mügge also obtained one at approximately 250°. N. S. Kurnakoff and E. J. Rode's observations on this subject have been discussed in connection with turgite—*vide supra.* E. Posnjak and H. E. Merwin's break at 200° was obtained with a 4 months' heating at the different temp. ; the others were obtained with a few hours' heating, so that equilibrium was more nearly attained than was the case with L. J. Spencer's, and O. Mügge's measurements. Expressing the time in hours and in brackets, the percentage losses of water at different temp. with a sample of coarse-grained goethite, from Crystal Park, were as follows (the sample when dried at 126° suffered an insignificant loss) :

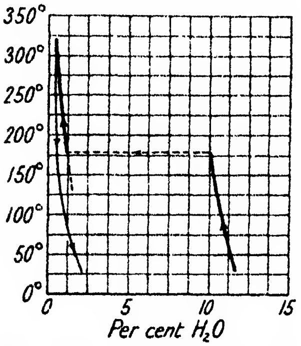


FIG. 543.—Dehydration and Re-hydration Curves of Goethite.

	153° (3)	192° (3)	244° (7)	264° (3)	282° (2)	303° (21)	305° (24)	376° (16)
Loss . .	0·04	0·05	0·24	0·90	1·37	7·77	9·62	9·72 per cent.

The loss over 376° (4) was 10·38 per cent. With a fine-grained sample, the losses were :

	132° (1)	220° (16)	275° (22)	304° (7)	353° (16)	400° (22)	>400° (0·5)
Loss . .	0·19	0·54	6·28	9·51	9·74	9·79	10·06 per cent.

Hence, the finer the grain-size, the faster the dehydration at the lower temp. The powder dehydrated at 354°, took up only 0·04 when exposed to a humid atmosphere. There is a sharp change in the optical properties of the sample heated to 250°. The sp. gr. rose from 4·193 to 4·318. C. F. Cross found that monohydrated ferric oxide, obtained by drying at 100° the ordinary precipitate, when exposed to a sat. atmosphere at 18°, gradually absorbs moisture, forming in about 67 hrs. a mixture eq. to $Fe_2O_3.3H_2O$, and in 192 days, one eq. to $Fe_2O_3.11H_2O$. The daily fluctuations of temp. gave variable results for the composition of the hydrated oxide. Observations were made by L. Hackspill and E. Stempfel, and P. A. Thiessen and R. Köppen.

E. S. Larsen gave for the indices of refraction of the rhombic crystals, $\alpha=2{\cdot}21$, and $\beta=\gamma=2{\cdot}33$ to $2{\cdot}35$ for Li-light. E. Posnjak and H. E. Merwin gave $\alpha=2{\cdot}26$, $\beta=2{\cdot}394$, and $\gamma=2{\cdot}400$ for rhombic goethite; and said with respect to fibrous goethite, that aggregates of thin blades and fibres, sub-parallel with respect to the *c*-axis, vary considerably physically and chemically. They usually appear microscopically homogeneous, but their refractive indices are low; they contain water, silica, etc., as impurities, and they show confused interference figures; they are uniaxial at shorter wave-lengths than is the case with goethite, owing to lack of parallel orientation with respect to the *a* and *b* axes. If the fibres or blades, elongated parallel to *c*, are fine—below $0{\cdot}5\mu$ in diameter—they can be packed without pore-space and with random orientation with respect to *a* and *b*, then slices of the apparently parallel-fibrous aggregates would have a maximum refractive index, parallel to the elongation, equal to 2·40, and a minimum, throughout the plane perpendicular to the elongation, equal to 2·33. Absorption would be slightly greater in the direction of the elongation. If instead of the random orientation, there is a tendency towards parallelism, there will be for any bundle of fibres considered as a unit, three principal refractive indices, namely, $\gamma=2{\cdot}40$, β variable between 2·40 and 2·33, and α variable between 2·26 and 2·33. Observations were also made by E. Palla, A. Michel-Lévy and A. Lacroix, and G. Cesaro and A. Abraham. F. Beijerinck found that goethite is a non-conductor of electricity. T. W. Case observed no change in the resistance of goethite on exposure to light. W. H. Albrecht found the magnetic susceptibility of artificial goethite to be 40×10^{-6} mass unit; J. Huggett and G. Chaudron studied the magnetic properties. E. F. Herroun and E. Wilson gave $28{\cdot}5\times10^{-6}$, and added that the susceptibility of α-$Fe_2O_3.H_2O$ does not change when it is heated. According to J. Huggett and G. Chaudron, goethite is paramagnetic, but it becomes ferromagnetic when heated in air at 360°. The magnetizability increases in vacuo owing to the removal of water, and at 570° it diminishes further. Goethite dehydrated in vacuo at 600° behaves like magnetite. Lepidocrocite, and rust conduct themselves similarly. G. F. Hüttig and H. Kittel studied the subject. G. Grenet gave 360×10^{-6} for the coeff. of magnetization of goethite. S. Berkman and H. Zocher studied the magnetic properties of $FeO(OH)$. G. F. Hüttig and H. Kittel found the magnetic susceptibility to vary from $30{\cdot}7\times10^{-6}$ to $43{\cdot}7\times10^{-6}$ mass unit according to the mode of preparation—*vide supra*, ferric oxide. G. Chaudron studied the magnetization curve of goethite; and lepidocrocite, heated in air. There is the magnetic transformation of magnetite at 570°, and an anomaly with ferric oxide at 660°. Goethite dissolves slowly and completely in conc. hydrochloric acid, but more easily in nitric acid. A residue of insoluble silica may appear.

G. F. Hüttig and H. Garside examined the hydrogel and found that when freshly-prepared it is amorphous, and that most of the water is united chemically with the ferric oxide, possibly as $Fe(OH)_3$ or $Fe(OH)_3.H_2O$, but a certain proportion of water in the colloid is mobile. If dehydrated to $Fe_2O_3.H_2O$, it is probable that water is all chemically united with the ferric oxide, and it cannot be removed without the application of heat. The heat transforms a part of the substance into crystalline ferric oxide. During ageing, the hydrogel becomes less active chemically, and the sp. ht. changes. The end-product of the ageing is $Fe_2O_3.H_2O$, or crystalline ferric oxide associated with water not chemically bonded. The stable form between 77° and 228° is goethite, and above 228°, crystalline ferric oxide associated with water not chemically combined. In ageing, part of the amorphous hydrogel forms crystalline ferric oxide, and a part forms goethite. The X-radiograms show that the space-lattice of the unstable ferric oxide associated with the water is expanded, but becomes normal when it passes into the stable form. The sp. ht., Table XC, and the vap. press. of the unaged hydrogel is less, and its activity in the catalytic decomposition of hydrogen dioxide is greater, than that of the aged hydrogel. S. Loebmann discussed the mechanical coagulation of goethite sols. P. P. von Weimarn and T. Hagiwara found that goethite can be transformed into hæmatite by mechanical disintegration.

TABLE XC.—SPECIFIC HEAT OF HYDRATED FERRIC OXIDE, $Fe_2O_3.nH_2O$.

Sample	Age in days	n	Temp.	Mean sp. ht.	Mol. ht.	Deviation from sum of mol. hts.	Apparent heat capacity of water	Apparent mol. ht. of water	Apparent mol. ht. of ferric oxide

A_1 is the hydrogel $Fe_2O_3.3·721H_2O$; A_2 is the same preparation dried at 30° for 5 hrs.—$Fe_2O_3.2·247H_2O$; A_3, the same dried another 5 hrs. at 30°—$Fe_2O_31·233H_2O$; A_4, is A_3 dried over phosphorus pentoxide at 40°—$Fe_2O_3.0·237H_2O$. B_1 is goethite from Bohemia; C_1 is ferric oxide dried in air at 60°, and C_2, C_3, and C_4 are preparations dehydrated in vacuo at 200° over phosphorus pentoxide; and n, mols. of H_2O.

A. Lacroix [6] stated that the optical properties of the reddish, scaly crystals of rubinglimmer and **lepidocrocite**—*vide supra*—show that they should be classed together as one mineral species, but are separated from goethite, with which they had previously been regarded as similar. J. Samojloff, and P. A. Schemjatschensky reported crystals of a mineral optically similar to lepidocrocite, but containing more water than goethite, and he called the mineral **hydrogoethite.** The mineral was found associated with limonite near Lipetzk, and Dankoff, Government Tula, Russia. The mineral is sometimes regarded as the γ-goethite. F. L. Hahn and M. Hertrich obtained it by boiling a neutral or feebly acidic soln. of a ferrous salt with sodium thiosulphate and iodate; or a ferric salt soln. with sodium thiosulphate. The reaction was studied by A. Stock and C. Massaciu. V. Rodt, and W. Mecklenburg and V. Rodt obtained it by exposing ferric sulphide, in the presence of alkalies, to air; and W. H. Albrecht, by oxidizing a soln. of ferrous chloride in the presence of pyridine. J. Huggett obtained lepidocrocite by the prolonged immersion of iron in aerated water.

The analyses of J. Samojloff, P. A. Schemjatschensky, and K. A. Nenadkewitsch correspond with $3Fe_2O_3.4H_2O$. N. S. Kurnakoff and E. J. Rode found 10·89 to

11·22 per cent. H_2O in the samples they analyzed. The analyses of E. Posnjak and H. E. Merwin closely approximate to $Fe_2O_3.H_2O$, so that the composition is taken to be the same as that of goethite. The colour and streak are brick-red, or orange-red. The pleochroism in thicker grains shows α=clear yellow, β=dark reddish-orange, and γ=a darker reddish-orange; in thinner grains, α is nearly colourless or slightly yellow, β and γ are orange to yellow according to the thickness. K. Willmann also discussed the colour and pleochroism of the mineral. The mineral forms red or orange-red, micaceous or scaly crystals on goethite; and it also occurs in bladed, fibrous, or scaly aggregates. The crystals are rhombic, and, according to E. Posnjak and H. E. Merwin, and G. Cesaro and A. Abraham, the axial ratios are $a:b:c=0·43:1:0·64$—*vide supra*, γ-goethite. J. Böhm found that the X-radiograms agreed better with halving the values for the a- and c-axis, thus making $a:b:c=0·308:1:0·246$, and a sp. gr. of 3·97. The dimensions of the elementary lattice are a=3·85 A., b=12·5 A., and c=3·07 A. The (010)-cleavage is perfect, and the (001)-cleavage is not so good. The optic axial angle $2V=83°$, and the axial dispersion is slight. The optical character is negative. P. Gaubert found that goethite and lepidocrocite behave differently in the variation of the dispersion of their optical axes with temp. P. A. Schemjatschensky gave 3·53 for the sp. gr., and J. Samojloff, 3·73. N. S. Kurnakoff and E. J. Rode found the sp. gr. to be between 3·88 and 3·95. E. Posnjak and H. E. Merwin gave 3·841 to 3·854 for the sp. gr. at 25°/25°, and when corrected for the contained siderite, silica, and manganite, 4·07 to 4·12 at 25°/25°. The sp. gr. is therefore smaller than that of goethite. The hardness is 4. The heating curve closely resembles that of goethite, and similarly also with the dehydration curve. The γ-monohydrate is not altered when it is heated in a sealed tube with water at 100°. The indices of refraction are, $\alpha=1·94$, $\beta=2·20$, and $\gamma=2·51$. Hence, although the chemical composition of lepidocrocite is the same as that of goethite, the crystallographic constants, the sp. gr., and the refractive index of the crystals are quite distinct. Consequently, monohydrated ferric oxide is dimorphous, and the two forms are represented by goethite and lepidocrocite; while hydrogoethite is a variety of lepidocrocite. According to W. H. Albrecht and co-workers, and O. Baudisch and W. H. Albrecht, the magnetic properties of artificial specimens of the hydrated ferric oxide show a distinct change with the age of the specimen, whereas determinations of the water-content and the X-radiograms indicate stability. Ageing under water causes a diminution of the susceptibility of both hydrates, whereas desiccation at 100° in a current of air diminishes the susceptibility of the α-hydrate but increases greatly that of the γ-hydrate. The natural or synthetic α-hydrate is more stable than the γ-hydrate; dehydration of the α-hydrate affords the α-oxide, whereas the γ-hydrate gives the γ-oxide which passes at a higher temp. into the α-oxide. W. H. Albrecht observed that the preparation obtained from the ferrous salt soln. had a magnetic susceptibility between 37×10^{-6} and 74×10^{-6}; E. F. Herroun and E. Wilson gave 42×10^{-6}. When heated, the susceptibility rises rapidly to $39,500\times10^{-6}$, and then falls again. For J. Huggett and G. Chaudron's observations, *vide* goethite.

In the first century of our era, Dioscorides, in his *Περί ὕλης ἰατρικῆς* spoke of the *σχίστος λίθος*, and Pliny, in his *Historia naturalis*, of the *schistos*; and G. Agricola,[7] J. G. Wallerius, and A. Cronstedt regarded these minerals as equivalent to the red iron ore, or *Glaskopf*—that is, with black, brown, or red *hæmatites hemisphæricus*. This subject was discussed in connection with hæmatite or ferric oxide. The *ὤχρα*, or *ochres*, mentioned in the *Περί λίθων* of Theophrastus about 315 B.C., is represented by the *ochra nativa* or the *Berggeel* of G. Agricola; the *ochra nativa*, the *Berggelb*, and the yellow ochre of C. Gesner; and the *ochriger Brauneisenstein* of A. G. Werner, and D. L. G. Karsten. J. G. Wallerius, A. G. Werner, R. Hermann, L. A. Emmerling, and A. Breithaupt co-ordinated with the iron ores—*Brauneisenstein*, and *Raseneisenstein*—various earths including *minera ferri subaquosa*, *minera ferri lacuotris*, and *minera ferri palustris*, as well as *brown ironstone*, *brown hæmatite*, *brown ochre*, *marsh ore*, *bog ore*, *meadow ore*, etc., and *Sumpferz*, *Modererz*, *Pfennigerz*, *Morasterz*, *Wiesenerz*, etc. J. S. Kennedy objects to the use of the term "brown hæmatite" for limonite. J. F. L. Hausmann included in the term *Brauneisenstein* various iron ores: *Rubinglimmer*, or *ruby mica*, ledpidocrocite, and *Sammetblende*; drossy, compact, and ochreous iron ores; *Pecheisenstein* or *Eisenpecherz*; *Glanzeisenstein*; *Hyposiderite*; *Quellerz*; *Gelbeisenstein*, etc., mentioned by C. K. Stifft, J. Brunner, J. L. Jordan, and J. C. Ullmann. The yellow, waxy, pitch-like ore was called by J. C. Ullmann *stilpnosiderite*—from στιλπνός, shining; and σίδηρος, iron—only in very exceptional cases can this be regarded as a shining ore; and D. L. G. Karsten, and M. H. Klaproth, *pittizite*—from πιττίζω or πισσίζω, waxy; but J. F. L. Hausmann's term **limonite**—from λεμών, a meadow—is usually employed for *Eisenoxydhydrat mit dem Minimum des Wassers*. F. S. Beudant employed the term "limonite" in a more general sense than the "yellow bog ore" of J. F. L. Hausmann. A. Breithaupt, F. von Kobell, C. C. von Leonhard, and E. F. Glocker made observations on this subject. The early analyses reported by J. F. d'Aubuisson de Voisins, R. J. Haüy, J. F. L. Hausmann, J. C. Ullmann, J. L. Proust, and M. H. Klaproth showed that the varieties of yellow bog ore had a composition ranging from $2Fe_2O_3.3H_2O$ to $Fe_2O_3.2H_2O$; while R. Hermann's *Quellerz* was represented by $Fe_2O_3.3H_2O$, and J. D. Dana applied the term **limnite**—from λίμνη, a lake—to this earth, while $2Fe_2O_3.3H_2O$ was regarded as the composition of limonite, the term **xanthosiderite**—from ξανθός, yellow; σίδηρος, iron—was applied by E. E. Schmid to the yellow ochreous, bog ore, or the *Gelbeisenstein* of J. F. L. Hausmann, to which the formula $Fe_2O_3.2H_2O$ had been assigned. This subject was discussed by G. Tschermak, J. Böhm, M. Bauer, and C. Hintze. The Hungarian *kaliphite* of M. Ivanoff is, according to J. D. Dana, a mixture of limonite, manganese oxides, and silicates of calcium and zinc.

J. D. Dana said that limonite has various shades of brown, generally dark and dull, and that it sometimes has a black, varnish-like, or pitch-like exterior; and when earthy, it is brownish-yellow, or ochreous-yellow. The streak is yellowish-brown. It does not occur crystalline, and commonly occurs in stalactitic, botryoidal, or mammillary forms having a fibrous or sub-fibrous structure; it also occurs concretionary, massive, and earthy. The varieties are: (i) *Compact*—with a submetallic or silky lustre, often stalactitic, botryoidal, etc. It includes brown *Glaskopf*. (ii) *Ochreous*—is brownish-yellow to buff-yellow and earthy; and it often contains impurities like clay, sand, etc. (iii) *Bog ore*—from marshy places, is loose or porous in texture, and contains fossilized leaves, wood, etc. (iv) *Brown clay ironstone*—in compact masses or concretionary nodules with a brownish-yellow streak different from the streak of clay ironstone. Brown clay ironstone may be (*a*) *pisolitic*, or in aggregate concretions the size of peas—*bean ore* or *Bohnerz*; and (*b*) *oolitic*. The brown limonite, found in Luxemburg, Lorraine, and the Rhineland, consists of oolitic grains bound together by a cement of chalk, clay, or silica. It is called minette. According to E. Schroedter, W. Gill, and H. Wandesleben, it is used in the manufacture of basic steel. Numerous analyses of limonite have been reported.

For example, L. C. Beck, C. Borgemann, A. W. G. Bleeck, R. Böttger, G. C. du Bois, A. Breithaupt, A. Brunlechner, G. J. Brush, C. F. Bucholz, A. H. Church, E. Cohen, J. D. Dana, A. S. Eakle, C. F. Eichleiter, J. Eyerman, G. Einecke and W. Köhler, R. Fluhr, H. B. von Foullon, C. Gäbert, C. W. von Gümbel, E. Hatle, C. von Hauer, S. Haughton, F. M. Heddle, R. Hermann, T. C. Hopkins, T. S. Hunt, W. Jaworsky, C. von John, F. Katzer, W. Knaust, G. A. Kenngott, F. Klockmann, F. von Kobell, W. Kohlmann, F. Kretschmer, A. Lacroix, H. Leitmeier and M. Goldschlag, T. Liebisch, E. Manasse, A. Müller, T. L. Phipson, J. J. Pohl, B. Popoff, E. Posnjak and H. E. Merwin, F. Prime, C. F. Rammelsberg, G. von Rath, R. W. Raymond, A. Sachs, J. Samojloff, P. A. Schemjatschensky, E. E. Schmid, J. B. Schober, H. Schönberg, A. von Schrötter, H. Simons, E. G. Smith, J. L. Smith, J. W. E. Söchting, H. Struve, J. Thiel, G. Tschermak, J. C. Ullmann, N. Watitsch, F. Weltzien, A. J. F. Wiegmann, T. Wiese, and S. Wittich and B. Neumann. N. S. Kurnakoff and E. J. Rode found 10·85 to 16·58 per cent. of H_2O in the samples they analyzed.

Many of the samples of limonite contain silica, according to F. Wöhler, mainly as silicates, or clay; others contain alumina as clay, bauxite, or laterite—a subject discussed by M. Bauer; phosphates, sulphates, and manganese compounds are commonly present; R. Böttger, T. Bodemann, A. Müller, F. J. Otto, V. Merz, L. R. von Fellenberg, and T. L. Phipson found vanadium present in some of the limonites; and W. N. Hartley and H. Ramage detected spectroscopically, sodium, potassium, rubidium, silver, copper, calcium, manganese, nickel, thallium, chromium, gallium and indium in different limonites. The *ochres* are yellow earthy varieties of limonite contaminated with clay, etc. They were discussed by G. Gin, G. H. Hurst, A. Bouchonnet, F. Rose, A. G. Gentèle, G. Zerr and R. Rübencamp, etc. Likewise also with the *terra di siena*, or the *siennas*, which derive their name from the Italian town of Sienna. The siennas are redder than the ochres, and they were discussed by G. H. Hurst, F. Rose, A. G. Gentèle, G. Zerr and R. Rübencamp, etc. Some of the red earths are called *bole*, *Indian red*, *Venetian red*, raddle, etc. The umbers are browner than either the ochres or the siennas. Their name is derived from Umbria, an Italian town now known as Spoleto. They were discussed by G. H. Hurst, F. Rose, A. G. Gentèle, G. Zerr and R. Rübencamp, etc. Some dark brands of umber are called *Cassel brown*, and *Cologne earth*.

Attempts to find a formula for limonite gave F. von Kobell, E. Manasse, and F. S. Beudant **hemitrihydrated ferric oxide,** $2Fe_2O_3.3H_2O$, or $H_6Fe_4O_9$, results commonly used to represent the composition of limonite. J. F. L. Hausmann said that J. L. Proust's analysis agreed better with $Fe_2.O_3.2H_2O$. E. Posnjak and H. E. Merwin found that when an allowance is made for impurities, and for capillary and adsorbed water, the composition approximates closely to $Fe_2O_3.H_2O$; and this agrees with F. von Kobell's hypothesis, that limonite or stilpnosiderite is *wahrscheinlich Goethite im amorphen Zustande*. C. Hintze also supported the hypothesis that limonite is **colloidal monohydrated ferric oxide,** or **colloidal goethite**—*vide infra*. P. A. Thiessen and R. Köppen found that the dehydration curves agreed best with the assumption that limonite is a hemihydrate, like goethite, but with adsorbed water. R. Gaubert came to a similar conclusion in his study of the dispersion of the optic axes of the two minerals, and also of the action of hydrochloric and hydrofluoric acids on fibrillar limonite and goethite.

There are numerous deposits of limonite and the hydrated ferric oxides being formed as deposits from spring waters, etc., at the present day. H. Leitmeier and M. Goldschlag observed brown xanthosiderite on the walls of a mine in Payerbach, Austria, where, after two years' exposure to the atmosphere, the colour darkened, and the structure became granular and crystalline. Thus, E. C. Case[8] found a deposit being formed by the well water near Lawrence close to the Kansas River. The cellular structure of the so-called *boxwork limonite* was discussed by F. P. Boswell and R. Blanchard. E. Cohen observed stilpnosiderite in the meteorite from Beaconsfield, Australia. C. G. Ehrenberg noticed that yellow ochre or limonite contains extremely delicate branched threads indicating the presence in the original waters of an organized body containing an extremely large proportion of iron. J. C. Brown, D. Ellis, and H. Molisch have shown that the slimy streamers which develop in water conduit pipes, and on the walls and bottoms of shallow, water-storage reservoirs, are masses of hydrated ferric oxide whose existence is due to the activities of *iron bacteria*—Leptothrix ochracea, Gallionella ferruginea, Spirophyllum ferrugineum, Crenothrix polyspora, Cladothrix dichotoma, etc. The nodular excrescences, and tubercular incrustations found in iron pipes conveying water are due to the chemical action of dissolved carbon dioxide in the water, and the local enrichments of carbon dioxide facilitate the change of iron into soluble carbonate which is then oxidized to hydrated ferric oxide. The ferruginous incrustations found on the walls of iron conduit pipes (the walls, however, are not corroded) are considered to be the work of iron bacteria, assisted possibly by other organisms. The formation of spongy iron in iron water-pipes is due to the attack of acids in the water, or soil, and not to iron bacteria. This subject has been discussed by

O. Aschan, J. M. van Bemmelen, A. Beythien and co-workers, O. Casagrandi, N. Cholodny, F. Cohn, C. L. Dake, W. D. Francis, N. Gaidukoff, J. W. Gruner, E. C. Harder, N. J. Harrar, W. H. Herdsmann, C. R. van Hise, K. Höflich, A. Irving, D. D. Jackson, J. D. Kendall, J. Lafar, C. Mettenheimer, W. Migula, A. Molisch, E. M. Mumford, B. V. Pyaskovsky, E. Raumer, O. Rössler, W. Rullmann, C. Sauvageau and M. Radais, J. B. Schober, H. Schwers, H. C. Sorby, R. L. Starkey and H. O. Halvorson, C. Tolomei, S. Winogradsky, C. Zapffe, and W. Zopf—*vide supra*, the corrosion of iron. J. W. Gruner summarized his conclusions on the action of humic acids as follows:

> Soln. from decaying plants dissolve all oxides and carbonates of iron, and most of the silicates, but do not seem to attack pyrite appreciably. The strength of such soln. is similar to that of carbonic acid. It is possible that carbonic acid is the chief acid of the so-called "natural organic acids" but the organic colloids in such soln. give special properties to them. One of the differences between natural organic soln. and carbonic acid is that the organic soln. reduce ferric iron compounds to soluble ferrous salts, while carbonic acid does not.

The solvent action of carbonated waters was discussed by W. B. and R. E. Rogers, R. Müller, W. P. Headden, and J. W. Gruner—*vide infra*. O. Schreiner and E. C. Shorey observed that:

> Hydroxy-acids of the fatty series are very widely distributed in the vegetable kingdom—malic, citric, tartaric, glycollic, lactic, butyric, formic, and acetic acids; there is no doubt that vegetable acids of this group are added to soils in large quantities and become, temporarily at least, a part of the organic matter of the soil;

while E. C. Harder stated that "according to the extent to which organic acids are present, iron may be carried in soln. as salts of those acids. It is not impossible that such organic salts as iron formate, iron butyrate, iron lactate, or iron citrate may occur in iron-bearing waters." The subject was investigated by N. J. Harrar.

There are many and varied deposits of limonite in various parts of the world. The limonite is in all cases assumed to have been formed by the alteration of ferruginous minerals and rocks by exposure to air, moisture, etc. The subject was reviewed by F. W. Clarke,[9] C. Doelter, and F. Beyschlag and co-workers. Pseudomorphs of limonite after copiapite, cerussite, and copper pyrites were mentioned by A. F. Rogers; after anhydrite and diabantite, by B. V. Emerson; and after marcasite, by H. Laubmann, P. von Jeremejeff, P. N. Tschirwinsky, H. B. North, N. Watistsch, and L. Dürr. Outcrops of sulphide ores—*e.g.* pyrite or chalcopyrite—are often altered to masses of porous limonite: and pseudomorphs after pyrite are very common—*e.g.* R. W. Raymond, etc. The gossan caps of limonite on sulphide ores have also been formed by the oxidation and hydration of the mineral—*vide* the formation of manganese deposits, **12.** 64, 2. E. Newton said that the manganiferous iron ores of Minnesota were partly formed by the leaching of ferruginous limestone by alkaline soln.; and the removal of iron by the leaching of iron silicate rocks was discussed by J. W. Gruner, T. S. Lovering, L. Cayeux, and R. A. F. Penrose; while L. Dieulafait, J. P. Kimball, C. W. Hayes, C. W. Hayes and E. C. Eckel, S. W. McCallie, H. C. Sorby, G. Keller, and A. F. Foerste discussed the pseudomorphous replacement of limestone by percolating soln. of iron salts, and the formation of residual limonite from ferruginous limestone by the simultaneous oxidation of ferrous carbonate, and the dissolution of calcium carbonate. The formation of limonite from pyrite and marcasite has been described by G. Bischof, P. N. Tschirwinsky, M. Watanabe, E. Cohen, H. M. Chance, F. Cornu and H. Leitmeier, O. Mügge, A. Pelikan, and J. von Roth; and from siderite by G. Bischof, K. von Bülow, E. Hatle, R. Helmhacker, and K. A. Redlich. E. V. Shannon said that the presence of chlorides promotes the formation of hydrated ferric oxide.

Limonite may be found as a residual deposit where it was formed, and, according to C. K. Leith and W. J. Mead, J. F. Kemp, W. G. Miller, W. E. Pratt, G. O. Smith and B. Willis, A. C. Spencer, and C. M. Weld, it may have been formed by processes analogous to those concerned in the production of laterites—**5**. 33, 8. Limonite, like clays, may have been mechanically transported by streamlets from surrounding hills and deposited as bog ore in marshy places, and in pools where the velocity of the streamlet is sluggish, and the excess may be carried by rivers into the sea. The iron may also be transported in soln. dissolved as (i) hydrocarbonate in carbonated waters, (ii) as sulphate in water with acids derived from the oxidation of the sulphur in pyrites, or (iii) as a salt of an organic acid in peaty and other waters. It may have been deposited from such waters in the form of bog ore, or in stalactitic, tuberose, and other concretionary forms. Carbonated waters extract iron as ferrous hydrocarbonate from silicate rocks or from disseminated magnetite, and the soln. of the hydrocarbonate in carbonated waters, or the soln. of iron as sulphate from oxidized pyrites may deposit limonite when oxidized either by exposure to air, or, according to N. S. Shaler, by contact with oxygen given off by the respiration of aquatic plants —*e.g.* bog ores are more abundant along the margins of swamps, and are often wanting at the centre. The decomposition of the soln. of ferrous hydrocarbonate may be facilitated or produced by iron-bacteria which adsorb iron and re-deposit it in the form of hydrated ferric oxide, as indicated by G. Tolomei, J. M. van Bemmelen, W. D. Francis, E. C. Harder, etc.—*vide supra*—and E. S. Moore discussed the formation of bog ore by the action of algæ and lower plants on chalybeate waters. H. Molisch, for instance, found that under the influence of light, there is a separation of hydrated ferric oxide from soln., and an evolution of oxygen. Sulphate soln. may oxidize on exposure to air to form hydrated ferric oxide, and sparingly soluble basic salts; or they may precipitate the hydrate by contact with limestone or other carbonates, or phosphates, or with organic matter. In illustration of the solvent action of the organic acids in peaty and swamp waters, A. Kindler said:

> On the declivities of sand-hills planted with pine trees, and where springs, lying lower down, cause falls of earth, dead roots which penetrate through the ferruginous quartz sand absorb the rain-water filtering through. A decomposition commences, by which acids are formed, which are capable of dissolving large quantities of ferrous or ferric oxide; for in a few months the sand becomes as white as if it had been treated with acid. The action of a root, two lines in thickness, extends to a distance of from one to two inches. This phenomenon also presents itself in woods and gardens, for decolorized sand is found everywhere under rotting leaves.

R. J. Hartman and R. M. Dickey discussed the formation of banded iron formations by the diffusion of iron salts in silica gels.

A. Daubrée also observed this decolorization of ferruginous sands by roots. If a decaying root and quartz sand coloured with iron oxide be often moistened with water, the filtrate will be found to contain iron. When such soln. are oxidized, hydrated ferric oxide is deposited. As mentioned by G. Bischof, the rusty deposits about chalybeate springs, and the iridescent films of hydrated ferric oxide on the surface of marshes and swamp waters illustrate this reaction. This subject was discussed by J. M. van Bemmelen, W. Spring, and O. Aschan. W. H. Weed explained the formation of *iron-sinter* by an analogous process. When the waters deposit their ferruginous load where air has free access, limonite is formed, but if the deposition occurs in the presence of decaying organic matter and carbon dioxide, ferrous carbonate or siderite may be deposited. Hence, also—as noticed by H. Taylor, R. Phillips, and P. Kremers--the presence of ferrous iron in ferruginous clays, and soils. O. C. S. Carter observed a ferruginized tree in which part of the wood was replaced by brown hæmatite. H. Hess found some stag antlers changed to iron ore in the bog-iron ore deposit of Posen. The cementing action of hydrated ferric oxide in rocks like sandstones was discussed by W. Spring. According to K. Endell, rust, or hydrated ferric oxide is found in meteorites penetrating into the iron mass in the form of a tube which exhibits a rhythmic structure. The formation is held to be due to the setting up of local electric currents when the mass is moist, whereby ferrous hydroxide is first formed; this is oxidized, and the ferric hydroxide is deposited. R. J. Hartman and R. M. Dickey discussed the rhythmic phenomenon in the iron ores of Lake Superior.

The formation of limonite was also discussed by B. Aarnio, J. Ahlburg, J. P. Arend, O. Aschan, A. Bergeat and A. W. Stelzner, R. Blanchard and P. F. Boswell, A. W. G. Bleeck, R. A. Brauns, E. van den Broeck, A. Brongniart, K. von Bülow, J. M. Campbell, L. Cayeux, C. L. Dake, A. Daubrée, C. Deffner, E. Döll, G. Einecke and W. Köhler, A. Gärtner, A. Gressley, A. de Grossouvre, G. D. Hubbard, P. von Jeremejeff, F. Katzer, K. Keilhack, J. F. Kemp, A. Kindler, J. Klärding, P. Krusch, A. E. Kupffer, M. Lazarevic, C. K. Leith and W. J. Mead, A. Leppla, J. Levallois, A. Merle, W. G. Miller, E. S. Moore, M. Neumayr, J. S. Newberry, H. W. Nichols, W. E. Pratt, R. W. Raymond, G. Reinders, G. Schmidt, F. Senft, H. Sjögren, G. O. Smith and B. Willis, A. C. Spencer, F. M. Stapff, M. Tecklenburg, E. Thirria, L. Tokody, P. von Tschirwinsky, A. Vierschilling, C. M. Weld, B. A. Wendeborn, and F. Zirkel. The formation of pisolitic ores was discussed by A. Bergeat and A. W. Stelzner, F. Beyschlag, M. Brauhäuser, C. Chelius, C. Deffner, R. Delkeskamp, B. Fach, O. F. Fraas, L. Hoffmann, E. Hollmann, F. Klockmann, W. Kuhn and W. Meigen, R. Lang, A. Moos, H. Münster, F. W. Pfaff, H. Simons, H. Stremme, H. Tasche, and F. W. Voit; and the formation of oolitic ores or mimette, by A. Bencke, L. Cayeux, F. Gaub, L. Hoffmann, J. M. Jegunoff, W. Kohlmann, A. E. Kupffer, B. Popoff, H. Schneiderhöhn, C. H. Smyth, J. Thoreau, and L. van Werveke.

The hemitrihydrated ferric oxide, $2Fe_2O_3.3H_2O$, formerly supposed to represent the composition of limonite, was reported by J. J. Berzelius [10] to be formed as *iron-rust*, or *crocus martis aperitivus*, when iron oxidizes in aerated water. J. Lefort obtained this hydrate by precipitating a hot soln. of a ferric salt with alkali-lye and drying the washed product over sulphuric acid; L. P. de St. Gilles used aq. ammonia as precipitant, and dried the product in vacuo. F. Muck said that the *tritapentahydrate*, $3Fe_2O_3.5H_2O$, is produced when a basic ferric sulphate is added to molten potassium hydroxide, and after a short time the product is cooled, washed with water, and dried at 100°. O. Ruff obtained a similar hydrate by heating red, colloidal ferric oxide with water between 30° and 42·5°, and at 5000 atm. press. H. Wölbling regarded O. Ruff's products as mixtures of anhydride and hydrate. From the preceding discussion, it follows that despite plausible formulæ based on analyses, there is nothing to show that a definite hydrate is formed as a chemical individual, for the composition depends on the arbitrary conditions selected for the desiccation. G. C. Wittstein added that if the amorphous hydrate be kept under water a couple of years it becomes crystalline. According to A. Krause, ferrous hydroxide precipitated from a soln. of ferrous sulphate by an equimolar quantity of sodium hydroxide, yields on atm. oxidation, hydrated ferric oxide, but if the soda-lye is highly concentrated, the oxidized product always contains ferrous oxide, the highest ratio being $FeO : Fe_2O_3 = 0·3 : 1$. As the ferrous oxide increases, the colour changes from yellow to black, with a decrease in the water-content corresponding with a change from *meta*ferric hydroxide to ferrous ferrite. The isoelectric point of the hydroxide with the composition approximately $Fe_2O_3.2H_2O$, is nearly $p_H = 5·2$. Confirmation of this hypothesis of ferrite formation is obtained by oxidizing ferrous hydroxide in the presence of magnesium hydroxide, when magnesium ferrite is formed. The meta-form of ferric hydroxide differs from the brown ortho-form in having its isoelectric point $p_H = 7·7$, its ease of peptization, and its greater grain-size. The ortho-form is less stable under water, where it gradually passes to the meta-form. This change is much accelerated by the presence of OH′-ions, and at the same time, the isoelectric point changes from $p_H = 5·2$ to 7·7. The dried meta-oxide contains less water than the ortho-form, it is brownish-yellow instead of black, is more friable, and adheres more firmly to glass. The meta-oxide can be readily peptized by either dil. acid or ammonia, but not so with the ortho-oxide.

The **colour** of limonite ranges from dark brown to light yellowish-brown, dark yellow, and ochre-yellow. A. Bergeat [11] considered that the colour depends on the proportion of contained clay, and not on the proportions of iron or manganese. He found with three samples:

	Clay	Fe per cent.	Mn per cent.
Dark chestnut-brown . . .	scarcely any	59·90	0·17
Chestnut-brown	a little	67·61	0·11
Ochre-brown	much	44·00	0·29

W. D. Bancroft attributed the colour to adsorbed iron salts—*vide supra.* For R. Gaubert's observations on the identity of fibrillar limonite with goethite, *vide supra,* goethite. J. Böhm examined the X-radiograms of xanthosiderite, limonite, and limnite. E. Wedekind and W. Albrecht noted the appearance of interference lines in the X-radiograms during the ageing of the gels. J. W. E. Söchting gave 3·40 to 4·17 for the **specific gravity** of limonite; C. Bergemann, 3·908; E. Posnjak and H. E. Merwin, 3·841 to 4·172 at 25°/25°; and when an allowance is made for the contained siderite, manganite, and silica, 4·30 to 4·34 at 25°/25°. N. S. Kurnakoff and E. J. Rode found the sp. gr. to range from 2·7 to 4·01. Brown compact limonite has a **hardness** of about 5, and when freshly dug, sometimes over 5; but the hardness of other kinds ranges from 1 to 5. F. D. Adams found a cubic pseudomorph of limonite after pyrite was crushed to powder under a compression of 43,000 lbs. applied in 17 mins., without showing signs of plastic deformation. J. Joly found the mean **specific heat** of limonite to be 0·2263 between 13·3° and 100°; and of limonite pseudomorphous after pyrite, 0·2215 between 13·6° and 100°. The values calculated by the additive rule are respectively 0·22632 and 0·22155. R. Ulrich gave 0·2235 for the sp. ht. between 17° and 98°. E. Posnjak and H. E. Merwin found that the **heating curves** of limonite may show a slight thermal effect at about 100°. N. S. Kurnakoff and E. J. Rode's observations on this subject have been discussed in connection with turgite (*q.v.*). H. W. Fischer found that the **dehydration curves** of limonite show that water is lost rapidly below 100°, then sparingly, though continuously, up to 165°, and beyond that temp. the loss is very large, and is accompanied by a change in colour from yellow to red. He said that this behaviour is characteristic of that of a colloidal hydrate, and a marked effect at about 300°. By measuring the loss of water when specimens are kept at different temp. over 4 months, they obtained a curve very similar to that obtained with goethite. This, coupled with the sp. gr. data, etc., favours the hypothesis that limonite is colloidal goethite or monohydrated ferric oxide. When bog-iron ore is heated to 325° to 400°, F. Muck, N. S. Kurnakoff and E. J. Rode, etc., found that a calorescence occurs—*vide supra,* hæmatite. The subject was studied by R. Gaubert. E. Posnjak and H. E. Merwin found that limonite contains layers, splinters, filaments, or other portions with a **refractive index** 1·99 to 2·07; and in some cases with a red material having a refractive index of 2·2 to 2·3 resembling turgite, and in other cases having a refractive index of 2·4 and a strong double refraction like turgite. A. Pelikan gave $\gamma-\alpha=0{\cdot}048$ for the **double refraction.** As a result of their examination of various limonites, E. Posnjak and H. E. Merwin said: When monohydrated ferric oxide is precipitated and hardened under natural conditions which do not permit definite crystallization, a porous mass is formed containing considerable excess of water, besides other impurities. So indefinite is the material that it cannot be characterized very satisfactorily. Its colour in fine powder is scarcely distinguishable from that of fibrous goethite. Although often occurring in compact layered or botryoidal forms, it does not possess decided fibrous fracture. The earthy varieties consist of minute, loosely agglomerated spheroidal grains. Air-dried material possesses some pores of such size that, although microscopically invisible, they readily fill with such liquids as are used to immerse the grains for microscopic study. Thus, refractive index determinations cannot be definitely interpreted; air-dried material does have observed apparent refractive indices within the rather narrow limits of about 2·00 to 2·10 when saturated with a liquid of corresponding refractive index. Such material is here regarded as limonite. Double refraction is common in such material, usually it is indefinite and not strong, but occasionally it reaches 0·04 and is almost as definite as in fibrous goethites. For example, in the cylindrical crusts around stalactites and in the spheroidal grains, the ray vibrating along the radius is not strongly refracted as in fibrous goethite. In rare cases a decided tendency for minute fragments to be splintery makes this material look somewhat like fibrous goethite. E. Puseddu and A. Marini found that limonite from Bena de Padru, Sardinia, contains radioactive impurities. F. Beijerinck observed that the **electrical conductivity** is negligible. R. D. Harvey studied the subject. T. W. Case observed no change in its resistance on exposure to light. E. E. Fairbanks found the **dielectric constant** to be 9·9 to 15. H. B. Kosmann observed that the limonite from Harteberg, Silesia, is **magnetic.** F. Stutzer and co-workers gave 222×10^{-6} for the coeff. of magnetization of limonite; and G. Grenet obtained values ranging from 27×10^{-6} to 160×10^{-6}. A. Abt observed that a sample of limonite shows scarcely any magnetic moment. For the magnetic susceptibility, *vide infra*, the *trihydrate*. The magnetic separation of limonite was discussed by C. Jones, W. B. Phillips, and H. A. J. Wilkens and H. B. C. Nitze. A. Quartaroli prepared a magnetic variety—*vide supra*, magnetic ferric axide.

According to L. P. de St. Gilles, the hydrated ferric oxide dissolves in **acetic acid.** The presence of a little ammonia hinders the dissolution. F. Cornu found that limonite may exhibit a strong acidic reaction, possibly owing to the presence of basic sulphates—which E. Cohen found in limonites derived from pyrite. Limonite is soluble in **hydrochloric acid,** and it may leave behind a siliceous skeleton—the silica in limonite was discussed by F. Wöhler, J. F. L. Hausmann, C. H. Smyth, F. M. Stapff, and L. van Werveke. The action of hydrofluoric acid and of hydrochloric acid was studied by R. Gaubert; of hydrogen sulphide, by M. Mainz and M. Mühlendyck; and the reducing action of methane, by O. Meyer and W. Eilender.

J. F. L. Hausmann [12] found silky needles of hydrated ferric oxide associated with the manganese ores at Ilmenau, and elsewhere. It was called **xanthosiderite** —*vide supra*—by E. E. Schmid. It forms golden-yellow needles or fibres which may also appear brown or brownish-red. As an ochreous earth it is different shades of brown or brownish-red. The needles may occur in radiating or concentric aggregates. Xanthosiderite may have a silky, greasy, pitch-like, or an earthy lustre; and the streak is ochreous yellow, or pale brown to dark brown. Analyses were reported by J. F. L. Hausmann, E. E. Schmid, C. F. Rammelsberg, and S. Haughton, and as a result it came to be regarded as **dihydrated ferric oxide,** $Fe_2O_3.2H_2O$, or, with less justification, $Fe_2O(OH)_4$. J. L. Proust's analysis of a substance like limonite agreed with the dihydrate formula. N. S. Kurnakoff and E. J. Rode found 11·84 to 13·83 per cent. of water. Samples examined by E. Posnjak and H. E. Merwin had 9·92 to 10·22 per cent. water, and then had more the character and composition of goethite. J. Lefort said that dihydrated ferric oxide is produced when it is precipitated from a cold soln. of a ferric salt by cold alkali-lye, and dried over sulphuric acid; and F. Weltzien, by mixing a soln. of ferrous sulphate with potash-lye, and then with an excess of hydrogen dioxide, and drying the product at 100°. E. Brescius found that when the precipitate obtained by adding ammonia to ferric chloride is washed and dried over sulphuric acid, for 3 months, it contains 13·6 per cent. of water; while if the precipitate be washed with alcohol and then with ether, and dried for 2 months under the same conditions, its composition corresponds with the dihydrate $Fe_2O_3.2H_2O$, which loses half its water at 100°. For D. Tommasi's observations on the α- and β-dihydrates, *vide supra*. A. Vesterberg obtained the dihydrated oxide, pseudomorphous after ferric sulphate, by adding reduced iron powder to hot, dil. sulphuric acid (1 : 1), and heating the mixture until the acid begins to fume and the iron is transformed into a faintly red, crystalline powder of ferric sulphate. The acid is poured off as completely as possible and the crystals, without being washed, are placed in water and shaken with a soln. of sodium hydroxide (1 : 2). The copper-coloured, crystalline meal is finally washed with hot water and dried at the ordinary temp. The substance forms six- or eight-sided, isotropic plates, has a yellowish-brown or reddish-brown colour, and is very friable. The sp. gr. of xanthosiderite, reported by N. S. Kurnakoff and E. J. Rode, is 3·76; A. Vesterberg gave 3·234 at 15°.

E. E. Schmid gave 2·5 for the hardness. A. Vesterberg's product passed into the monohydrate in a desiccator, and lost more water at 100°. J. Lefort's product also lost water at 75°. E. Posnjak and H. E. Merwin obtained a dehydration curve very like that obtained for goethite (*q.v.*). H. W. Fischer discussed this subject; and N. S. Kurnakoff and E. J. Rode's observations are also indicated in connection with goethite. It is supposed that a colloidal γ-solid soln. of xanthosiderite and water decomposes at 120°–150°, forming the β-solid soln. of goethite and water; and that this, at about 200°, forms the α-solid soln. of hæmatite and water. F. Muck said that the dihydrate does not show a calorescence when heated. E. Posnjak and H. E. Merwin's samples of xanthosiderite had fibres with the index of refraction α near 2·27, β near 2·33, and γ near 2·37, but all were variable. The yellow colour was attributed to the presence of minute pores and inclusions. A. Vesterberg said that the dihydrate dissolves rapidly in 20 per cent. hydrochloric acid.

According to J. D. Dana,[13] the analyses of A. H. Church, R. Hermann, and C. J. B. Karsten of bog ore, the *Quellerz* of R. Hermann, and *Raseneisenerz,* approximate in composition to **trihydrated ferric oxide,** $Fe_2O_3.3H_2O$, and J. D. Dana called the earth **limnite**—from λίμνη, a marsh—*vide supra.* E. F. Glocker had previously proposed the term as a substitute for limonite. It occurs as an earthy, yellow ochre; and in stalactites and tuberose forms resembling limonite. It is not regarded as a definite mineral species, but rather as a hydrated limonite; the hydrate is also designated **ferric hydroxide,** $Fe(OH)_3$, but here again there is little evidence in favour of the assumption of a definite hydroxide in the chemical sense of the word. P. A. Thiessen and R. Köppen's dehydration curves indicate that limonite is goethite with absorbed water. G. C. Wittstein obtained what he regarded as this substance by adding ammonia to a soln. of ferric sulphate, and washing the product, and drying it first at a gentle heat and then at 100°. The amorphous, yellow product, under freezing water, forms a granular, yellowish-brown powder which appears to consist of microscopic crystals. P. Fireman, and R. S. Penniman and N. M. Zoph observed the formation of a hydrated oxide with 13·63 per cent. of water by passing air through a soln. of an iron salt in the presence of iron. J. Matuschek observed the formation of the hydrated oxide when soln. of potassium ferrocyanide are exposed to light. F. L. Hahn and M. Hertrich obtained the hydrated oxide in a heavy, powdery form which is easily filtered and washed, and which is free from basic salt, by warming on a water-bath a neutral soln. of a ferric salt—containing, say, 0·2 grm. Fe_2O_3 per 400 c.c.—with sodium thiosulphate until the soln. is colourless; the soln. of ferrous salt is then warmed with a slight excess of potassium iodate: $2Fe^{\cdot\cdot}+3H_2O+IO_3'+4S_2O_3''=2Fe(OH)_3+I'+2S_4O_6''$. H. V. Kohlschütter studied the product obtained by the action of aq. ammonia on crystals of ferric sulphate. D. N. Ghosh observed the rhythmic precipitation of the hydroxide. N. J. Harrar and F. E. E. Germann studied the colours of soln. of ferric hydroxide in various acids; and G. G. Rao and N. R. Dhar, the catalytic action on the photo-synthesis of formaldehyde from alkali hydrocarbonates. According to H. Molisch, hydrated ferric hydroxide is precipitated by the action of light on certain dil. soln, containing salts of iron; for example, iron ammonium citrate; whilst a soln. of ferrous sulphate and ferrous hydrogen carbonate deposits ferric hydroxide on remaining even in the dark. J. Thomsen gave for the **heat of formation** $(2Fe,3O,3H_2O)=191:15$ Cals.; and $(2Fe(OH)_2,O,H_2O)=54·59$ Cals. K. Inoue studied the heat of dehydration of bog-iron ore. K. Jellinek and H. Gordon gave 10^{-38} for the solubility product $[Fe^{\cdot\cdot\cdot}][OH']^3$, and G. F. Hüttig and H. Kittel found that the magnetic susceptibility varies with the mode of preparation. Samples with $Fe_2O_3.nH_2O$, with $n=3·162$, 2·434, and 1·699, had the respective values $105·4\times10^{-6}$, $114·3\times10^{-6}$, and $124·5\times10^{-6}$ mass unit.

Observations on the magnetic susceptibility were made by M. Faraday, C. B. Greiss, and A. Abt. E. F. Herroun and E. Wilson obtained for limonite $31·6\times10^{-6}$ mass unit; G. Wistrand, $123·8\times10^{-6}$; and F. Stutzer and co-workers, $59·4\times10^{-6}$. S. Veil found that the magnetic susceptibility depends on the previous states through which the material has passed, and the temp. to which it has been heated. W. Albrecht found that the magnetic susceptibility of the hydrated ferric oxides depends on the mode of preparation, etc.—*e.g.* dehydration in open or sealed tubes under water at 100° ; interaction of iron pentacarbonyl and an alcoholic soln. of hydrogen dioxide ; adding anhydrous ferric sulphate, or ammonium ferric sulphate to 35 per cent. ammonia, etc. With hydrated oxides containing varying proportions of water, there is a maximum in the curve corresponding approximately with $Fe_2O_3.3H_2O$, but hydrates having almost identical proportions of water may differ greatly in their magnetic properties. P. Hausknecht found the susceptibility of the trihydrated oxide to be five times as great as that of the anhydrous oxide—*vide supra*, ferric oxide.

J. W. Gruner observed that peat-water dissolved 14 parts of iron per million from limonite in 77 days, and 30 parts in 182 days. B. Aarnio found that hydrated ferric oxide precipitated by ammonia, and dried at 100°, contains 10 per cent. of water, and has a **hygroscopicity** of 34 per cent. ; when dried at 200°, the corresponding values are 1·5 and 42 per cent. ; dried at 300°, respectively 1·0 and 29·6 per cent. ; and when dried at 700°, the hydrate becomes anhydrous, and loses its hygroscopicity. When various hydrated oxides are heated in chlorine to 900°, W. Kangro and R. Flügge found that 88 to 100 per cent. of the iron is removed as ferric chloride in about 150 mins. The trihydrated oxide readily dissolves in acids to form ferric salts. According to G. Bodländer, the **solubility** of this hydrate in **water** is represented by $3·73 \times 10^{-12}$ gram-equivalent of $Fe(OH)_3$ per litre ; G. Almkvist gave $1·51 \times 10^{-4}$ grm. per litre for the solubility at 20° ; K. Jellinek and H. Gordon, 3×10^{-10} mol per litre ; and E. Müller, $1·35 \times 10^{-9}$ mol per litre. G. Bodländer represented the **solubility product** as $[Fe^{\cdot\cdot\cdot}][OH']^3 = 6·5 \times 10^{-47}$ on the assumption that the ionization is complete. H. T. S. Britton said that the solubility product with very weak bases like hydrated ferric oxide, has probably very little meaning. K. Jellinek and H. Gordon's value for the solubility product $[Fe^{\cdot\cdot\cdot}][OH']^3 = 10^{-37·9}$. O. Ruff and B. Hirsch's value is $1·1 \times 10^{-36}$; and E. Müller's $6·5 \times 10^{-47}$. K. Jellinek and H. Gordon measured the $H^{\cdot}$-ion conc. with the hydrogen electrode of soln. of ferric chloride, containing potassium chloride to coagulate the colloidal soln., to which varying amounts of sodium hydroxide had been added. H. T. S. Britton added that if it be assumed that in the titration the appearance of opalescence marked the point at which ferric hydroxide actually began to separate, and that the amount of free ferric ions was eq. to the remaining amount of alkali to be added to decompose the ferric chloride completely, the value for the solubility product becomes $10^{-37·7}$. Thus, opalescence occurred on the addition of 39 c.c. of $0·10N$-alkali ; $p_H = 2·3$. Hence, $[OH'] = 10^{-11·8}$ and $[Fe^{\cdot\cdot\cdot}] = 10^{-2·3}$—*vide supra*, hydrated ferric oxide. P. P. von Weimarn estimated the solubility to be much less than that of hydrated alumina because of the concentration of the soln. required for the separation of gelatinous precipitate. G. Almkvist gave for the solubility, 0·151 mgrm. of $Fe(OH)_3$ per litre at 20°—*vide supra* for the hydrosol.

E. Reichardt and E. Blumtritt found that 100 grms. of air-dried hydrated ferric oxide absorbed 375 c.c. of gas from the air, and the gas contained 26 per cent. of N_2, 4 per cent. of O_2, and 90 per cent. of CO_2 ; and A. von Dobeneck found that hydrated ferric oxide absorbed 6·975 grms. of carbon dioxide at 0°, 5·702 grms. at 10° ; 5·054 grms. at 20° ; and 4·274 grms. at 30°. L. P. de St. Gilles observed that when trihydrated ferric oxide is boiled with water for several hours, it gradually becomes brick-red, and passes into the monohydrated oxide. P. Nicolardot inquired why is hydrated ferric oxide not white when the normal ferric salts are white ? He found that by adding a freshly prepared, conc. of soln. of ferric salt to cooled, aq. ammonia, the hydrate obtained is white, but it rapidly turns brown, due, he supposed, to polymerization—*vide supra.* D. Tommasi and G. Pellizzari found that when hydrated ferric oxide is kept under water for a year, it loses its gelatinous structure, and changes in colour from brown to yellowish-red. About

30 per cent. passes into a modification insoluble in dil. acids, and about 0·3 per cent. is converted into a soluble modification identical with Graham's colloidal hydrate. The change is very slightly, if at all, affected by light. For the solubility of limonite in various menstrua, *vide supra*, hydrated ferric oxide. O. Meyer and W. Eilender discussed the reduction of limonite with methane. For W. von W. Scholten's observations on the solid soln. of ferrous and ferric hydroxides, *vide supra*, ferric oxide. H. Handovsky found that ferric hydroxide, but not iron, ferrous sulphate, ferrosic oxide or the hydrosol of ferric oxide, acts catalytically in the oxidation of leucine.

A mineral was obtained by L. J. Igelström from the Längban iron-mine in Sweden, and he called it **pyriaurite**; M. F. Heddle obtained a similar mineral from the serpentine of Haaf-Grunay, Scotland, and called it *igelströmite*. The analysis by L. J. Igelström, M. F. Heddle, and G. Aminoff and B. Broome corresponds with magnesium ferric hydroxide, $Fe(OH)_3.3Mg(OH)_2.3H_2O$. It occurs in golden or silvery, six-sided plates, and with an obscure fibrous structure. G. Aminoff and B. Broome found that the crystals are of two types: (i) The six-sided plates have X-radiograms corresponding with a hexagonal cell having $a=3{\cdot}097$ A., and $c=15{\cdot}56$ A., or $a:c=1:5{\cdot}024$; and (ii) small rhombohedral crystals having a trigonal cell with $a=3{\cdot}089$ A., and $c=23{\cdot}23$ A., or $a:c=1:7{\cdot}520$.

According to A. S. Eakle and W. T. Schaller,[14] a mineral occurs in Esmeralds Co., Nevada, and it was accordingly called **esmeraldite.** Its composition approximates **tetrahydrated ferric oxide,** $Fe_2O_3.4H_2O$, after making due allowance for impurities. It occurs in the earthy limonite as pod-shaped masses of a coal-black colour; bright, vitreous lustre; and glassy fracture. The edges are translucent, and appear yellowish-red by transmitted light. The streak is yellowish-brown. The sp. gr. is 2·578; and the hardness of the brittle mineral is 2·5. W. Spring reported a tetrahydrate to be formed when the voluminous precipitate of hydrated oxide, obtained by adding ammonia to a dil. soln. of ferric sulphate or chloride, is allowed to dry in air. The black, vitreous mass appears red by transmitted light. Its sp. gr. is 2·436 at 15°; it is not decomposed by press.; and it loses water in a desiccator. P. A. Thiessen and R. Köppen obtained the tetrahydrate by the slow hydrolysis of a boiling, dil. soln. of ferric ethylate in absolute alcohol. The crystals are probably cubic; and the sp. gr. is 3·0 to 3·1.

§ 33. The Ferrites and Perferrites

Ferric oxide unites with many bases to form salts commonly called **ferrites**, just as the salts of chromic oxide with the bases are called *chromites*, and those of manganic oxide with the bases, *manganites*. To keep the nomenclature more or less uniform, the salts of the acid anhydride MnO_2 are called *permanganites*, and those of the acid unknown anhydride, FeO_2, are called **perferrites.** Similarly, the salts of the acid anhydride CrO_3 are called *chromates*, those of MnO_3, manganates, and those of FeO_3, ferrates. The ferrites can thus be regarded as salts of a monobasic *ferrous acid*, $HFeO_2$, which was obtained by J. M. van Bemmelen and E. A. Klobbie [1] as indicated below. It may be convenient to regard the ordinary ferrites as **metaferrites,** $R'FeO_2$, and the acid, $HFeO_2$, as **metaferrous acid.** The **orthoferrites,** $R_3'FeO_3$, are then regarded as salts of a tribasic **orthoferrous acid,** H_3FeO_3. The " ous " and " ic " nomenclature unfortunately goes wrong with the

chromites, manganites, and ferrites; the orthoferrous acid, H_3FeO_3, is analogous with ferric hydroxide, $Fe(OH)_3$; and the iron is in the "ic" form. In a special case, discussed previously, it was convenient to consider ferric oxide, Fe_2O_3, as *ferric orthoferrite*, $Fe(FeO_3)$. Some **polyferrites** are known. The ferrites were discussed by L. E. R. Dufau, H. le Chatelier, S. Hilpert, etc.

A. Chondew observed that a ferrite is probably formed when potassium hydroxide is fused in an iron crucible, for, when the cold mass is boiled with water, some ferric oxide remains in soln.; and a similar soln. is produced when hydrated ferric oxide is boiled with conc. alkali-lye. The alkali ferrites are formed by the interaction of fused or conc. aq. soln. of the alkali hydroxides and ferric oxide or iron-rust. The removal of ferrites from caustic alkali-lye picked up in the evaporators is an important operation in the finishing of commercial caustic alkalies. Reducing agents—*e.g.* sulphur—is one method employed in reducing the ferrites and causing the iron hydroxides to separate from the soln. and ultimately to settle as a deposit at the bottom of the caustic pot. The dilution of the lye to less than 40 per cent. NaOH will precipitate most of the iron as hydrated oxide. G. C. Wittstein said that hydrated ferric oxide is slightly soluble in conc. alkali-lye, but L. Schaffner observed that this is a mistake, for the ferric oxide is only in a state of fine mechanical suspension. A. W. Bull and J. R. Adams studied the adsorption of sodium hydroxide by hydrated ferric oxide, and the results are summarized in Fig. 544. There is here no sign of the formation of a ferrite.

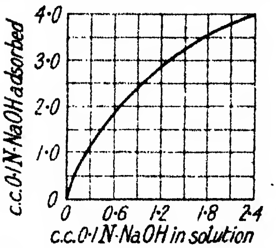

FIG. 544.—The Adsorption of Sodium Hydroxide by Hydrated Ferric Oxide.

E. Posnjak and T. F. W. Barth prepared **lithium ferrite,** $Li(FeO_2)$, or $Li_2O.Fe_2O_3$, by heating a conc. soln. of lithium hydroxide and ferric hydroxide in a press. bomb below 600°. The crystals were anisotropic. If the temp. exceeds 600°, an isotropic, cubic modification is produced, and also when lithium carbonate and ferric oxide in theoretical proportions are heated to redness. The X-radiograms show that the cubic form has one $Li_2O.Fe_2O_3$-molecule per unit cube which is of the sodium chloride type. The length of one edge is 4·141 A.; the sp. gr. is 4·368; and the refractive index, 2·40 for Li-light. S. Hilpert and co-workers studied the magnetization of this salt.

F. von Schaffgotsch prepared **sodium ferrite,** with the formula—presumably from the analyses of W. F. Salm-Horstmar, and J. M. van Bemmelen and E. A. Klobbie—$Na_2O.Fe_2O_3$, or $NaFeO_2$. F. von Schaffgotsch found that a mixture of a mol, or 78 parts of ferric oxide and a small excess of anhydrous sodium carbonate at a red-heat, gives off a little more than a mol or 23·9 parts of carbon dioxide, forming a liver-brown sodium ferrite which does not readily melt. The fracture is waxy and conchoidal. On exposure to air, sodium ferrite becomes reddish-brown and dull. Hot and cold water extract the alkali, leaving ferric oxide behind. W. F. Salm-Horstmar, O. Loew, and E. Mitscherlich prepared the salt in a similar way; M. O. Charmandarian and G. V. Martschenko, by heating a mixture (3 : 1) of iron oxide and sodium carbonate at 950°; and E. Mitscherlich, by calcining sodium ferric oxalate in air. The yellow product is decomposed by acids. J. d'Ans and J. Löffler obtained the ferrite by the action of ferric oxide on sodium hydroxide; and G. Rousseau and co-workers, by heating hydrated ferric oxide mixed with sodium hydroxide or carbonate up to 800° or 1000°. J. M. van Bemmelen and E. A. Klobbie prepared the alkali ferrites by the prolonged heating of ferric oxide with conc. alkali-lye, the resulting ferrite is partially soluble and gradually crystallizes. The crystals of the sodium salt appear at first to be crossed prisms, but they afterwards form hexagonal plates which sometimes become rhombohedral and spherical, or else they form long needles. The same crystals are produced when ferric oxide is heated with fused alkali carbonate or chloride. Excepting the hexagonal plates, the crystals of sodium ferrite are decomposed by water when they assume at first a pseudocrystalline form, and then pass into amorphous, hydrated ferric oxide.

The hexagonal plates of sodium ferrite, when treated with water, furnish *ferrous acid*, $Fe_2O_3.H_2O$, or $HFeO_2$, with the same crystalline form, transparency, and optical properties as the original ferrite. S. Goldsztaub found that the rhombohedral crystals have the parameters a=5·59 A., α=35° 20′, and the density 4·23. Ferrous acid is not hygroscopic, and it begins to lose water at 100°, whereas goethite can be heated to 300° without losing water.

According to G. Zirnité, when a strong current of air is blown into a hot, conc. soln. of soda containing about 34 per cent. of hydroxide, standing in an iron vessel, or to which finely divided hydrated ferric oxide has been added, perceptible quantities of iron are dissolved without colouring the liquid. The soln. remains clear and colourless for several days at the ordinary temp., but ultimately becomes turbid, yellow, and finally red, owing to the separation of the hydrated ferric oxide; this colour, however, disappears again on heating. When the colourless soln. is diluted, the ferric oxide is precipitated in about half an hour, but is re-dissolved by concentrating the dil. soln. Hydrogen sulphide at first produces a deep, cherry-red coloration in the colourless liquid, and on continuing the action a greenish-black precipitate is formed, leaving a clear soln. free from iron, but slightly yellow from the presence of sodium sulphide. G. Zirnité assumed that sodium ferrate is formed, but this hypothesis does not agree with F. Haber's observations, which show that sodium ferrite is produced. According to F. Haber, when a soln. of sodium ferrate is boiled for a sufficiently long time, it becomes colourless or pale yellow, provided that care has been taken to use materials which are free from manganese. The yellowish soln. contains a soluble ferrite, and when kept, deposits colourless crystals of a compound which very quickly decomposes when it is removed from the strongly alkaline liquid. The same soln. of ferric oxide is obtained by boiling ferric hydroxide with a conc. soln. of sodium hydroxide. Addition of an alkaline sulphide gives a red coloration, due to the formation of the double alkali iron sulphide to which the red liquors of Leblanc's alkali manufacture owe their colour. When pure iron is boiled gently for a few minutes with conc. sodium hydroxide soln., the liquid is found to contain ferrous oxide. When exposed to air, this soln. readily oxidizes to the ferric oxide soln. Both the soln. of ferrous and ferric oxide are readily oxidized to ferrate by electrolytic oxygen. O. Loew said that the salt is soluble in a conc. soln. of sodium hydroxide; but O. Sackur observed that it is insoluble in molten alkali chlorides or carbonates, and in molten alkaline earth chlorides. W. G. Mixter gave for the thermal value of the reaction: $Fe_2O_3+nNa_2O=Fe_2O_3.nNa_2O+58$ Cals. M. Matsui and co-workers found for the heat of the reaction $Na_2O+Fe_2O_3=2NaFeO_2+44·82$ Cals.; $Na_2CO_3+Fe_2O_3=2NaFeO_2+CO_2-32·06$ Cals.; $(2Na,2Fe,2O_2)=2Na_2FeO_2+248·08$ Cals.; and $2NaFeO_2+H_2O=2NaOH_{aq.}+Fe_2O_3-101·32$ Cals. V. I. Sokoloff found that the decomposition of sodium ferrite by water is endothermal—55·14 Cals.—and the heat of formation $(Na_2O,Fe_2O_3)=58$ Cals. The reaction between ferric oxide and sodium carbonate begins at 820°; and the press. of the gas is given by $\log p=-7539·6T^{-1}+1·75 \log T-0·001626T+6·0808$, from which it follows that $2NaFeO_2+CO_2=Na_2CO_3+Fe_2O_3+34·873$ Cals. at 25°. G. Grube and H. Gmelin showed that when iron which has been rendered active by cathode treatment is anodically polarized by a low-current density in a 40 per cent. soln. of sodium hydroxide and in complete absence of air, it passes into soln., in the bivalent condition, as *sodium hypoferrite*, Na_2FeO_2. at 80°, with a current density of 0·166 amp. per sq. dcm., 0·026M-soln. of sodium ferrite is formed. Sodium ferrite can be obtained by the anodic oxidation of an alkaline soln. of ferrous hydroxide, or by the cathodic reduction of sodium ferrate using platinum electrodes. A soln. of sodium ferrite is much more complex than an alkaline soln. of ferrous hydroxide. The anodic soln. of bivalent iron in 40 per cent. sodium hydroxide takes place at 80° at potentials ϵH −0·84 to −0·82 volt. At a slightly higher potential, ϵH --0·8 to —0·7, the oxidation process $2FeO_2'' + 2\oplus \rightleftharpoons Fe_2O_4''$ takes place. In 40 per cent. sodium hydroxide soln., the equilibrium potential of the process $Fe + 2\oplus \rightleftharpoons 2Fe''$ lies at $\epsilon H = -0·86$ volt. The subject was discussed by L. Rolla and R. Salani. S. Hilpert and co-workers studied the magnetization of the ferrites. W. G. Mixter reported the ferrite Na_3FeO_3; T. Wallace and A. Fleck, $Na_2Fe_3O_6$ or $Na_3Fe_5O_9$; and W. H. Schramm, $Na_2Fe_2O_5$.

W. F. Salm-Horstmar, E. Mitscherlich, and J. M. van Bemmelen and E. A. Klobbie prepared **potassium ferrite,** $K_2O.Fe_2O_3$, or $KFeO_2$, by the process employed for the sodium salt. The crystals of the potassium salt appear at first to be rhombic plates, but, as the heating is continued, and the water expelled, they become regular octahedra. W. F. Salm-Horstmar's analysis agrees with $3K_2O.4Fe_2O_3$, but J. M. van Bemmelen and E. A. Klobbie found $KFeO_2$. According to G. Rousseau and J. Bernheim, potassium ferrate is rapidly decomposed by fused potassium chloride or hydroxide to form potassium ferrite and oxygen. The alkalinity of the flux has no influence on the result, as is also the case with barium ferrate. If potassium hydroxide be employed, the ferrite is not changed by continued heating at bright redness, but if the flux is a mixture of hydroxide and chloride, the ferrite is gradually converted into reddish, transparent crystals of hydrated ferric hydroxide, containing about 3 per cent. of alkali. The general properties of potassium and sodium ferrite are similar. S. Hilpert and co-workers found that the alkali ferrites prepared in the wet way are indifferent in a strong magnetic field, but when prepared in the dry way, they are strongly magnetic. The magnetic properties are lost at 150°. S. Hilpert and A. Lindner prepared the potassium ferrites $K_2O.Fe_2O_3$, $K_2O.2Fe_2O_3$, and $K_2O.7Fe_2O_3$, and examined their X-radiograms. Similarly with the **rubidium ferrite,** $Rb_2O.Fe_2O_3$; and with the **cæsium ferrite,** $Cs_2O.Fe_2O_3$.

C. Friedel found a dark grey mineral on the lithomarge of Ekaterinburg, Siberia, and he called it **delafossite**—after G. Delafosse. It occurs in small, tabular crystals which are cleavable into thin, opaque laminæ of sp. gr. 5·07. According to A. F. Rogers, delafossite occurs in mines at Bisbee, Arizona, and the analysis corresponds with **cuprous ferrite,** $CuFeO_2$. The rhombohedral crystals are trigonal with the axial ratio $a : c = 1 : 1·94$. The hardness is 5·5. The mineral fuses easily and becomes magnetic. It is soluble in hydrochloric and sulphuric acids, but not in nitric acid. S. Hilpert melted together cuprous oxide and ferric oxide at 1250° in an atm. of nitrogen and obtained a black, magnetic mass; by treating a mixed soln. of cuprous and ferric salts with alkali, cuprous ferrite is formed, as a flocculent black mass which becomes crystalline at 900°. A. C. Halferdahl found that copper ferrite melts at 1458°; and F. S. Wartman and G. L. Oldright said that copper ferrite probably exists in the slags from pyrite smelting. E. V. Shannon discussed the formation of ferromagnetic $CuO.Fe_2O_3$. K. List obtained **cupric ferrite,** $Cu(FeO_2)_2$, by heating a powdered mixture of cupric and ferric oxides; V. Y. Mostovich and G. S. Uspensky said that the reaction begins at 600°, and proceeds rapidly at 750°. P. T. Walden recommended heating the mixture in an electric furnace, and removing the excess of ferric oxide by a magnet and levigation; and W. Stähl recommended heating a mixture of 5 grms. of cuprous oxide and 16·7 grms. of ferric oxide at 750° to 800° in a covered porcelain crucible in a muffle. K. List also obtained it by heating to redness a mixture of cupric and ferrous nitrates, and by adding potash-lye to a mixed soln. of ferric chloride and cupric sulphate to precipitate all the copper and iron. The dirty yellow precipitate when dried in vacuo over sulphuric acid forms a cinnamon-brown powder of the *pentahydrate*. It becomes anhydrous at a red-heat. K. List also prepared cupric ferrite by treating a soln. of ferric chloride with cupric oxide, when a brownish-yellow precipitate is formed. S. Holgersson found that the X-radiograms of the spinel-like crystals had the lattice parameter $a = 8·445$ A. This was confirmed by H. Forestier. W. Biltz and co-workers found that the $Cu(FeO_2)_2$ spinel had the mol. vol. 45·3, where the CuO has the mol. vol. 12·6, and the Fe_2O_3, 32·7. H. Forestier found that the curve showing the expansion at different temp. has a break at 455°. S. Loria and C. Zakrzewsky found the indices of refraction, μ, and the coeff. of extinction, k, for light of wave-length, λ, to be :

λ .	4390	4660	5530	5896	6330	7040
μ .	2·77	2·76	2·73	2·71	2·67	2·59
k .	0·69	0·59	0·47	0·29	0·25	0·16

The brownish-black cupric ferrite is magnetic. S. Hilpert obtained cupric ferrite as in the case of cuprous ferrite ; and by compressing a mixture of powdered cupric and ferric oxides, and sintering at 100°. The magnetic permeability disappears at 280°. O. C. Ralston observed the formation of zinc and copper ferrites in the roasting of sulphide ores at about 650°, and the cupric ferrite so formed resists the action of the 5 to 10 per cent. sulphuric acid used in leaching, so that losses occur. H. Forestier and G. Chaudron obtained the ferrite by precipitation from a mixture of the component chlorides,by sodium hydroxide, and then heating the precipitate. The mean magnetic susceptibility of copper ferrite obtained by H. Forestier and G. Chaudron, is 102×10^{-3} mass unit between 0 and 100 gauss. S. Hilpert and co-workers, and A. Serres made observations on this subject. H. Forestier observed that the magnetization decreases slowly with rise of temp., but there is an abrupt decrease at 420° which ends at 450°, a temp. corresponding with the Curie point. The relation between the strength of the magnetic field and the intensity of magnetization is shown in Fig. 545. A. Serres, and S. Veil studied the magnetic properties of copper ferrite. E. Wilson and E. F. Herroun found that the ferrites have higher magnetic susceptibilities than ferric oxide, and observed values for cupric ferrite. V. Y. Mostovich and G. S. Uspensky found that the ferrite is insoluble in soln. used for extracting copper oxide in hydrometallurgy. It is decomposed by sulphur dioxide at 500° to 600° ; and by calcium oxide, and other strong bases. P. T. Walden said that no blue precipitate is formed when cupric ferrite is treated with a soln. of potassium ferricyanide.

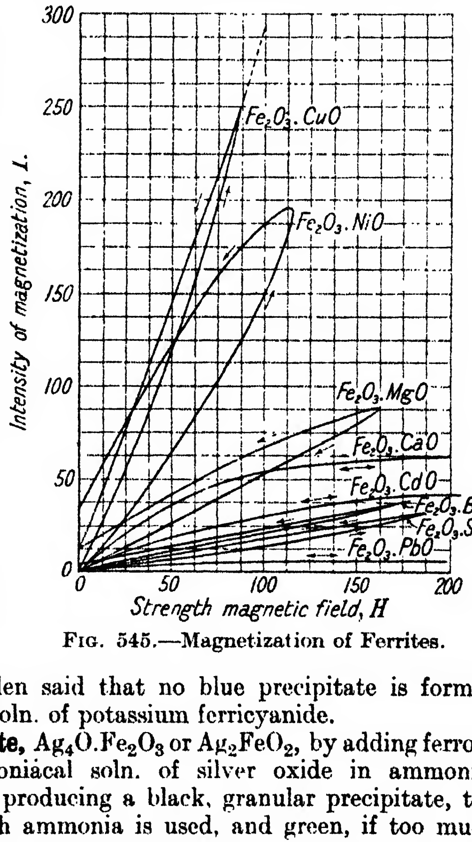

FIG. 545.—Magnetization of Ferrites.

H. Rose prepared **silver hemiferrite,** $Ag_4O.Fe_2O_3$ or Ag_2FeO_2, by adding ferrous sulphate to an excess of an ammoniacal soln. of silver oxide in ammonia. N. W. Fischer found that instead of producing a black, granular precipitate, the colour is yellowish-brown if too much ammonia is used, and green, if too much ferrous sulphate is added. Ammonia extracts a little silver oxide from the precipitate and colours it yellowish-brown. Hydrochloric acid converts it into ferric chloride and a precipitate of reddish-grey silver chlorides, and if the precipitate be treated with ammonia, metallic silver remains undissolved, suggesting that the precipitate contains silver suboxide. It is probable that this product contains some ferric hydroxide associated with colloidal silver. According to M. C. Lea, a soln. of ferric alum readily dissolves silver at the ordinary temp., with production of a ferrous salt, and if the ferric compound is in excess, the whole of the silver is dissolved. When ferrous sulphate soln. is mixed with successive quantities of silver oxide until a fresh quantity of the latter is no longer affected, the whole of the iron is precipitated, and a black product is obtained which is probably the compound $Ag_4O.2FeO.Fe_2O_3$ obtained by H. Rose in the same way. When a soln. of ammonium ferric alum is mixed with a large excess of finely divided silver in a well-closed vessel and allowed to remain for several days, with frequent agitation, the liquid acquires a deep red colour, which may persist for several days, but then gradually disappears, the soln. becoming greenish, although it still contains a considerable quantity of ferric salt. It follows that the reducing action of silver on ferric salts is limited and ceases before reduction is complete, even when the silver is present in large excess. K. Pilawsky, and A. Krause and K. Pilawsky prepared **silver ferrite,** $(AgFeO_2)n$, by the action of a soln. of silver nitrate on yellow metaferric hydroxide, FeO.OH, obtained by the action of air on ferrous hydroxide, or ferrous acid, $(HFeO_2)_n$, in soln. of $p_H=5{\cdot}2$, and peptized in $0{\cdot}01N$-acetic acid; if brown orthoferric hydroxide, obtained by the action of alkali on a ferric salt, $p_H=7{\cdot}7$, is used, then **silver hydroferrite,** $Ag_3H(FeO_2)_2$, is formed. The salt was studied by A. Krause and W. Buczkowsky.

The bleaching action of calcium oxide on the yellowish or reddish-brown colour produced by ferric oxide in clays has long been known in the ceramic industries, and attributed to the formation of a calcium ferrite of paler tint. Thus, the effect is mentioned by H. Seger. According to J. Percy, ferric oxide forms fusible compounds with calcium oxide if the mixture in theoretical proportions for **calcium ferrite,** $CaO.Fe_2O_3$, or $(CaFeO_2)_2$, be heated to whiteness in an oxidizing atmosphere. The mass of dark brown, interlacing, acicular crystals is magnetic, and it has a sp. gr. 4·693. The composition is said to be analogous to that of magnetite with ferrous oxide replaced by calcium oxide, or to that of a spinel with alumina replaced by ferric oxide. S. Hilpert and A. Lindner examined the X-radiograms of $CaO.Fe_2O_3$. H. O. Hofmann and W. Mostowitsch prepared a crystalline calcium ferrite by heating equimolar proportions of calcium sulphate and ferric oxide. Sulphur dioxide and oxygen were given off at 1100°, and at 1250° the mass was molten. The calcium ferrites in Portland cements were described by H. Kühl, and R. Nacken and M. E. Grünewald. C. E. Swartz and F. C. Krauskopf obtained non-magnetic calcium ferrite by heating calcium oxide and ferric oxide above 650°. L. Jacqué found that the first clear signs of fusion with mixtures of ferric and calcium oxides were obtained at the following temp.:

CaO .	0	5	10	20	26	30	40	50	60	70 per cent.
Temp. .	>1500°	1455°	1290°	1230°	1220°	1220°	1245°	1370°	1430°	>1500°

If the mixtures are kept until completely fused, a portion of the ferric oxide is dissociated, and some ferrous oxide is formed. This reduces the f.p. of the mixture. The ratio $Fe_2O_3 : FeO$ approaches 2·22 on prolonged heating, and the ratio 2·22 corresponds with Fe_3O_4. J. Pelouze obtained a product, which he represented by the formula $4CaO.Fe_2O_3$, by adding an excess of potash-lye to a soln. containing a mol of ferric and 4 mols of calcium chloride; H. Forestier and G. Chaudron obtained calcium ferrite by a similar process; K. List, by adding lime-water to a soln. of ferric chloride, washing the product with lime-water, and heating it to redness. S. Hilpert prepared calcium ferrite by the fusion process. J. Guillissen did not obtain definite results for the temp. at which the reaction between ferric oxide and calcium carbonate begins. H. Forestier observed that the ferromagnetic crystals are not cubic, and may have a face-centred, tetragonal lattice with $a : c=1 : 0{\cdot}8$. The ferromagnetic property relates to an unstable state which is lost at higher temp.

S. Hilpert and E. J. Kohlmeyer studied the binary system, $CaO-Fe_2O_3$, thermally, and their results are summarized in the curve, Fig. 546. Under the conditions of the experiments, mixtures with less than 31 molar per cent. of ferric oxide were very viscid, and the last portion solidified at 1410°. The calcium oxide formed well-developed crystals. With less than 75 molar per cent. of calcium oxide, the primary crystallization is that of **calcium orthoferrite,** $3CaO.Fe_2O_3$, which melts at 1410°, and disintegrates, like calcium orthosilicate, when cooled. The next compound formed is $3CaO.2Fe_2O_3$, or **calcium tetraferrite,** which melts at 1450°. This solid, at 1220°, undergoes a reaction forming a compound **pentacalcium hexaferrite,** $5CaO.3Fe_2O_3$, resembling the corresponding aluminate, $5CaO{\cdot}3Al_2O_3$. E. D. Campbell obtained a ferrite, $5CaO.3Fe_2O_3$, and said that it is isomorphous with $5CaO.3Al_2O_3$. R. Nacken and M. E. Grünewald examined the red crystals of this salt and found them to be doubly refracting. N. M. Yasuirkin gave 6·9 Cals. for the heat of formation of $3CaO.Fe_2O_3$; and 2·9 Cals. for that of $4CaO.Fe_2O_3$.

J. Pelouze, and W. Pukall reported $4CaO.Fe_2O_3$; W. Pukall, and E. Diepschlag and E. Horn, $3CaO.Fe_2O_3$; R. Nacken and M. E. Grünewald, $5CaO.3Fe_2O_3$; F. Martin and O. Fuchs, $3CaO.2Fe_2O_3$; and Z. Weyberg, $2CaO.5Fe_2O_3$. E. Martin reported the hydrate, $CaO.4Fe_2O_3.6H_2O$, or $CaO.3Fe_2O_3.5H_2O$; and $CaO.2Fe_2O_3.2H_2O$; $CaO.Fe_2O_3.H_2O$; $3CaO.2Fe_2O_3.3H_2O$; $4CaO.2Fe_2O_3.3H_2O$; $6CaO.2Fe_2O_3.3H_2O$; W. Michaelis, $3CaO.Fe_2O_3.3H_2O$; and H. le Chatelier, $4CaO.Fe_2O_3.12H_2O$.

Returning to S. Hilpert and E. J. Kohlmeyer's diagram, Fig. 546, there is a eutectic at 1200°, and 50 mol. per cent. of calcium oxide; and a second maximum at 1400°, corresponding with **dicalcium hexaferrite,** $2CaO.3Fe_2O_3$. Below the eutectic temp., **calcium metaferrite,** $CaO.Fe_2O_3$, or $Ca(FeO_2)_2$, is present. The behaviour of mixtures rich in ferric oxide is complicated, partly owing to the escape of oxygen, and the formation of magnetite. Calcium metaferrite was also prepared by W. C. Hansen and co-workers—*vide infra*—W. F. Salm-Horstmar, W. Pukall, K. List, S. Peacock, K. Endel, C. E. Swartz and E. C. Krauskopf, H. O. Hofmann and W. Mostowitsch, O. Schott, H. Moissan, and J. Percy; whilst E. Diepschlag and E. Horn prepared the 2 : 1, 5 : 3, and the 1 : 1 ferrites. R. B. Sosman and H. E. Merwin could not confirm S. Hilpert and E. J. Kohlmeyer's five calcium ferrites. The equilibrium diagram is summarized in Fig. 547, and only two ferrites were observed. The compound $2CaO.Fe_2O_3$ dissociates and is in equilibrium with calcium oxide and liquid at 1436°, and all mixtures with less than 36 molar per cent. of calcium oxide, up to pure calcium oxide, liquefy in part at this temp., leaving pure calcium oxide as the solid phase in excess. The compound $CaO.Fe_2O_3$ dissociates and is in equilibrium with $2CaO.Fe_2O_3$, and liquid at 1216°, and all mixtures between about 35 and 62 molar per cent. Fe_2O_3 liquefy in part at 1216°, forming liquid, and $2CaO.Fe_2O_3$ as solid phase in excess. This dissolves as the temp. rises and disappears at the liquidus curve. The compound $CaO.Fe_2O_3$ dissociates and is nearly all liquefied at 1216°—J. Konarzewsky gave 1251°—and at 1250° the solid phase, $2CaO.Fe_2O_3$, formed by dissociation, all disappears. The

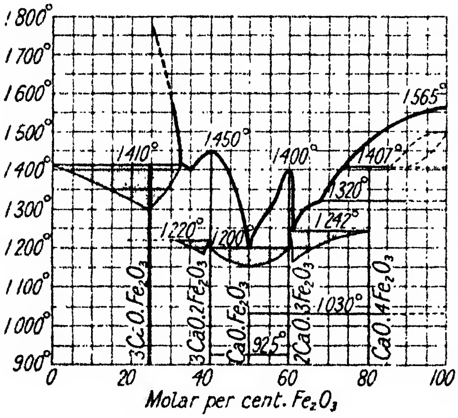

FIG. 546.—Freezing-point Curves of the Binary System : $CaO–Fe_2O_3$.

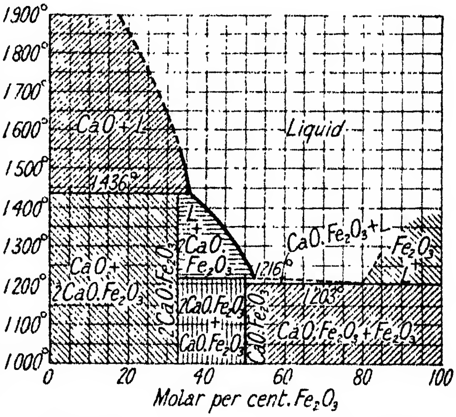

FIG. 547.—Freezing-point Curve of the System : $CaO–Fe_2O_3$.

eutectic at 1203° between calcium metaferrite and ferric oxide has between 75 and 90 per cent. ferric oxide and is probably nearer the former amount. No optical evidence of solid soln. of calcium oxymetaferrite with calcium oxide or calcium metaferrite, or of calcium metaferrite with calcium oxymetaferrite or ferric oxide was observed. M. E. Grünewald verified the results with 40 to 65 molar per cent. of calcium oxide. E. D. Campbell studied the mixed crystals with calcium aluminate. N. M. Yasuirkin gave 1·5 Cals. for the heat of formation of $CaO.Fe_2O_3$. S. Nagai and K. Asaoka found that calcium metaferrite is not acted on by water. E. Diepschlag and E. Horn said that the orthoferrite reacts with calcium sulphide at 800°, but not with ferrous sulphide below 1150°. **Calcium oxymetaferrite,** or *calcium oxyferrite*, $2CaO.Fe_2O_3$ or $Ca_2O(FeO_2)_2$, is formed at 1436° in well-developed, black crystals, which are yellowish-brown by transmitted light. M. E. Grünewald also obtained tabular crystals of calcium oxymetaferrite. E. Martin gave 1300° to 1325°, R. Nacken and M. E. Grünewald, 1380° to 1420°; J. Konarzewsky, 1440°; O. Schott, 1500°; and O. Andersen, 1436° for the incongruent m.p. of the oxymetaferrite. This compound was also prepared by C. W. Hansen and co-workers, and by S. Nagai and K. Asaoka, W. Pukall, V. Vincent, W. Lerch and R. H. Bogue, and O. Schott—*vide infra*. According to R. B. Sosman and H. E. Merwin, the melted substance may be under-cooled to 1385°, but it always shows traces of the dissociation products, calcium metaferrite and oxide. Calcium oxymetaferrite furnishes positive, biaxial crystals with a moderate optic axial angle. N. M. Yasuirkin gave 32·03 Cals. for the heat of formation of $2CaO.Fe_2O_3$. The indices of refraction for Li-light are: $\alpha=2{\cdot}200$, $\beta=2{\cdot}220$, and $\gamma=2{\cdot}290$; and for Na-light, $\alpha=2{\cdot}25$, whilst β and γ have a lower dispersion. The transition temp. at which the metaferrite dissociates and is in equilibrium with the oxymetaferrite is 1216°. Calcium metaferrite forms deep red crystals which are negative, and uniaxial. E. Martin gave 1225° to 1250°; R. Nacken and M. E. Grünewald, 1220° to 1230°; H. O. Hofmann and W. Mostowitsch, 1250°; S. Hilpert, 1200°; and O. Andersen, and R. B. Sosman and H. E. Merwin, 1216°, for the incongruent m.p. of the metaferrite. According to R. B. Sosmann and H. E. Merwin, the refractive indices are: $\omega=2{\cdot}465$ and $\epsilon=2{\cdot}345$ for Li-light; and for Na-light, $\omega=2{\cdot}58$ and $\epsilon=2{\cdot}43$. S. Nagai and K. Asaoka observed that $2CaO.Fe_2O_3$ is slowly decomposed by water. According to R. B. Sosman and H. E. Merwin, a considerable amount of ferrous oxide or magnetite was formed with mixtures containing less than 50 mol. per cent. of lime, but with higher proportions of lime, the amount of ferrous oxide formed below 1500° is relatively small.

O. Andersen, R. Nacken and M. E. Grünewald, and E. D. Campbell obtained results confirming R. B. Sosman and H. E. Merwin's view that there are only two definite calcium ferrites. According to E. Martin, the calcium ferrite which is formed on heating a mixture of ferric oxide and calcium carbonate depends on the proportions in which the ingredients are mixed, and not on the temp. attained; thus, at 1200°, the 1 : 1 mixture furnishes the metaferrite, and the 1 : 2 mixture, the oxymetaferrite. The powdered metaferrite has a sp. gr. near 4, it is magnetic, and non-hydraulic; the powdered oxymetaferrite has a sp. gr. below 4, it is magnetic, and has a hardness of 6. H. Forestier said that the structure, from the X-radiograms, is not cubic. R. Nacken and M. E. Grünewald said that in the presence of much molten calcium chloride, the metaferrite forms rhombic needles, and the oxymetaferrite, plates. Only these two compounds are formed in the presence of an excess of molten calcium chloride. When equimolar proportions of ferric and calcium oxides with half their weight of calcium chloride are melted 2 to 4 days at 1200°, $5CaO.3Fe_2O_3$ is formed, and if 3 mols or more of calcium oxide and 1 mol of ferric chloride be treated in a similar way, calcium oxymetaferrite is formed. The fusion curve of calcium metaferrite and aluminate is shown in Fig. 547.

According to S. Hilpert and E. J. Kohlmeyer, molten mixtures of calcium and ferric oxides furnish brown to black products—those with a large proportion of ferric oxide are steel-grey, and the colour becomes paler with increasing proportions of calcium oxide. Many different tints were observed, according to the temp. at which the different mixtures were sintered. M. E. Grünewald found the crystals of $CaO.Fe_2O_3$ are rhombic. The hardness decreases with increasing proportions of calcium oxide. The sp. vol. curve shows a sharp change of direction when $CaO.Fe_2O_3$ is formed, and another, less distinct break occurs near 20 molar per cent. CaO. The following is a selection from the sp. gr. and sp. vol. data for different molar percentages of calcium oxide of sp. gr. 3·316, and ferric oxide, of sp. gr. 5·190:

CaO .	10	17·5	22	27	41	50	56	64
Sp. gr. .	5·025	4·878	4·844	4·785	4·724	4·683	4·480	4·213
Sp. vol. .	0·1982	0·2018	0·2064	0·2089	0·2177	0·2135	0·2232	0·2374

R. Nacken and M. E. Grünewald gave 5·08 for the sp. gr. of $CaO.Fe_2O_3$; 3·98 for that of $2CaO.Fe_2O_3$; and 4·02 for that of $5CaO.3Fe_2O_3$. The electrical conductivity is very small even with fused ferric oxide, which is only 10^{-10} of that of iron. Solid soln. are not formed. The magnetic properties diminish with the proportion of iron, and become insignificant with over 67 molar per cent. of calcium oxide. H. Forestier and G. Chaudron gave $42·3\times10^{-3}$ mass unit for the mean magnetic susceptibility of calcium ferrite between 0 and 100 gauss; and they found that it loses its magnetic properties irreversibly when heated to 700°. The heating and cooling magnetization temp. curves coincide, unless the heating has been above the Curie point, in which case the Curie point is depressed from 425° to 150°, so that it is completely transformed into a paramagnetic substance if kept at a high temp. for some time. H. Forestier's observations on the relation between the strength of the magnetic field, and the intensity of magnetization were discussed in connection with Fig. 545. S. Hilpert and co-workers added that this ferrite loses its magnetic permeability at 160°. The calcium ferrites were also studied by S. Nagai and K. Asaoka. S. Hilpert and E. J. Kohlmeyer observed that the calcium ferrites are much less readily attacked by reagents than the silicates, and hence they are better than silicates in cements for resisting the attack of sea-water. Mixtures with 60 to 70 molar per cent. of calcium oxide are hydraulic. W. Pukall, S. Nagai and K. Asaoka, E. Martin, and J. Konarzewsky said that $CaO.Fe_2O_3$ is not changed by long contact with water, and it possesses no hydraulic properties, but O. Schott, and K. Zulkowsky did not accept this conclusion. J. Konarzewsky, W. Pukall, S. Nagai and K. Asaoka, and K. Zulkowsky noted that $2CaO.Fe_2O_3$ does possess hydraulic properties in hardening under water, but not so much as Portland cement. Calcium ferrites are less readily reduced than ferric oxide. W. Odling said that hydrogen sulphide does not attack calcium ferrite. According to E. Martin, the metaferrite is insoluble in 10 per cent. acetic acid, and in a hot or cold soln. of sodium carbonate, or of ammonium chloride. It is slightly soluble in a soln. of lime and sugar, and it is slowly attacked by oxalic acid. An excess of alumina decomposes the ferrite at a high temp., 1200°, whilst with silica, silicoferrites are formed. The oxymetaferrite resembles the metaferrite in its chemical behaviour, except that it is attacked slowly by 10 per cent. acetic acid, it is also slightly attacked by a boiling soln. of sodium carbonate, and is entirely decomposed by a hot soln. of ammonium chloride. W. H. MacIntyre and W. M. Shaw observed that whilst ignited ferric oxide shows no tendency to absorb appreciable amounts of calcium sulphate, freshly precipitated ferric oxide and lime, in the proportions $3CaO : Fe_2O_3$, readily does do. H. le Chatelier, and K. List obtained a **calcium dichlorometaferrite,** $CaCl_2.Ca(FeO_2)_2$, or $Ca(Cl)FeO_2$, in bright, prismatic crystals, by dissolving calcium and ferric oxide in fused calcium chloride. It is not decomposed by water or air.

H. Forestier prepared **strontium ferrite,** $SrO.Fe_2O_3$, and observed an irregularity in the dilation curve near 480°, the Curie point. The relation between the magnetic field and intensity of magnetization are shown in Fig. 545. H. Forestier said that the X-radiogram indicates a hexagonal lattice with the ratio $a:c=0:1·8$. F. Martin and O. Fuchs prepared $2SrO.Fe_2O_3$; and H. Borck reported a hydrated strontium ferrite. S. Hilpert and A. Lindner studied the X-radiograms of the strontium ferrites $SrO.Fe_2O_3$, $2SrO.3Fe_2O_3$, $SrO.2Fe_2O_3$, and $SrO.4Fe_2O_3$. E. Martin prepared **barium ferrites** as in the case of calcium ferrites; and similarly with E. J. Maumené, and W. Mostowitsch. J. Guillissen found that the reaction between ferric oxide and barium carbonate begins at about 830°, and with barium oxide at about 1300°. The reaction was studied by J. Guillissen and P. J. van Rysselberghe. G. Rousseau and J. Bernheim found that if barium ferrate is introduced into barium chloride or barium bromide fused at 800° to 1300°, it rapidly decomposes with effervescence, owing to the liberation of oxygen, and leaves a residue of ferric oxide. If, however, about 3 grms. of barium ferrate are added gradually to a fused mixture of 15 grms. of barium chloride or bromide, and 5 grms. of barium oxide, and the product is treated with water, it yields brownish-black crystals of barium ferrite. At 1100°, about 6 grms. of barium oxide are required to prevent the decomposition of the ferrite, and at an orange-red heat 12 grms. are necessary. It follows from these results, that whereas barium ferrate, if heated alone, decomposes into oxygen, ferric oxide, and barium oxide, yet, when heated with barium oxide, it yields oxygen and barium ferrite. The decomposition of the ferrate in presence of neutral or slightly basic fluxes is analogous to the decomposition of alcoholates by dilution, but the latter is progressive whilst the former takes place suddenly as soon as the proportion of barium oxide has fallen below a certain limit. If barium carbonate is present, it crystallizes from the oxychloride which is formed, and the crystals are not readily separated from those of the ferrite. S. Hilpert prepared barium ferrite in the wet way as in the case of calcium ferrite. It is non-magnetic unless it has been heated to 800° and cooled. S. Hilpert and A. Lindner studied the X-radiograms of the barium ferrites $BaO.Fe_2O_3$, $2BaO.3Fe_2O_3$, $BaO.2Fe_2O_3$, $BaO.3Fe_2O_3$, and $BaO.4Fe_2O_3$. H. Forestier said that the X-radiogram of $BaO.Fe_2O_3$ corresponds with a hexagonal lattice. H. Forestier and G. Chaudron prepared barium ferrite as in the case of calcium ferrite, and found that its mean magnetic susceptibility is $9·9\times10^{-5}$ mass unit between 0 and 100 gauss. H. Forestier observed a break in the dilation curve near 445°, and this temp. is also the Curie point. The relation between the strength of the magnetic field, and the intensity of magnetization is shown in Fig. 547. S. Hilpert and co-workers studied the magnetic properties of these ferrites.

H. Forestier and M. Galand prepared **beryllium ferrite,** $Be(FeO_2)_2$, and found that the crystal lattice has the structure of lepidocrocite; so that BeO in the ferrite plays the part of water in lepidocrocite. The ferrite decomposes at 360° into BeO and Fe_2O_3. S. Hilpert and co-workers studied the magnetic properties. C. F. Rammelsberg described crystals of a mineral resembling magnetite which was obtained in the vicinity of the fumaroles of Vesuvius, and particularly about those of the eruption of 1855. He called the mineral *magnoferrite*, G. A. Kenngott, *magneferrite*, and J. D. Dana, **magnesioferrite.** The crystals and their associations were described by A. Scacchi, G. vom Rath, H. Bücking, G. Leonhard, A. Lacroix, and F. Zambonini. Before C. F. Rammelsberg's examination, the crystals had been mistaken by T. Monticelli and N. Covelli, D. F. Wiser, A. Scacchi, and A. Krantz, for magnetite, hæmatite, or martite. According to F. Cornu, magnesite crucibles made from sintered magnesite contain crystals of periclase and of magnesioferrite. The analyses of C. F. Rammelsberg correspond with $3MgO.4Fe_2O_3$, but the presence of ferric oxide as an impurity in the samples lead him to suggest the formula for **magnesium ferrite,** $MgO.Fe_2O_3$, or $Mg(FeO_2)_2$. W. Weyl, and S. Holgersson obtained crystals by sintering at 1200° a mixture of equimolar parts of magnesia and ferric oxide, and heating the product with three times its weight of potassium chloride at 1200° in a platinum crucible for 40 hrs. K. A. Hofmann and K. Höschele found that magnesium chloride is an excellent mineralizer for making crystals of this spinel. Analyses were reported by T. L. Watson, G. S. Rogers, and E. Hugel. K. A. Hofmann and K. Höschele heated the mixture with an excess of magnesium chloride; H. Müller heated ferric oxide with an excess of potassium magnesium sulphate; and F. Hundeshagen heated the metal with molten hydrated magnesium chloride. H. St. C. Deville, E. Posnjak, and R. Nacken and M. E. Grünewald prepared magnesioferrite crystals by heating a mixture of magnesia and ferric oxide in a current of hydrogen chloride. J. Morozewicz obtained crystals of magnesioferrite, associated with spinel, on heating silicate magma rich in ferric oxide, magnesia, and alumina. T. Weyl, and R. Nacken and M. E. Grünewald said that the constituent oxides do not react at temp. up to 1200°, but K. Endel, L. E. R. Dufau, C. W. Parmelee and co-workers, and C. E. Swartz and F. C. Krauskopf obtained magnesium ferrite by heating an intimate mixture of magnesia with ferric oxide above 650°—H. Forestier said that the reaction commences at about 350°; W. C. Hansen and L. T. Brownmiller recommended a calcination temp. of 1450°. K. A. Redlich reported that some black crystals he observed in some magnesite refractories employed in the lining of a steel furnace were probably those of magnesium ferrite.

H. S. Roberts and H. E. Merwin studied the ternary system $MgO-FeO-Fe_2O_3$ above 1000°, and with an oxygen pressure on the isobar 0·2 atm. They observed two solid soln. fields: The solid soln. *A* begins at MgO below 1000° and extends with increasing temp. towards $Mg(FeO_2)_2$ and FeO. In Fig. 548, the field *A* is bounded by curve I, the $MgO-Fe_2O_3$ side of the triangle. A liquid phase appears at 1770°, where the solid soln. contains iron oxide equivalent to 73 per cent. of Fe_2O_3. The solid soln. *B* extends with increasing temp. from $Mg(FeO_2)_2$ towards the iron oxide boundary which it reaches at 1386°. Solid soln. of about 1 per cent. of MgO in $Mg(FeO_2)_2$ may occur between 1750° and about 1000°. In Fig. 548, the field *B* is bounded by the curves III and V. The isotropic grains had the index of refraction 2·34 for Li-light. X-radiograms of the crystals were obtained. It forms a solid soln. with 91 per cent. $MgO.Al_2O_3$. The structure was also studied by H. Forestier, and T. F. W. Barth and E. Posnjak. For solid soln. of magnesium ferrite with ferric oxide and with magnesia, see Fig. 548. The subject was discussed by H. S. Roberts and H. E. Merwin, R. Nacken and M. E. Grünewald, C. E. Swartz and F. C. Krauskopf, and R. Schenck and T. Dingmann.

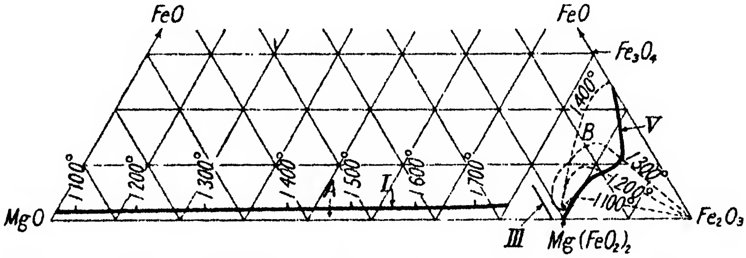

FIG. 548.—Portion of the Equilibrium Diagram of the Ternary System: $MgO-FeO-Fe_2O_3$.

According to C. F. Rammelsberg, and H. St. C. Deville, the cubic crystals of magnesioferrite occur in octahedra, or octahedra with truncated edges. W. Weyl's observations with the X-radiograms show that the crystal-lattice is of the spinel type. E. Posnjak found a=8·36 A., for the unit lattice containing 8 mols. $Mg(FeO_2)_2$ per unit cell; G. L. Clark and co-workers gave a=8·366 A.; and S. Holgersson gave a=8·342 A.; and L. Passerini, a=8·360 A. M. L. Huggins discussed the electronic structure. E. Posnjak found that the calculated density is 4·518 and the observed 4·481. L. Passerini gave 4·436; and S. Holgersson, 4·53; W. Biltz and co-workers found the mol. vol. to be 44·1 with 11·3 belonging to MgO, and 3·28 to Fe_2O_3. The index of refraction for Li-light is 2·34. The sp. gr. ranges from 4·568 to 4·654; A. Bergeat gave 4·998 to 5·247. The hardness ranges from 6·0 to 6·5. H. Forestier observed a reversible break in the dilation curve at about 315°. R. Nacken and M. E. Grünewald found the m.p. to be too high for them to obtain an equilibrium diagram of the binary system MgO–Fe_2O_3. They observed no reaction occurred with the well-mixed, powdered components at 1200°. K. A. Hofmann and K. Höschele obtained magnesium ferrite in solid soln. with magnetite, and in octahedral crystals by fusing mixtures of magnesia and ferric oxide with an excess of dehydrated magnesium chloride. R. Nacken and M. E. Grünewald examined the effect of heat on various mixtures of the components and in every case obtained no complex other than $Mg(FeO_2)_2$; they employed H. St. C. Deville's process and obtained black, octahedral crystals of sp. gr. 3·6. There was evidence that between 1350° and 1450° some change occurs in the crystals; there was no sign of fusion at 1550°. H. S. Roberts and H. E. Merwin said that this compound dissociates slightly and begins to melt at 1750°, and they observed the formation of a solid soln. with magnesia. H. Forestier gave 1650° to 1700° for the m.p. F. Beijerinck said that magnesioferrite is a good electrical conductor. H. Forestier and G. Chaudron gave 1700° for the m.p. and added that it is stable below that temp. They observed the temp. of the magnetic transformation of mixtures of magnesia with 2 to 50 per cent. of ferric oxide to remain constant at 310°, and magnesium ferrite remains in the free state; with 50 to 56 per cent. of ferric oxide, the temp. rises to 400°, and a solid soln. of the ferrite in ferric oxide is formed; with 56 to 100 per cent. of ferric oxide, the temp. is 675° corresponding with that of ferric oxide alone. The mean magnetic susceptibility of magnesium ferrite is 54×10^{-3} mass unit. The Curie point observed by H. Forestier with different mixtures is shown in Fig. 549. The relation between the strength of the magnetic field and the intensity of magnetization is shown in Fig. 545. S. Hilpert and co-workers, A. Serres, S. Holgersson and A. Serres, and E. Wilson and E. F. Herroun studied the susceptibility of magnesium ferrite. S. Hilpert said that magnesium ferrite prepared in the wet way is non-magnetic until fused. A. Serres studied the magnetic properties of magnesium ferrite. H. St. C. Deville observed magnesium ferrite is insoluble in hot nitric acid; and C. E. Swartz and F. C. Krauskopf, that it is insoluble in alkali-lye, and in dil. acids, but soluble in conc. hydrochloric acid.

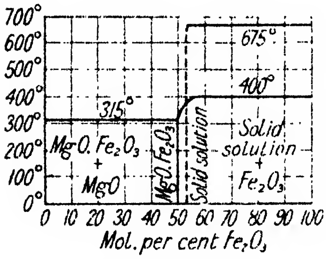

FIG. 549.—The Curie Point with the MgO–Fe_2O_3 System.

K. Kraut added a mixed soln. of a mol of a ferric salt and 6 mols of a magnesium salt to potash-lye of sp. gr. 1·1, and boiled the mixture for some hours. The brown precipitate first formed becomes white. It can be dried without change of colour at 120°, but if heated to redness, it becomes a rust-brown colour. Its composition was assumed to be that of the *enneahydrate* of **magnesium pentoxyferrite,** $5MgO.Mg(FeO_2)_2.H_2O$. It attracts carbon dioxide from the air; it becomes green when in contact with ammonium sulphide for 24 hrs.; it is not changed by ammonia; and when it is heated with ammonium chloride, it forms ferric oxide and magnesium chloride. According to L. J. Igelström, golden yellow or silvery white scales of a mineral occur in the iron-mine of Långban, Wermland, Sweden, and it was called **pyroaurite**—M. F. Heddle proposed calling it *igelströmite*. The mineral approximates to the *pentadecahydrate*, $5MgO.Mg(FeO_2)_2.15H_2O$, or $Fe(OH)_3.3Mg(OH)_2.3H_2O$. It occurs in six-sided plates belonging to the hexagonal system, or else in masses with a fibrous structure—*vide supra*, ferric hydroxide. H. Sjögren, and G. Flink described the yellow to yellowish-brown crystals of pyroaurite, and said that they are optically negative with a low birefringence. The axial ratio is $a : c = 1 : 1·6557$. The sp. gr. is 2·07, and the hardness 2·5.

P. Berthier described a mineral from Franklin Furnace, New Jersey, and named it *franklinite*—after B. Franklin. The mineral also occurs near Eibach, Nassau; and at Altenberg near Aix-la-Chapelle. It is now called **franklinite.** Analyses reported by P. Berthier, T. Thomson, H. Abich, G. J. Brush, H. Steffens, C. F. Rammelsberg, F. von Kobell, G. H. Seyms, G. C. Stone, and C. Palache correspond with $(Fe,Mn,Zn)O.(Fe,Mn)_2O_3$, with the **zinc ferrite,** $Zn(FeO_2)_2$, or $ZnO.Fe_2O_3$, predominant. A. Daubrée prepared crystals of zinc ferrite by passing the vapours of the chlorides of zinc and iron over red-hot calcium oxide; J. J. Ebelmen heated a mixture of the component oxides with boric acid at a high temp.; F. Reich, and C. E. Swartz and F. C. Krauskopf, by strongly heating an intimate mixture of finely divided zinc and ferric oxides; J. Guillissen and co-workers found that ferric and zinc oxides react at about 620° to 650° yielding zinc ferrite; and O. C. Ralston pointed out that the zinc ferrite formed in the roasting of sulphide ores is difficult to extract by 5 to 10 per cent. sulphuric acid usually employed in the leaching of the roasted ore. The ferrite can be decomposed by treatment with hot 20 to 30 per cent. sulphuric acid near the b.p.; or by hot dil. acid acting for a long time. The zinc ferrite being ferromagnetic can be removed by magnetic concentration and treated separately; or the ferrite can be decomposed by using a carbonaceous reducing agent—say, by sprinkling coal-dust on the hot calcine before it is discharged from the roasting furnace. Y. Kato and T. Takei obtained zinc ferrite by heating a mixture of zinc and ferric oxides above 700°, and extracting the product with a soln. of ammonium chloride so as to leave insoluble zinc ferrite. The compound forms with appreciable velocity at 600°, and rapidly above 700°. The reaction was studied by J. Guillissen and P. J. van Rysselberghe, G. L. Oldright and D. P. Niconoff, E. H. Hamilton and co-workers, G. Murray and D. McIntosh, C. W. Parmelee and co-workers, V. Tafel and H. Grosse, and K. List. W. Florence reported that he had obtained crystals by fusion in a mixture of lead oxide and borax. According to A. Gorgeu, the crystals are formed when a soln. of a mol of sodium sulphate, 1 to 2 mols of zinc sulphate, and 0·25 to 0·5 mol of ferric sulphate is evaporated to dryness, and the product fused at a cherry red-heat, a small quantity of the mixture being removed from time to time and treated with boiling water. When nothing but octahedra appear in the liquid, together with some basic zinc sulphate, fusion is stopped, and the cooled mass is extracted with boiling water, the basic zinc sulphate being removed by means of dil. acetic acid. The formation of zinc ferrite under these conditions is due to the action of the ferric oxide, formed by the decomposition of the ferric sulphate, on the mixture of sodium sulphate and basic zinc sulphate. The ferrite can, in fact, also be obtained by the action of powdered hæmatite on a mixture of zinc and sodium sulphates, fused at a cherry red-heat. If the hæmatite contains sand, crystals of willemite appear after the formation of franklinite, and before the formation of crystallized zinc oxide. This fact assists in explaining the association of these three minerals in certain veins. Franklinite can also be formed from zinc chloride or fluoride. The chloride is heated in moist air with ferric chloride, or with powdered hæmatite. In the case of the fluoride, 4 parts are mixed with 6 parts of potassium fluoride, and 2 parts of ferric fluoride or 1 part of ferric oxide. Any crystals of zincite which are formed are removed by treatment with dil. acetic acid. A franklinite identical with the natural mineral is obtained by fusing together sodium sulphate and 10 per cent. each of zinc, manganese, and ferric sulphates, and adding a small quantity of a reducing agent, such as ferrous sulphide, during fusion. The small quantity of ferrous oxide thus formed combines with some of the ferric oxide and forms magnetite, which crystallizes with the zinc ferrite. K. List, and H. Forestier and G. Chaudron obtained zinc ferrite by adding sodium hydroxide to a mixed soln. of zinc and ferric chlorides, and strongly heating the precipitate; and S. Hilpert used a somewhat similar method. J. S. Wells reported the compounds $2ZnO.Fe_2O_3$, and $4ZnO.Fe_2O_3$.

Franklinite is an iron-black mineral with a reddish-brown or black streak; artificial zinc ferrite is reddish-brown with a yellowish-red streak. Franklinite may occur in coarse or fine granular or compact masses, and in octahedral crystals belonging to the cubic system. There is an octahedral pseudo-cleavage or parting as with magnetite. F. Becke found that the corrosion figures with 17·5 per cent. hydrochloric acid resemble those of spinel or magnetite; and O. Mügge obtained similar results with potassium hydrosulphate, etc. Observations on the crystals were also made by A. H. Phillips, F. R. van Horn, W. J. Mead and C. O. Swanson, and H. Mierke; and J. Königsberger studied the optical anisotropy. A. Gorgeu said that the artificial crystals appear in regular octahedra modified by facets of the rhomboidal dodecahedron. P. F. Kerr studied the X-radiograms. E. Posnjak found the cubic space-lattice is of the spinel type with eight molecules per unit cell, and with $a=8·41$ A.; G. L. Clark and co-workers gave $a=8·423$ A.; and S. Holgersson gave $a=8·403$. M. L. Huggins discussed the electronic structure. The calculated density is 5·349, and the observed 5·290. G. C. Stone gave 5·09 to 5·215 for the sp. gr. of franklinite; A. Gorgeu, 5·09, and for artificial zinc ferrite, 5·33, while J. J. Ebelmen gave 5·12. W. Biltz and co-workers found that the mol. vol. is 44·6, of which 14·3 belongs to ZnO, and 30·3 to Fe_2O_3. The hardness of franklinite is 5·5 to 6·5; and of artificial zinc ferrite, 6·5. H. Forestier observed no anomaly on the dilation curve up to 800°. G. Spezia said that the mineral is infusible before the blow-pipe. E. S. Larsen gave 2·36 for the index of refraction; and E. Posnjak, 2·31 for Li-light. E. T. Wherry found franklinite to be a medium radiodetector. F. Beijerinck found that the mineral is a good conductor of electricity, particularly at high temp. E. E. Fairbanks gave >81 (water 81) for the dielectric constant. A. Gorgeu said that the artificial ferrite is non-magnetic, while franklinite is magnetic; S. Hilpert found that artificial zinc ferrite is non-magnetic until it has been fused; and H. Forestier and G. Chaudron stated that zinc ferrite gives a magnetization-temp. curve with no discontinuity, and which is reversible throughout. The mean magnetic susceptibility of zinc ferrite is $0·16\times10^{-3}$ mass unit. F. Stutzer and co-workers found the coeff. of magnetization of franklinite to be $35·64\times10^{-6}$; and E. F. Herroun and E. Wilson, the magnetic susceptibility to be 455×10^{-6}, and W. R. Crane, 33×10^{-6}. According to Y. Kato and T. Takei, the most highly magnetic products are obtained by heating zinc and ferric oxides in the proportion 2 : 3. The product obtained by heating this mixture at 1130° and then quenching, was black and almost non-magnetic, but if allowed to cool slowly in the air it was reddish-brown and either magnetic or non-magnetic, according to the rate of cooling. Black specimens turned reddish-brown and became more magnetic when heated at 450°. The magnetic character of the brown specimens is attributed mainly to mechanically mixed ferric oxide. Magnetite can form solid soln. with zinc ferrite and thereby greatly increase its magnetic character. S. Hilpert and co-workers, and S. Holgersson and A. Serres studied the magnetic properties of the ferrites. H. Kittel and G. F. Hüttig said that mixtures of the component oxides when calcined at 620° show no marked change in magnetic properties or in their X-radiograms; at 620° to 670°, the magnetic susceptibility is increased; and at 670° to 770°, the compound becomes ferromagnetic, and there is a change in internal structure. H. A. J. Wilkens and H. B. C. Nitze discussed the magnetic separation of franklinite. H. Forestier could not fix a definite Curie point. A. Gorgeu said that zinc ferrite is attacked very slowly by acids; franklinite dissolves in hydrochloric acid with the evolution of a little chlorine—this is attributed to the effect of the admixed manganic oxide. C. E. Swartz and F. C. Krauskop found that zinc ferrite can be partially decomposed by calcium oxide or magnesium oxide at 850°. V. Tafel and H. Grosse observed that at 1050°, zinc ferrite is reduced by charcoal as rapidly as zinc oxide, but below this temp., it is reduced more slowly; zinc oxide is more easily reduced by metallic iron; the addition of some lime to the ferrite favours reduction. The transformations of franklinite in nature were discussed by J. Roth; and A. R. Leeds reported a pseudomorph of franklinite after calcite.

H. Forestier and G. Chaudron prepared **cadmium ferrite**, $Cd(FeO_2)_2$, by the methods they employed for zinc ferrite. The magnetic properties disappear on heating, and ultimately disappear at the Curie point, about 400°, but are restored on cooling; the heating and cooling curves give coincident curves unless heated above the Curie point, when this point is depressed, and by keeping the ferrite at a high temp. for some time it can be transformed into a paramagnetic form. E. Posnjak found that the cubic space-lattice is of the spinel type with 8 mols. per unit cell, and a=8·67 A.; the calculated density is 5·835, and the observed. 5·764. S. Holgersson gave a=8·731 A. W. Biltz and co-workers found the mol. vol. is 50·0, of which 15·8 belongs to CdO, and 34·2 to Fe_2O_3. H. Forestier said that the lattice is hexagonal with the ratio $a : c$=1 : 1·64. Paramagnetic cadmium ferrite loses its magnetism when heated. There is an allotropic change with the ferromagnetic state unstable. The index of refraction with Li-light is 2·39. H. Forestier observed that the magnetic transition temp. is not reversible, being about 250° on the heating curve, and 150° on the cooling curve. The relation between the strength of the magnetic field and the intensity of magnetization is shown in Fig. 545.

No **aluminium ferrite** has been prepared. A. Salvétat observed the bleaching action of alumina on ferric oxide. A. Béchamp found that freshly precipitated aluminium hydroxide added to a dil. or conc. soln. of ferric chloride slowly withdraws the iron from soln. as hydrated ferric oxide, but the reverse action does not occur, since freshly precipitated ferric hydroxide does not dissolve in dil. or conc. soln. of aluminium chloride. In some of the bauxites analyzed by P. Berthier, H. St. C. Deville, and M. von Lill, some ferric oxide seems to replace alumina isomorphously. According to N. Kühnl and W. Pauli, when precipitated aluminium hydroxide is peptized with ferric chloride, or ferric hydroxide with aluminium chloride, brown sols are obtained containing roughly equivalent amounts of aluminium and iron, the proportions varying with the mode of preparation. In the replacement of chlorine by coagulating anions, and in the relations exhibited by the transport numbers, and the size of particles, these sols resemble pure ferric hydroxide peptized sols. It is suggested that the sol particles have the same constitution as solid soln. H. Forestier observed that the break in the dilation curve of different mixtures varied as indicated in Fig. 550. S. Hilpert and co-workers studied the magnetic properties of the aluminium ferrites or solid soln.—$Al_2O_3.3Fe_2O_3$. The mineral *hercynite*, analyzed by B. Quadrat, and synthesized by J. J. Ebelmen, is a ferrous aluminate—**5.** 33, 12. According to H. Warth, when mixtures of alumina and ferric oxide are heated before the blow-pipe, they become pure white in colour provided the proportion of the ferric oxide does not exceed 7 per cent.; beyond that stage, the mixtures are brown after they have been heated. The bleaching action of alumina on ferric oxide was observed by A. Salvétat, and attributed by L. A. Keane, F. H. Scheetz, and J. H. Yoe, to be due to the fine particles of peptized ferric oxide being prevented from agglomerating to red ferric oxide by alumina. For *ferric aluminate, vide infra*, ferric chloride.

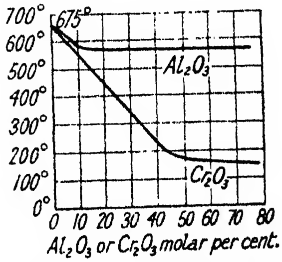

FIG. 550.—Anomalous Point in the Dilation Curve of Mixtures of Ferric Oxide with Aluminium and Chromium Oxides.

According to E. D. Campbell, if a soln. of lime in molten $5CaO.3Al_2O_3$ contains alumina and ferric oxide in the molar proportion 1 : 3, and is slowly cooled, a solid soln. of ferric oxide and alumina crystallizes out in the ratio 1 : 7 until the ratio in the soln. has increased to 1 : 3·5, when crystals of the solid soln. in this ratio crystallize out, and the ratio in the soln. has attained 1 : 1 at about 1370°. The solubility of calcium oxide in fused calcium aluminates in which part of the alumina is replaced by ferric oxide is less than in pure aluminates. H. Forestier and G. Chaudron found that the presence of alumina in ferric oxide does not lower the transition point, 675°, of ferric oxide if the mixture has previously been heated to 400°. This is taken to show a mere juxtaposition of the two oxides, not solid soln. Mixtures heated to 700° afford evidence of the formation of solid soln., which is completed at 900° in 2 hrs. The addition of up to 12 per cent. of alumina decreases the transition point to 575°, but further additions produce no other change. H. le Chatelier believed that a calcium aluminatoferrite, $3CaO.Al_2O_3.Fe_2O_3$, exists; while E. S. Shepherd and co-workers observed that calcium oxyferrite, $2CaO.Fe_2O_3$, reacted with $5CaO.3Al_2O_3$. W. C. Hansen, and L. T. Brownmiller and R. H. Bogue studied a part of the ternary system: Al_2O_3–Fe_2O_3–CaO, and their results are summarized in Fig. 551. The area A is the zone where calcium oxide occurs as primary phase; B, the aluminate, $3CaO.Al_2O_3$; C, the aluminate, $5CaO.3Al_2O_3$; D, the complex $4CaO.Al_2O_3.Fe_2O_3$; and E, the zone of solid soln. of $4CaO.Al_2O_3.Fe_2O_3$ and $2CaO.Fe_2O_3$. The dotted line is not a true boundary line since, owing to the formation of a continuous series of solid soln., there can be no true boundary line separating the fields where $4CaO.Al_2O_3.Fe_2O_3$ and $2CaO.Fe_2O_3$ occur as primary phases.

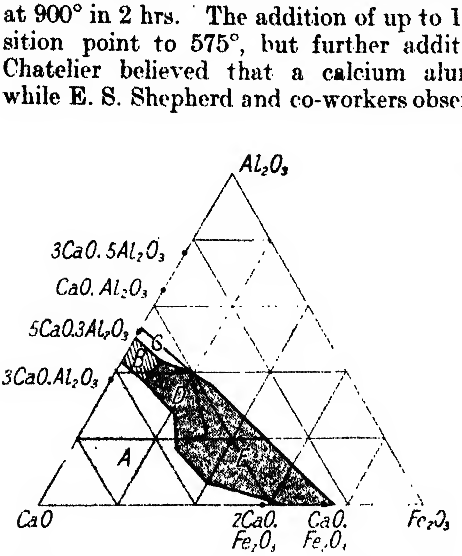

FIG. 551.—Phase Diagram of a Portion of the Ternary System: CaO–Al_2O_3–Fe_2O_3.

Crystalline **calcium aluminatoferrite,** $4CaO.Al_2O_3.Fe_2O_3$—also called *brownmillerite*—is readily formed by heating a mixture of its components below 1400°. It has a sp. gr. 3·77, and it melts congruently at 1415°. The compound is biaxial, and negative; it has a medium optic axial angle; there is occasional polysynthetic twinning, and the prismatic grains have the extinction angle against the prismatic faces very small; the pleochroism γ is brown, and α, yellowish-brown. The indices of refraction are: $\alpha = 1·96$, $\beta = 2·01$, and $\gamma = 2·04$ for Li-light; and $\alpha = 1·98$, $\beta = 2·05$, and $\gamma = 2·08$ for the yellow mercury line, $\lambda = 578$. S. Solacoln established the individuality of this salt. It is stable in the presence of an excess of lime, and forms solid soln. with dicalcium ferrite. According to W. C. Hansen, and L. T. Brownmiller and R. H. Bogue, the f.p. curve of calcium aluminatoferrite with calcium oxide forms a eutectic mixture melting at 1395°, Fig. 552.

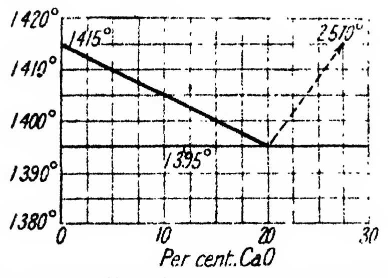

FIG. 552.—Freezing-point Curves of the System: $4CaO.Al_2O_3.Fe_2O_3$ and CaO.

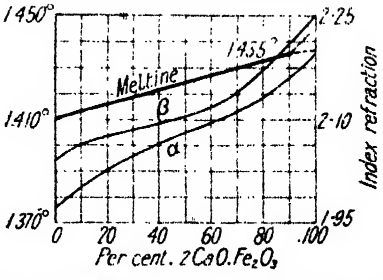

FIG. 553.—Melting-points and Refractive Indices of Solid Solutions of $4CaO.Al_2O_3.Fe_2O_3$ and $2CaO.Fe_2O_3$.

Mixtures of calcium aluminatoferrite, and calcium oxyferrite, Fig. 553, form a complete series of solid soln. The oxyferrite dissociates at 1435° into calcium oxide and liquid. The indices of refraction of the solid soln. are shown in Fig. 553. Those rich in $4CaO.Al_2O_3.Fe_2O_3$ are negative, those rich in $2CaO.Fe_2O_3$ are positive. Mixtures of calcium aluminatoferrite with calcium dioxytrialuminate, $5CaO.3Al_2O_3$, or $2CaO.3Ca(AlO_2)_2$, have a eutectic at 1335°, Fig. 554. With the system calcium aluminate and ferrite, Fig. 555, there is a eutectic at 1205°. W. C. Hansen and L. T. Brownmiller made a partial study of the f.p. of the system :

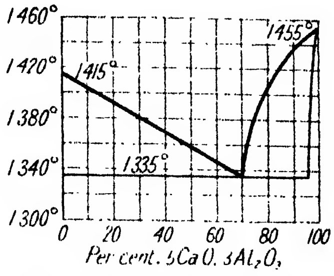

FIG. 554.—Freezing-point Curve of the System : $4CaO.Al_2O_3.Fe_2O_3$ and $5CaO.3Al_2O_3$.

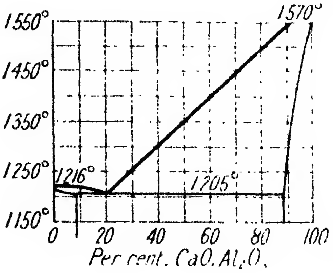

FIG. 555.—Freezing-point Curve of the System : $CaO.Fe_2O_3$ and $CaO.Al_2O_3$.

$MgO–4CaO.Al_2O_3.Fe_2O_3$, and the results are summarized in Fig. 556. The solid soln. dissociate at 1370° ; and undergo a thermal change at 1300°. A **calcium magnesium aluminatoferrite,** $4CaO.2MgO.Al_2O_3.Fe_2O_3$, is formed, which dissociates at 1370°, and changes from an α- to a β-form at 1300°. Its sp. gr. is 3·72 ; the crystals are uniaxial or biaxial, with a very small optic axial angle : α = 1·92, and γ = 1·97 for Li-light. The pleochroic crystals have α = yellowish-brown, and γ = dark brown almost opaque. The X-radiograms were examined. T. F. W. Barth and E. Posnjak studied the ferrite, and favoured the structure $Fe''MgFeO_4$.

H. von Wartenberg and W. Gurr observed that no **zirconium ferrite** is formed by heating mixtures of the constituent oxides—see Fig. 530. S. Hilpert and co-workers studied the magnetic properties of the **stannic ferrites,** $SnO_2.2Fe_2O_3$ and $SnO_2.3Fe_2O_3$. According to K. List, **lead ferrite,** $Pb(FeO_2)_2$, is formed by the action of lead oxide on a soln. of ferric chloride ; according to O. Proske, when lead sulphate is decomposed by ferric oxide ; and, according to H. Forestier and G. Chaudron, and S. Hilpert, by adding alkali-lye to a mixed soln. of lead and ferric chlorides, and heating the precipitate to redness. H. Forestier said that the X-radiograms correspond with a hexagonal lattice. S. Hilpert and A. Lindner examined the X-radiograms of the lead ferrites: $PbO.Fe_2O_3$, $PbO.2Fe_2O_3$, and $PbO.8Fe_2O_3$. E. J. Kohlmeyer obtained cooling curves of mixtures of lead and ferric oxides, and obtained evidence of the possible existence of compounds with the molar ratio, $PbO : Fe_2O_3 = 3 : 1$, 3 : 2, 1 : 1, 2 : 3, and 1 : 2. The microstructure of the mixtures agrees with these results. The sp. gr. and sp.-vol. of the mixtures were :

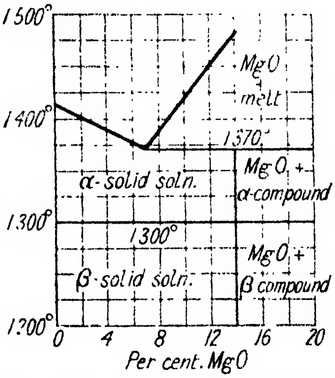

FIG. 556.—Freezing-point Curves of the System : MgO $4CaO.Al_2O_3.Fe_2O_2$.

PbO . .	100	75	60·22	51·48	40·12	28·26	18·39	9·71
Sp. gr. .	9·514	8·170	7·896	6·936	6·337	5·974	5·461	5·353
Sp. vol. .	0·105	0·122	0·137	0·144	0·158	0·167	0·177	0·187

The curve with full data has breaks corresponding with 3 : 1, 3 : 2, and 2 : 3. The hardness increases with increasing proportions of ferric oxide. The curve of the relative magnetic permeabilities has a small maximum with the 1 : 1 compound, and there is a break corresponding with the 1 : 2 compound. E. J. Kohlmeyer, and M. Feiser observed that the lead is less volatile than it is with litharge. According to E. J. Kohlmeyer, the colour of all the mixtures in hydrogen darkens at 220° ; and at 260° to 280° some metal is formed. When heated in air or oxygen some red lead is formed, and water extracts a little lead oxide; if exposed to air and water, a skin of basic lead carbonate is formed; boiling conc. hydrochloric acid extracts the lead oxide; hydrogen sulphide blackens the moist powder; and nitric acid extracts most of the lead but leaves a little behind as lead dioxide. The lead ferrites are decomposed when heated with silica. H. Forestier observed no break in the dilation curve up to 600°; the Curie point is at 335°, and it is nearly reversible. The relation between the strength of the magnetic field and the intensity of magnetization is shown in Fig. 545. H. Sachse studied the Curie point; and S. Hilpert and co-workers, the magnetic properties. A. Serres studied the magnetic properties of lead ferrite. L. J. Igelström, and G. Aminoff described a mineral from the Jacobsberg mine, Nordmark, Wermland, Sweden. He called it **plumboferrite.** Its composition approximates $Pb(FeO_2)_2$ in which part of the lead is replaced by calcium, magnesium, manganese(ous), and iron(ous). It occurs in nearly black, cleavable masses, with a red streak, and a hardness of 5. K. Johansson calculated from the analysis the formula $(Pb,Mn,Fe)O.2Fe_2O_3$. The axial ratio of the hexagonal crystals is $a:c=1:3{\cdot}9719$; and the X-radiograms correspond with a hexagonal lattice having $a=11{\cdot}86$ A., and $c=47{\cdot}14$ A., or $a:c=1:3{\cdot}9747$. There are 42 mols. or 504 atoms in each elementary parallelopipedal cell. The sp. gr. is 6·07. The mineral acts feebly on a magnet. According to H. Forestier and co-workers, the magnetization decreases as the temp. rises, and disappears at the Curie point; the heating and cooling curves coincide; and the mean magnetic susceptibility is $1{\cdot}2\times10^{-3}$ mass unit. S. Hilpert said that lead ferrite prepared in the wet way is non-magnetic until fused. The transformation point of lead ferrite is near 200°. A mixed lead and cupric ferrite is as strongly magnetic as pure cupric ferrite if rapidly cooled from 1000°, but loses this property if slowly cooled, or if melted at 1300°. The permeability is restored by heating to 900° and slowly cooling. H. Sachse, and S. Hilpert studied the subject. G. Aminoff described **magneto-plumbite** as a related mineral from Langban, Sweden. It has a complex composition approximating $2RO.3Fe_2O_3$ or $3RO.4Fe_2O_3$—the X-radiogram favours the former. It occurs in black, acute, hexagonal pyramids with the axial ratio $a:c=1:3{\cdot}91$; the basal cleavage is perfect. The X-radiogram indicates a holohedral, hexagonal crystal with a unit cell of dimensions $a=606$ A., and $c=23{\cdot}69$ A., containing four mols. $2RO.3Fe_2O_3$. The streak of magnetoferrite is brown; the sp. gr., 5·517; and the hardness, about 6. Unlike plumboferrite, magnetoferrite is strongly magnetic. K. Johansson described a mineral from Jacobsberg, Wermland, and he called it **hämatophanite.** It occurs in thin plates with a mica-like cleavage. The mineral is dark reddish-brown; the powder is yellowish-red. When in very thin plates, the colour by transmitted light is blood-red. The analysis corresponds with **lead chloroferrite,** $Pb(Cl,OH).4PbO.2Fe_2O_3$. The tetragonal crystals have the axial ratio $a:c=1:1{\cdot}95$, and the X-radiogram shows that the lattice has $a=7{\cdot}801$ A., and $c=15{\cdot}23$ A., or $a:c=1:1{\cdot}952$. There are 3 mols. in each parallelopipedal cell. The sp. gr. is 7·70; and the hardness, 2 to 3.

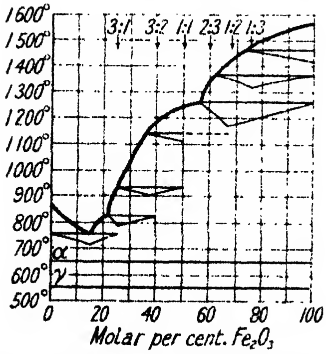

FIG. 557.—Freezing-point Curve of Mixtures of Lead and Ferric Oxides.

No **chromic ferrite** has been prepared—*vide* ferrous chromite. H. Forestier and G. Chaudron observed that the addition of chromic oxide to ferric oxide lowers the transition point of ferric oxide 230° when 40 per cent. has been added, and there is no sharp break in the temperature–chromic oxide curve. With high percentages of chromic oxide, the effect on the transition point is less. Ferric and chromic oxides are miscible in all proportions in agreement with the fact that the ratio of their mol. vols. is nearly unity. H. Forestier observed that the anomalies in the dilation curves of different mixtures of chromic and ferric oxides vary as shown in Fig. 550. S. Hilpert and A. Wille studied the subject. The *chromitite* of M. Z. Jovicic is a mineral from Western Siberia whose analysis corresponds approximately with $Cr_2O_3.Fe_2O_3$, but the ferrous and ferric iron were not separated in the analysis—*vide* chromite. A. Wolff prepared some **tungstatoferrites**—*vide* tungstates, **11.** 62, 14 and 16.

J. H. Andrew and co-workers observed that manganous and ferrous oxides form solid soln.; and P. Oberhoffer and O. von Keil made some determinations of the m.p. of mixtures of the oxides. K. List added alkali-lye to a mixed soln. of equimolar proportions of manganous and ferric chlorides and obtained a dark brown precipitate, which, after calcination, was regarded as a magnetic **manganous ferrite,** $Mn(FeO_2)_2$; but S. Hilpert regarded it as a ferrous manganite. E. Diepschlag and E. Horn, and C. W. Parmelee and co-workers, observed that at a high temp., manganous and ferric oxides unite to form the ferrite. E. Wilson and E. F. Herroun studied the magnetic susceptibility of manganese ferrite A. Damour described a black mineral, **jacobsite,** from Jacobsberg, Wermland, Sweden. Analyses were reported by A. Damour, C. F. Rammelsberg, O. Lindström, L. J. Igelström, G. Flink, and F. Kovar, and the results agree with $(Mn,Fe)O.(Fe,Mn)_2O_3$. The distorted octahedral crystals belong to the cubic system. K. Johansson gave $MgFe_2O_4+(Mn,Fe)Fe_2O_4$. The X-radiograms of the cubic crystals indicate a lattice of side $a=8{\cdot}42$ A., L. Passerini gave $a=8{\cdot}515$ A.; and the lattice is of the magnetite type, with 8 mols., $(Mg,Mn)Fe_2O_4$, per unit cell. The sp. gr. is 4·76; L. Passerini gave 4·436. S. Holgersson gave for artificial $Mn(FeO_2)_2$, $a=8{\cdot}572$ A.; and G. L. Clark and co-workers, $a=8{\cdot}457$ A. A. Damour gave for the sp. gr. 4·75, and for the hardness, 6. W. Biltz and co-workers gave 47·3 for the mol. vol., of which 13·3 belongs to the MnO, and 34·0 to Fe_2O_3. H. Forestier gave 54×10^{-6} for the magnetic susceptibility. S. Hilpert and A. Wille studied the magnetic properties. According to F. A. Genth, a variety of black *Eisenmulm* can be represented as a manganiferous magnetite, $(Fe,Mn)O.Fe_2O_3$; its sp. gr. was 3·76; and M. Weibull, E. Hugel, and A. H. Chester also described manganiferous magnesian magnetites, $(Fe,Mn,Mg)O.(Fe,Mn)_2O_3$. W. M. Bradley described a mineral, **skemmatite,** from Iva, South Carolina. Its composition is $3MnO_2.2Fe_2O_3.6H_2O$, and it is an alteration product of pyroxmangite, $(Fe,Mn)SiO_3$. Its hardness is 5·5 to 6; and it is soluble in hydrochloric acid. P. E. Wretblad observed no sign of the formation of **manganic ferrite,** $Mn_2O_3.Fe_2O_3$.

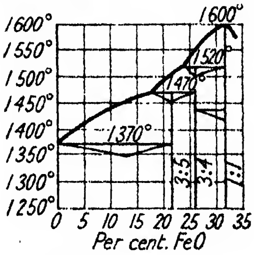

FIG. 558.—Freezing-point Curves of Mixtures of Ferrous and Ferric Oxides.

For **ferrous ferrite,** $Fe(FeO_2)_2$, *vide supra*, magnetite, and ferric oxide, and hydroxide. According to S. Hilpert, ferric hydroxide prepared by oxidizing freshly precipitated ferrous hydroxide with ammonium persulphate is non-magnetic, but if first oxidized by air to the Fe_3O_4-stage, the persulphate gives a highly magnetic product which becomes ordinary ferric oxide at 400°. The ferric hydroxide obtained by the action of air on ferrous carbonate is non-magnetic if rapidly prepared, but if oxidized slowly so that ferroso-ferric oxide is first formed, the final product is magnetic. The magnetic ferrites all contain Fe_2O_3 as an acid-forming oxide, and it is probable that the magnetic ferric oxides described also retain the same constitution: $2(FeO^{+}+2(Fe_2O_3)^{-}+O=(Fe_2O_3{}^{+}.2(Fe_2O_3)^{-}$; this molecular arrangement, however, being unstable, was changed on heating. The results of E. J. Kohlmeyer are summarized in Fig. 558, where there are indications of the formation of the ferrous ferrites, $FeO : Fe_2O_3=1:1$, $3:4$, and $3:5$—*vide supra*, solid soln. of ferric and ferrous oxides; and also ferrosic oxide.

Ferrous ferrites can be obtained: (i) *from orthohydroxide.* F. Wöhler, J. Lefort, and L. A. Welo and O. Baudisch obtained ferrous ferrite by treating a mixed soln. of ferrous and ferric salts with alkali; A. Krause and co-workers by the action of an excess of ammonia on a mixture of peptized yellow ferric metahydroxide in 0·01*N*-HCl and ferrous chloride at 18°; and E. Deiss and G. Schikorr obtained it by mixing hydrosols of ferrous hydroxide and ferric orthohydroxide. The product is brownish-black. The ferrous ferrites can also be obtained (ii) from *metahydroxide*. J. Liebig and F. Wöhler, and R. Böttger obtained ferrous ferrite by treating a soln. of a ferrous salt with alkali-lye, and oxidizing the boiling mixture with oxygen; and A. Krause and co-workers, by treating a mixed soln. of ferrous and ferric chlorides with an excess of aq. ammonia at 18°; and E. Kaufmann and F. Haber, by treating a soln. of ferrous sulphate with ammonia, and oxidizing the boiling mixture with sodium nitrate. The product is deep black with a bluish streak.

A. Krause and J. Tulecki found that the ferrite prepared from the orthohydroxide is more hydrated than the other ferrite. The ferrite obtained from the metahydroxide, unlike that from the orthohydroxide, is stable in air and not readily oxidized. The ferrite from the metahydroxide contains rather more ferrous iron than that from the orthohydroxide. The preparation richest in ferrous iron had the composition $FeO : Fe_2O_3 : H_2O = 1 : 1·13 : 0·54$, or $Fe''(Fe'''O_2)_2.nH_2O$. Both types are ferromagnetic. W. Biltz and co-workers gave 45·1 for the mol. vol. of ferrous ferrite, and of this, 12·0 belongs to the FeO, and 33·1 to the Fe_2O_3.

T. F. W. Barth and E. Posnjak discussed the titanium salt, $FeTiFeO_4$, or $Ti(FeO_2)_2$—**titanium ferrite.** E. J. Kohlmeyer also reported a **lead ferrous ferrite,** $PbO.FeO.4Fe_2O_3$. For ferric orthoferrite, $Fe(FeO_3)$, see magnetic ferric oxide. H. Forestier and G. Chaudron found the mean magnetic susceptibility to be 80×10^{-3} mass unit. S. Hilpert's product was obtained by precipitating a soln. of a mixture of ferrous and ferric salts with soda-lye. The black precipitate becomes red when calcined in air, and its magnetic transformation point is 525°.

According to S. Hilpert, if a colloidal soln. obtained by treating an aq. soln. of cobaltous nitrate and ferric chloride with *N*-NaOH is treated with ammonia, the precipitated **cobaltous ferrite,** $Co(FeO_2)_2$, is distinctly magnetic. S. Hilpert and A. Wille studied the magnetic properties. The amorphous black powder when dried and heated to 280° to 290° loses its magnetic properties, but they are restored on cooling. S. Holgersson found the spinel-like crystals had the lattice parameter $a = 8·359$ A., G. Natta and L. Passerini gave $a = 8·36$ A.; the vol., 584×10^{-24} c.c.; and sp. gr. 5·19. S. B. Hendricks and W. H. Albrecht gave $a = 8·35$ A., and sp. gr. 5·5. R. J. Elliot obtained cobaltous ferrite by joint precipitation, with ammonia, from a mixed soln. of cobaltous and ferric salts and heating the mixture in a crucible. The sp. gr. is 4·82 at 10°. W. Biltz and co-workers gave 44·5 for the mol. vol., of which 11·7 belongs to the CoO, and 32·8 to the Fe_2O_3. When heated in a current of hydrogen sulphide, it forms a magnetic sulphide. S. Veil observed that the magnetization coeff. of the ferrites are more than 1000 times as great as those of the pure constituents. There is a maximum in the magnetization coeff. of calcined mixtures of the constituent oxides of cobalt ferrite corresponding with that of the pure ferrite. E. V. Shannon discussed the formation of ferromagnetic cobalt ferrite. S. B. Hendricks and W. H. Albrecht found that the X-radiograms of cobalt ferrite prepared by adding a mixed soln. of cobalt chloride and ferrous ammonium sulphate to boiling sodium hydroxide, are analogous to those of Co_3O_4 and Fe_3O_4. Cobalt ferrite is paramagnetic. The compound cannot be completely dehydrated at 100°, the residual water being merely adsorbed. The magnetic susceptibility of preparations oxidized in varying degree indicates an increase of this property with diminishing content of $Co_2O_3.2Fe_2O_3$, the value for the homogeneous material being $45·6 \times 10^{-6}$ mass unit. The oxidized product exhibits the same X-ray spectrum as the oxide, $CoO.Fe_2O_3$, but the lines are less sharply defined. When the substance is heated, the lines become more distinct and completely identical with those of the lower oxide if the temp. has been raised above 250°. The magnetic properties were examined by S. Hilpert, P. Martin, S. Veil, and E. F. Herroun and E. Wilson. S. B. Hendricks and W. H. Albrecht prepared what may be **cobaltic ferrite,** $Co_2O_3.Fe_2O_3$, in the homogeneous state, by adding potassium persulphate to the soln. employed for making cobaltous ferrite.

H. Forestier and G. Chaudron prepared **nickelous ferrite,** $Ni(FeO_2)_2$, by adding alkali-lye to a mixed soln. of nickelous and ferric chlorides, and heating the precipitate to redness. L. Passerini found that the space-lattice of the cubic spinel has the side 8·340 A.; the vol. $580{\cdot}09\times10^{-24}$ c.c.; and sp. gr. 5·268. H. Forestier said that the salt has a spinel lattice. W. Biltz and co-workers gave 44·7 for the mol. vol., of which 11·0 belongs to the NiO, and 33·7 to the Fe_2O_3. J. A. Hedvall, K. List, and S. Holgersson prepared brown magnetic nickel ferrite in a similar manner. H. Forestier and G. Chaudron found that its mean magnetic susceptibility is 78×10^{-3} mass unit; and its magnetic transition point is 590°. H. Forestier observed a break in the dilation curve near 590°, and the Curie point is about the same temp. The relation between the strength of the magnetic field and the intensity of magnetization is shown in Fig. 545. Nickel ferrite is stable at a high temp. A. Serres, and H. Sachse also studied the Curie point, and S. Hilpert and A. Wille, the magnetic properties. S. Veil obtained results with the magnetization coeff. of nickel ferrite similar to those which she obtained with cobalt ferrite. W. Stahl, and A. Serres studied the nickel ferrites. A. F. Grosse described a black nickel magnetite which was called **trevorite.** Analyses by A. F. Grosse, and T. L. Walker correspond with $Ni(FeO_2)_2$. E. V. Shannon discussed the formation of ferromagnetic trevorite. Its sp. gr. is 5·165, and its hardness 5.

Higher oxides than ferric oxide have been assumed to exist. Thus, C. Zimmermann [2] explained the reaction between potassium permanganate and ferrous chloride in the presence of hydrochloric acid on the assumption that a higher iron oxide was formed; J. Brode, the action of hydrogen dioxide on a soln. of ferric chloride; A. Bach, the action of air on iron; and C. W. Bennett and W. S. Burnham, and W. D. Bancroft, the action of nitric acid on iron. Although the oxide with quadrivalent iron, **iron dioxide,** FeO_2, has not been prepared, some salts—**perferrites**—supposed to contain this oxide as an acid anhydride have been reported by L. Möser and H. Borck. According to G. Pellini and D. Meneghini, when hydrogen dioxide acts on ferrous or ferric chloride, or on ferrous or ferric hydroxide, there is formed a very unstable, pale red substance resembling colloidal ferric hydroxide, but having the properties of a true peroxide. The composition could not be established with certainty, but experiments show that the ratio Fe : O is not less than 2 and not greater than 3. It is thought that the product is *iron peroxide*, O=Fe–O–O–Fe : O, or

$$Fe<\overset{O}{\underset{O}{:}}$$

They also found that an alcoholic soln. of ferrous chloride exhibits a yellowish-green coloration, the intensity of which is only slightly diminished by intense cold; with ferric chloride, the soln. has a yellowish-brown colour, which fades appreciably on cooling. The soln. of the ferrous salt reacts energetically with hydrogen dioxide, developing a considerable amount of heat and an intense brown coloration, which is not sensibly lightened by cooling; the soln. of the ferric salt reacts feebly with hydrogen dioxide, the liquid obtained not differing appreciably from the original soln., and losing its colour in the same way on cooling. This behaviour indicates that some sort of chemical combination takes place between the ferrous salt and hydrogen dioxide, whilst with ferric chloride such combination takes place either not at all or only extremely slowly. W. Manchot and F. Glaser supposed that the dioxide is formed when ferrous compounds are oxidized with free oxygen; L. Losana, as ferrous ferrate, $Fe(FeO_4)$, when barium ferrate is treated with a soln. of ferrous nitrate; and C. A. O. Rosell, when barium ferrate is treated with a soln. of ferric chloride. In connection with the ferrates obtained by L. Losana—*vide infra*—ferrous ferrate, $Fe(FeO_4)$, has the ultimate composition FeO_2; and ferric ferrate, $Fe_2(FeO_4)_3$, the ultimate composition Fe_5O_{12}.

According to L. Möser and H. Borck, if a mixture of conc. soln. of a mol of ferric nitrate and 1 to 2 mols of strontium nitrate be evaporated to dryness, and the finely powdered residue heated to a temp. not exceeding 600°, in a current of oxygen, until all the nitrogen oxides are expelled, a compound is obtained whose composition corresponds with **strontium perferrite,** $SrO.FeO_2$, or $SrFeO_3$, and not with $2SrO_2.Fe_2O_3$. A hydrated product is obtained as a yellowish-brown precipitate on warming on a water-bath for some time a suspension of freshly precipitated ferric hydroxide in a conc. soln. of strontium hydroxide. When heated, it loses water and becomes brown, and at temp. exceeding 300°, it absorbs oxygen to form $SrO.FeO_2$. It can also be obtained by oxidizing a mixture of freshly precipitated ferric hydroxide and a conc. soln. of, say, lithium hydroxide, with bromine, and also by heating the ferrate until the oxygen is evolved, and then heating the brown product in air or oxygen so as to re-oxidize it to perferrite. The salt was also prepared by W. Eidmann and L. Möser; and K. Albert and H. Schulz recommended it as a catalyst for the oxidation of sulphur dioxide. L. Möser and H. Borck prepared **barium perferrite,** $BaFeO_3$, by heating to 400°, in a current of oxygen, a mixture of barium and ferric hydroxides; and it was studied by L. Losana. Impure **lithium perferrite,** Li_2FeO_3, was prepared by L. Möser and H. Borck, by oxidizing a mixture of lithium and ferric hydroxides with bromine. If a mixture of barium or sodium and ferric hydroxides be oxidized with bromine, the perferrites are produced.

These perferrites are black substances which are stable below 640°, but beyond that temp. they decompose slowly with the evolution of oxygen; the reaction: $4SrFeO_3 \rightleftharpoons 4SrO + 2Fe_2O_3 + O_2$ is reversible. The perferrites are slowly decomposed by water with the evolution of oxygen: $4SrFeO_3 + 10H_2O = 4Sr(OH)_2 + 4Fe(OH)_3 + O_2$; there is a violent reaction with hydrogen dioxide: $4SrFeO_3 + 2H_2O_2 + 8H_2O = 4Sr(OH)_2 + 4Fe(OH)_3 + 2O_2$; with hydrochloric acid, both chlorine and oxygen are evolved: $2SrFeO_3 + 10HCl = 2SrCl_2 + 2FeCl_3 + 5H_2O + O$, and $O + 2HCl = H_2O + Cl_2$. It can be assumed that an unstable iron tetrachloride, $FeCl_4$, is formed: $2SrFeO_3 + 12HCl = 2SrCl_2 + 2FeCl_4 + 6H_2O$ followed by $2FeCl_4 = 2FeCl_3 + Cl_2$; with sulphuric acid, oxygen is evolved; $4SrFeO_3 + 10H_2SO_4 = 4SrSO_4 + 2Fe_2(SO_4)_3 + 10H_2O + O_2$; with nitric acid, oxygen is vigorously evolved and nitrates are formed; with acetic acid, acetates are formed and oxygen is evolved; with oxalic acid, oxygen and carbon dioxide are formed; there is no perceptible reaction with dry carbon dioxide at ordinary temp., but at a red-heat, the perferrite is completely decomposed; thus, at 600° to 700° the reaction is symbolized: $4SrFeO_3 + 4CO_2 \rightleftharpoons 4SrCO_3 + 2Fe_2O_3 + O_2$, and the reaction is reversible, but there are side reactions: $SrCO_3 \rightleftharpoons SrO + CO_2$, and $6Fe_2O_3 = 4Fe_3O_4 + O_2$; moist carbon dioxide slowly decomposes the perferrite at ordinary temp.; and mixtures of air and alcohol or other inflammable vapours, when led over the heated perferrite, are oxidized to water and carbon dioxide, and when once the combination has started, combustion proceeds of its own accord. The perferrites are fairly stable towards alkaline liquids; thus soln. of the alkali or alkaline earth hydroxides decompose the perferrite less and less with increasing concentration; similarly also with soln. of alkali carbonates and phosphates.

W. Manchot and O. Wilhelms inferred that in the liberation of iodine from potassium iodide by hydrogen dioxide in the presence of a ferrous salt, the iron does not act catalytically but is itself oxidized in such a way that every 2 atoms of ferrous iron require 2 mols of hydrogen dioxide, and 2 atoms of iodine are liberated. Allowing for the oxidation of ferrous to ferric iron, this means that an *iron peroxide*—**iron hemipentoxide,** Fe_2O_5, or iron pentiodide, FeI_5—is formed. Again, if half a mol of hydrogen dioxide be added to a soln. of a mol of ferrous sulphate, the whole of the latter is oxidized to ferric sulphate; but if a mol of ferrous sulphate soln. be added to a soln. of 0·5 mol to 1·4 mols of hydrogen dioxide, both ferrous and ferric salts exist side by side—particularly at 0°—and varying quantities of oxygen are evolved. With a mol of ferrous salt and 1·5 mols of hydrogen dioxide at 0°, between 1 and 1½ mols of hydrogen dioxide are consumed, corresponding, as before, with the formation of iron hemipentoxide. In acidic soln., the interaction of ferrous salts, hydrogen dioxide, and potassium iodide is more complex, the iodine being liberated more slowly; the iron here acts catalytically, and there is no well-defined end-point of the action. The addition of dil. sulphuric acid to a soln. of hydrogen dioxide containing sufficient ferric ammonium sulphate to destroy the whole of the dioxide in about 70 hrs., practically prevented the iron from changing the conc. of the soln. Acid also retards the oxidation of ferrous salts by hydrogen dioxide and the addition of oxygen (or hydrogen dioxide) to ferric salts. Ferric salts destroy hydrogen dioxide more slowly than do ferrous salts. W. Manchot also drew similar conclusions from the action of hydrogen dioxide, potassium permanganate and chromic acid on a ferrous compound in the presence of an acceptor; and N. R. Dhar, for the induced oxidation of sodium formate. The reactions were studied by A. K. Goard and E. K. Rideal, R. Kuhn and A. Wassermann, C. S. Mummery, W. Manchot and G. Lehmann, and H. Wieland and W. Franke.

§ 34. Iron Trioxide.—Ferric Acid and the Ferrates

G. E. Stahl,[1] in his *Specimene Becheriano* (Franckfurth, 1702), said that when iron is heated with nitre, and the product digested with water, the alkali produced by the decomposition of the nitre takes up some iron to form an amethyst or purple soln. Again, if a very dil. soln. of iron in nitric acid be poured by small portions at a time into conc. potash-lye, and the liquid be agitated, the iron dissolves to form a blood-red soln. According to C. Neumann,

> A mixture of equal parts of iron filings and nitre, injected into a strongly heated crucible, and, after detonation, thrown into water, tinges the liquor of a violet or purple-blue colour. This soln., however, is not permanent. Though the liquor at first passes through a filter without any separation of iron, yet, on standing for a few hours, the metal falls to the bottom in the form of a brick-coloured powder. It is pretty singular, that volatile alkalies instantly precipitate the iron from this fixed alkaline soln.

A. G. Ekeberg also observed that when gadolinite is fused with potassium hydroxide, a dark red soln. is obtained which, on standing, deposits a brick-red precipitate; and he added that the red colour is not due to manganese; for the alkali hydroxide can dissolve iron, producing a beautiful purple colour. A. C. Becquerel found that when ferric oxide is heated with 4 to 6 times its weight of potassium hydroxide in a silver crucible, some ferric oxide dissolves, but separates out again with the simultaneous evolution of oxygen when the product is dissolved in water. The escape of oxygen was attributed to the decomposition of potassium peroxide formed in the reaction. R. Phillips discussed ferric acid in 1843, and E. Frémy, in his *Recherches sur les acids métalliques*, 1844, showed that a salt of a ferric acid, or of **iron trioxide,** FeO_3, is formed and decomposed in A. C. Becquerel's experiment. Attempts to prepare the trioxide have not been successful; it is, however, considered to be the anhydride—*ferric anhydride*—of **ferric acid,** H_2FeO_4, a reputed parent of a series of salts formed by the union of this dibasic acid with the basic oxides. The salts are called **ferrates,** and are symbolized $R_2'FeO_4$. W. Manchot and O. Wilhelms assumed that this oxide is formed as an intermediate product in the oxidation of a ferrous salt with hypochlorous acid; and the subject was discussed by W. D. Bancroft. D. R. Hale supposed that FeO_3 is formed as an intermediate compound when hydrogen dioxide or potassium permanganate acts on neutral soln. of a ferrous salt; and that Fe_2O_4 is the intermediate oxide formed when oxygen acts on ferrous iron in alkaline soln. J. W. Retgers' experiments on the solid soln., or isomorphous mixtures formed by potassium ferrate are in harmony in that definite ferrates are formed. These formulæ are also in accord with the analyses of E. Frémy, J. D. Smith, H. Rose, and J. de Mollins.

According to E. Frémy, if a fireclay crucible containing 5 grms. of iron filings be heated to redness, and 10 grms. of the powder of fused potassium nitrate be projected therein, a lively reaction occurs, and a portion of the mixture may be thrown out of the crucible. The covered crucible is then allowed to cool. A reddish-violet mass of **potassium ferrate,** K_2FeO_4, is formed. H. Trommsdorff recommended projecting a mixture of finely divided iron and nitre, in the proportions 1 : 2, into a crucible at a dull red-heat. If the temp. is too high, the ferrate may be decomposed as fast as it is formed. H. W. F. Wackenroder said that if the crucible be too hot, the nitre fuses without deflagrating, and the mass must then be poured into an iron mortar, powdered, and again projected into the crucible. The crucible should be so heated that it is perceptibly red only at the bottom and a few inches up the sides, and the mixture projected into the middle and somewhat to the side. The deflagration occurs in a few seconds, it is attended by a bright glow, and an intumescence of the mass. The crucible is removed from the fire during or immediately after the deflagration. The product is contaminated with alkali nitrite so that the red soln. it forms with water, quickly loses its colour owing to the reduction of the ferrate. E. Frémy found that the reddish-brown, highly deliquescent mass which is obtained by heating ferric oxide for a considerable time with potassium hydroxide, contains the ferrate; but it is best prepared by strongly igniting a mixture of ferric oxide, and potassium nitrate and hydroxide for some minutes. If the heat is too low, potassium nitrite remains undecomposed, and then, on the addition of water, the ferrate is reduced to ferric oxide. A. W. Hofmann used a similar process. J. D. Smith recommended the following mode of preparation. He said:

> Wash the *ferri sesquioxidum* of the shops with boiling water until free from sulphate of soda, dry and ignite at a low red-heat; this furnishes a very pure oxide of iron and in a state of minute division; 1 part of this is to be intimately mixed with 4 of dried nitre, reduced to fine powder; place this mixture in a crucible of about twice the capacity of the bulk of the mixture, lute a well-fitting cover on, making a few small holes in the lute to allow the escape of gas, and ignite at a full red-heat for about an hour, if 6 or 8 ounces are made: the time of ignition depends much on the quantity prepared, and the temperature should never be raised above a full red-heat. When well prepared it presents the appearance of a dark reddish-brown porous mass, rapidly deliquescing on exposure to the air, so that I have found it advantageous to powder it whilst still warm, when it may be preserved for use, in a well-stoppered bottle, apparently for any length of time.

A soln. of potassium ferrate is formed by dissolving the dry salt in ice-cold water; some heat is developed in the act of soln., and there is always a slight decomposition and an evolution of oxygen, owing, said D. Smith, to the decomposition of potassium peroxide. The soln. must be separated from the undissolved portion by subsidence and decantation, not by filtration through filter-paper. E. Frémy obtained a soln. of the salt by passing chlorine through conc. potash-lye in which ferric oxide is suspended, until the oxide is all dissolved, to form a red soln. of potassium ferrate: $Fe_2O_3.3H_2O+10KOH+3Cl_2=6KCl+8H_2O+2K_2FeO_4$. H. W. F. Wackenroder said that 5 parts of hydrated ferric oxide dried between bibulous paper, 10 parts of potassium hydroxide, and 16 parts of water can be used. The hydrated oxide quickly dissolves as chlorine is passed into the liquid. There is a gradual rise in temp., and potassium chlorate is deposited by the cooling liquid. If too much water, or too much hydrated ferric oxide be used, the liquid remains colourless; and H. Rose added that if an excess of chlorine is used, the ferrate will be decomposed. L. Losana, C. A. O. Rosell, G. Merz, and L. E. Rivot and co-workers also used chlorine as the oxidizing agent; A. Mailfert said that the chlorine can be replaced by ozone; A. Mennet, M. Muspratt and E. S. Smith, G. Blattner, and W. Foster used calcium or sodium hypochlorite; D. K. Goralevich, potassium nitrate; C. L. Bloxam, and C. A. O. Rosell, bromine—iodine did not work satisfactorily; and W. Foster, hypobromite. According to H. G. Elledge, the red colour with some hypochlorite soln. is not due to alkali ferrate, but to permanganate. L. Möser recommended the following process:

> Gradually add 50 grms. of bromine to a suspension of 80 to 90 grms. of hydrated ferric oxide in a cooled soln. of 50 grms. of potassium hydroxide in 80 grms. of water; more potassium hydroxide is then added, and the mixture kept at 50° to 60° for 30 mins. The ferrate from the cold soln. is drained on a tile, and the excess of alkali removed by alcohol. The potassium bromide is then removed by dissolving the product in a little water, and re-precipitating it with alcohol.

F. Haber and W. Pick observed that soln. of ferrous and ferric salts are readily oxidized to ferrate by electrolytic oxygen. J. C. Poggendorff passed a current of electricity from 6 pairs of Grove's batteries for 24 hrs. through an anode of cast-iron into a sat. soln. of potassium hydroxide containing a clay cylinder with the platinum cathode. The whole is cooled by ice. H. Rose said that the preparation is less stable if dil. potash-lye be employed. No oxygen is evolved about the anode excepting just at the beginning or end of the electrolysis. If the current be long continued, microscopic crystals of potassium ferrate may be deposited on the iron anode, and a little iron may collect on the platinum cathode. F. Haber and W. Pick found that immediately after closing the circuit, all varieties of iron are oxidized to ferrate, and that the action is continuous provided a conc. soln. of alkali-lye and a low current density—say, 0·001 amp. per cm.—be employed. The yield of ferrate is greatest with cast iron and smallest with wrought iron; it is also greater with sodium than with potassium hydroxide, possibly on account of the greater solubility of sodium ferrate. The quantity of ferrate reduced at the cathode of platinum wire, in a cell without a diaphragm, is comparatively trifling. The yield of ferrate depends on the temp., so that under comparable conditions, traces only of ferrate were formed at 0°, whilst at 70°, the current efficiency was almost 100 per cent. According to W. Pick, when iron, especially one of the purer kinds, is used as anode in a soln. of an alkali hydroxide, a temporary formation of ferrate occurs; by reversing the current for a short time after the formation of ferrate has ceased, the iron returns to the condition in which it can be oxidized to ferrate, and after several repetitions of the treatment this condition becomes permanent. The same result is obtained by using the iron as anode in a conc. soln. of an alkali hydroxide and passing a very small current for some time. The iron is found to be covered by a dark grey skin which prevents atm. oxidation. G. Grube and H. Gmelin found that increasing the temp. and conc. of the soda-lye increases the yield; and that by increasing the current density, the yield rises to a maximum, and then falls with any further increase in the current density. The current-yield of sodium ferrate can be considerably increased by superimposing an alternating current over the direct current. The increase in the yield for constant direct current reaches a maximum for a definite alternating current density. Using as electrolyte 40 per cent. sodium hydroxide with an iron anode and a platinum cathode, and electrolyzing at 35° with a direct current of 3·33 amps. per sq. dcm. and an alternating current of 5·0 amps. per sq. dcm., an increase of 160 per cent. in the yield of sodium ferrate is obtained. In the preparation of conc. soln. of ferrates, the anode and cathode should be separated, and since ferrates lose oxygen at 50°, and yield a precipitate of hydrated oxide, this temp. must not be exceeded in the preparation, and the velocity of formation must be increased by imposing an alternating current on the direct current. In this way undecomposed sat. soln. and the crystalline salts may be obtained. The oxidation potential for the conversion of a ferrite to a ferrate is 0·78 volt at 20° to 70°; and the potential of conc. alkali-lye towards active iron is —0·6 volt. G. Grube and H. Gmelin also observed that the anodic dissolution of iron in conc. soln. of soda-lye, at a high temp., occurs in two stages; in the first stage, iron dissolves in the bivalent condition; and in the second stage, the iron in soln. passes into the sexivalent condition as ferrate with the simultaneous evolution of oxygen. Nowhere does the iron pass into soln. in the tervalent state—*vide* sodium ferrite. In a 40 per cent. soln. of sodium hydroxide, the equilibrium potential of the process $\mathrm{Fe}+2\oplus\rightleftharpoons\mathrm{Fe}^{\cdot\cdot}$ lies at $\epsilon_H-0{\cdot}86$ volt; that of the process $\mathrm{Fe}^{\cdot\cdot}+\oplus\rightleftharpoons\mathrm{Fe}^{\cdot\cdot\cdot}$ at $\epsilon_H-0{\cdot}69$ volt; and that of the process $\mathrm{Fe}^{\cdot\cdot\cdot}+3\oplus\rightleftharpoons\mathrm{Fe}^{\cdot\cdot\cdot\cdot\cdot\cdot}$ at $\epsilon_H+0{\cdot}55$ volt. Hence, the potential of the reaction $\mathrm{Fe}+3\oplus\rightleftharpoons\mathrm{Fe}^{\cdot\cdot\cdot}$ is $-0{\cdot}80$ volt; and that of the reaction $\mathrm{Fe}+6\oplus=\mathrm{Fe}^{\cdot\cdot\cdot\cdot\cdot\cdot}$ is $-0{\cdot}13$ volt.

According to L. Möser, potassium ferrate forms a reddish-black powder. P. Niggli and W. Nowaski discussed the crystal structure of the ferrates. J. W. Retgers added that a soln. of the ferrate can be kept some days without decomposition, and that it may be crystallized at a gentle heat in black, microscopic, rhombic prisms or pyramids; it forms solid soln. with potassium sulphate, selenate, chromate, tungstate, and molybdate, and it is therefore isomorphous with these salts; but no isomorphous mixtures could be obtained with potassium tellurate. The solid soln. with potassium chromate range in colour from pink through dark red to dark brown. V. L. Bohnson and A. C. Robertson found that the energy of formation of the ferrate ion, FeO_4'', is near —140,000 cals. V. L. Bohnson and A. C. Robertson measured the absorption spectra of soln. of potassium and barium ferrates, and the results are summarized in Fig. 559. The absorption spectrum was examined by E. Baschieri, and E. Hardtmann. L. Möser found that when potassium

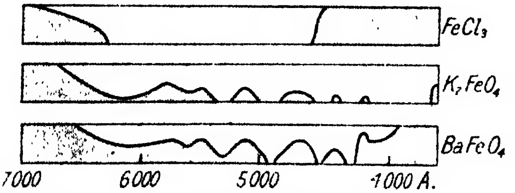

Fig. 559.—The Absorption Spectra of Potassium and Barium Ferrates.

ferrate is ignited, it loses oxygen and passes into green ferrite, which is very deliquescent, and, on exposure to air, rapidly oxidizes into potassium hydroxide, and hydrated ferric oxide. O. Liebknecht and A. P. Wills said that potassium ferrate is paramagnetic, and he measured the susceptibility of the aq. soln.

Potassium ferrate is very soluble in **water,** and the aq. soln. is deep red. E. Frémy, and J. D. Smith found that an aq. soln. of potassium ferrate is of a deep amethyst-red or cherry-red and that it is pervious to light only when it is in thin strata. The aq. soln., on standing for some time, loses its colour, gives off oxygen, and deposits hydrated ferric oxide. L. Möser found that alkali ferrate hydrolyzes in aq. soln., $2Na_2FeO_4+5H_2O\rightleftharpoons4NaOH+2Fe(OH)_3+3O$. This decomposition is faster with the more dil. soln., and when the temp. is raised. A conc. soln. may be kept in closed vessels for several months without complete decomposition, and when evaporated, it leaves a reddish residue. In some cases, the conc. soln. can be boiled without decomposition, but it afterwards deposits hydrated ferric oxide more quickly than if it had not been boiled. The dilution of the soln. of the ferrate with various **alkali salts** makes the soln. more stable than if it is diluted with water. H. Rose, and C. A. O. Rosell observed that if the decomposed soln., after the deposition of hydrated ferric oxide, is green, some manganese salt is present, probably derived from the iron employed in the preparation of the salt, the green colour is not due to the presence of ferrous iron, as was thought to be the case by J. D. Smith. O. Kassner said that the addition of **sodium peroxide** to the aq. soln. precipitates ferric hydroxide. The ferrate is quickly decomposed by reducing agents. C. A. O. Rosell said that in their oxidizing properties, the ferrates resemble the manganates more closely than the chromates. E. Frémy, and J. D. Smith found that **hydrochloric acid** forms a double potassium ferric chloride with the evolution of chlorine, while with a smaller quantity of acid, hydrated ferric oxide is precipitated. H. Rose, and H. W. F. Wackenroder found that by treating the soln. with **hydrogen sulphide,** dark green or black iron sulphide is formed. The green soln. reported by E. Frémy is, according to C. A. O. Rosell, produced by manganese present as impurity. L. Möser said that potassium ferrate is converted by **alkali sulphides** into a green substance, possibly a sulphoferrate. H. Rose observed that **sulphurous acid** forms potassium sulphate and hydrated ferric oxide; and E. Frémy, that **sulphuric acid** forms potassium ferric sulphate with the liberation of oxygen. H. Rose, and H. W. F. Wackenroder observed that **ammonia,** and all **ammonium salts** decompose the ferrate because the ammonia which is evolved reduces the ferric acid to ferric oxide. C. A. O. Rosell made a similar observation with respect to the oxidation of ammonia by the ferrates. C. A. O. Rosell found that the **nitrites** are readily oxidized by ferrates. E. Frémy found that **nitric acid** forms potassium ferric nitrate with the liberation of oxygen.

According to E. Frémy, all **organic substances** reduce the ferrate so that the soln. cannot be filtered through paper without decomposition; and L. Möser observed that paper, wood, and other organic substances are slowly oxidized by a dilute soln. of potassium ferrate, but the action is slower than with potassium permanganate. Potassium ferrate is insoluble in **ether,** and in **chloroform.** L. Möser observed that **alcohol** can have up to 20 per cent. of water. without exercising any solvent action, or without decomposing potassium ferrate. Alcohol precipitates potassium ferrate from its aq. soln. H. Rose found that alcohol is oxidized to aldehyde; while **sugar** decolorizes the soln. quickly with the precipitation of hydrated ferric oxide; and **egg-albumin** decolorizes the soln. without precipitation. H. W. F. Wackenroder found that the soln. of ferrate is decolorized by **potassium ferrocyanide**; and H. Rose, that **alkali racemates, tartrates, and malates** quickly decolorize the soln. without precipitating hydrated ferric oxide; alkali **citrates** act slowly with the occasional precipitation of hydrated ferric oxide; while **potassium oxalate, formate, acetate, and benzoate** decolorize the liquid as slowly as the inorganic salts of potassium; and **potassium succinate** acts still more slowly. C. A. O. Rosell found that the ferrates readily oxidize tartrates, and

glycerol; and also oxalates, alcohol, and **urea,** as well as most soluble organic compounds with the exception of acetates. J. D. Smith observed that when the soln. is treated with a **zinc salt,** oxygen is slowly evolved; with **nickel salts** and **manganese salts,** the peroxides are precipitated; L. Möser found that **silver nitrate** gives a precipitate, probably silver ferrite, and oxygen is given off; and similarly with **mercuric chloride,** and with **copper sulphate**; while H. W. F. Wackenroder showed that alum, and the heavy **metal salts** decolorize the liquid, and the metal base is precipitated along with hydrated ferric oxide—*vide infra.*

According to L. Möser and co-workers, when barium ferrate is digested with alkali carbonate, a soln. of the alkali ferrate is formed, and in this way, **rubidium ferrate,** Rb_2FeO_4, and **cæsium ferrate,** Cs_2FeO_4, were produced. W. Eidmann and L. Möser recommended strontium ferrate in place of the barium salt. E. Frémy found that **sodium ferrate,** Na_2FeO_4, can be prepared by the methods used for the potassium salt (*q.v.*); C. A. O. Rosell could not prepare the sodium salt in the dry way by calcining ferric oxide with sodium hydroxide, carbonate and nitrate, and with mixtures of sodium hydroxide and nitrate, and also with sodium nitrate and carbonate; but it was obtained by heating ferric oxide with sodium dioxide, and, by treating the cold mass with ice, instead of water, a soln. of sodium ferrate was obtained. A soln. of this salt was also prepared by the action of chlorine on soda-lye holding hydrated ferric oxide in suspension. The salt was also prepared by J. d'Ans and J. Löffler. T. Wallace and A. Fleck, and C. Zengelis and S. Horsch passed carbon dioxide over a mixture of sodium dioxide and finely-divided iron; and A. Holt obtained the ferrate by the action of sodium hydroxide on ferric oxide. The treatment of barium ferrate with lithium carbonate furnishes **lithium ferrate,** Li_2FeO_4. W. Eidmann and L. Möser recommended strontium ferrate in place of the barium salt.

L. Losana prepared **copper ferrate,** $CuFeO_4.H_2O$, by the action of copper nitrate on barium ferrate, suspended in water, washing the green powder with water, and drying it over sulphuric acid. The salt decomposes in vacuo over sulphuric acid, so that the anhydrous salt was not obtained. The salt begins to decompose when heated to about 50°, giving off water and oxygen. The reaction: $K_2FeO_4+2AgNO_3=2KNO_3+Ag_2FeO_4$, is not suitable for the preparation of **silver ferrate,** Ag_2FeO_4, but if barium ferrate, suspended in water, be treated with silver nitrate, silver ferrate is produced as a black powder with a pink reflexion. It can be washed and dried at 15° over sulphuric acid. When heated to 30°, the salt begins to decompose in accord with $4Ag_2FeO_4=4Ag_2O+2Fe_2O_3+3O_2$.

When a soln. of potassium ferrate is treated with an excess of a dil. soln. of a barium salt, J. D. Smith, and L. Losana found that a bulky, carmine-red precipitate of **barium ferrate,** $BaFeO_4.H_2O$, is formed. The precipitate is washed, and dried over sulphuric acid, or at 100°. The precipitate when fresh is cochineal-red, but after washing and drying, it is brick-red. C. L. Bloxam prepared barium ferrate as a purple precipitate by adding barium chloride to a soln. of the calcium ferrate; by C. A. O. Rosell, by adding barium carbonate to a soln. of sodium ferrate; and J. A. Hedvall and N. von Zweigbergh, by the action of barium peroxide on ferric oxide. J. D. Smith said that when barium ferrate is heated, it loses water and turns green, and at a higher temp., it gives off oxygen and loses its colour. L. Losana found that the salt begins to lose weight at 105°. The losses in weight of two grams of the salt, after heating it to different temp., was as follows (the time in hours is indicated in brackets):

	50°	100°	105°	108°
Weight .	2·0000	2·0002 (4)	1·9988 (6)	1·8772 (26) grms.
	116°	123°	144°	160°
Weight .	1·8772 (3)	1·7584 (3)	1·7004 (3)	1·7002 (3) grms.

This is the only ferrate examined which did not lose oxygen continuously, so that the decomposition: $4BaFeO_4=4BaO+2Fe_2O_3+3O_2$ is thought to proceed *viâ* the formation of $BaFeO_3$ as an intermediate compound. The anhydride can also be obtained by gently heating the hydrate; but the hydrate is stable over conc. sulphuric acid in vacuo. Barium ferrate was said by C. A. O. Rosell, J. D. Smith, and H. W. F. Wackenroder to be insoluble in water, and before drying to be readily decomposed by all the acids, even carbonic acid; but after drying it is not so easily acted upon. E. Frémy stated that barium ferrate is one of the most stable salts of the series. It can be suspended in water, and boiled without decomposition. A. Baschieri found that dil. hydrochloric acid, of sp. gr. 1·09, decomposes barium ferrate with the formation of ferric and barium chlorides, and the evolution of chlorine; with more dil. hydrochloric acid, in the cold there is a vigorous evolution of chlorine, the precipitate gradually disappears, and the soln. assumes a vermilion colour; this liquid continues to evolve chlorine for about a day and slowly turns colourless. The vermilion colour of the soln. is due, not to the intermediate formation of a chloroferrate, but to the presence of the ion FeO_4''. J. de Mollins found that the reaction $2BaFeO_4+8KI+16HCl=2BaCl_2+2FeCl_2+8KCl+8H_2O+4I_2$ is quantitative. A. Baschieri found that barium ferrate is not decomposed by dil. sulphuric acid, but decomposition increases as the temp. rises until it becomes complete in the boiling acid. The action of sulphuric acid was also discussed by H. W. F. Wackenroder, and J. D. Smith. A. Baschieri found that the salt is instantly decomposed by nitric acid; while the salt dissolves in soln. of organic acids, the solubility and intensity of colour imparted to the soln. increases as the acid becomes more energetic. E. Frémy said that while the salt is decomposed immediately by mineral acids, it forms a red soln. when treated with acetic acid. According to C. A. O. Rosell, an alkali sulphate decomposes barium ferrate if it has not been dried, forming barium sulphate and hydrated ferric oxide, and giving off oxygen. A. Naumann found barium ferrate to be insoluble in acetone. W. Eidmann and L. Möser prepared **strontium ferrate**, $SrFeO_4$, by the double decomposition of potassium ferrate with a sat., neutral soln. of strontium bromide, and washing the precipitate with alcohol and ether. Some admixed ferric oxide is present. L. Losana obtained the strontium salt by the process employed for the barium salt, and found that when dried over sulphuric acid it forms the *dihydrate*, $SrFeO_4.2H_2O$. This salt forms a dark red amorphous powder; it begins to decompose at about 52°, for the weight of 2 grms. after heating 3 hrs. at 25°, was as follows (the time of heating, in hours, is indicated in brackets):

	25°	35°	52°	68°	85°	150°
Weight .	2·0000 (5)	1·9978 (6)	1·7000 (11)	1·5062 (16)	1·5062 (10)	1·5066 (3) grms.

The anhydride can be prepared by gently heating the hydrate. W. Eidmann and L. Möser observed that strontium ferrate is sparingly soluble in water, and that the soln. is readily decomposed with the evolution of oxygen, forming strontium hydroxide and hydrated ferric oxide. It is insoluble in alcohol, and ether. W. Eidmann and L. Möser prepared **calcium ferrate**, $CaFeO_4.2H_2O$, by double decomposition of a calcium salt with strontium ferrate; C. L. Bloxam, by boiling a mixture of ferric chloride and bleaching powder; and E. Frémy, and L. Losana, by the action of a calcium salt soln. on potassium ferrate. A gram of the salt heated 5 hrs. at 20° lost 0·1110 grm. in 18 hrs. at 44°. E. Frémy said that the salt is not soluble in water, but C. A. O. Rosell, and L. Losana found it to be soluble. The anhydride was not obtained, since the dihydrate decomposes in vacuo over sulphuric acid. Observations were made by C. L. Bloxam, and T. L. Bailley and P. H. Jones.

W. Eidmann and L. Möser prepared **magnesium ferrate**, $MgFeO_4$, by double decomposition of strontium ferrate and a magnesium salt; but L. Losana did not succeed in obtaining it by the action of magnesium nitrate on barium ferrate; or by the action of magnesium nitrate on potassium ferrate. L. Losana obtained **zinc ferrate**, $ZnFeO_4$, by the action of a soln. of zinc nitrate on barium ferrate. The rose-coloured powder forms a rose-red soln. with water; and when dried for 3 hrs. at 20°, the salt loses 0·30 per cent. in 4 hrs. at 30°, and 11·32 per cent. in 11 hrs. at 30°.

L. Losana obtained **mercurous ferrate,** Hg_2FeO_4, by the action of a soln. of mercurous nitrate on barium ferrate. The salt decomposes during the drying. No definite **mercuric ferrate,** $HgFeO_4$, was obtained by the action of a soln. of mercuric nitrate on barium ferrate; but with aluminium nitrate and barium ferrate, **aluminium ferrate,** $Al_2(FeO_4)_3$, was obtained as a rose-red powder, which decomposed on drying. L. Losana did not obtain a definite **thallium ferrate,** Tl_2FeO_4, by the action of a soln. of thallous nitrate on barium ferrate; **thorium ferrate,** $Th(FeO_4)_2$, was obtained by the action of thorium nitrate on barium ferrate, but the salt decomposed on drying. L. Losana prepared **lead ferrate,** $PbFeO_4$, by the action of a soln. of lead nitrate on barium ferrate. The rose-coloured powder lost 0·22 per cent. when heated 3 hrs. at 30°, and 3·58 per cent. in 5 hrs. at 40°. In the attempt to prepare **chromium ferrate,** $Cr_2(FeO_4)_3$, by the action of chromic nitrate on barium ferrate, a voluminous yellow precipitate was obtained containing barium chromate and ferric oxide. It is probable that the reaction proceeds $6BaFeO_4+4Cr(NO_3)_3=6Ba(NO_3)_2+2Cr_2(FeO_4)_3$; followed by $2Cr_2(FeO_4)_3+4H_2O=4H_2CrO_4+6FeO_2$, and $6FeO_2=3Fe_2O_3+3O$; while the chromic acid reacts with two-thirds of the barium nitrate: $4H_2CrO_4+4Ba(NO_3)_2=4BaCrO_4+8HNO_3$; and part of the ferric oxide reacts with the nitric acid: $Fe_2O_3+6HNO_3=2Fe(NO_3)_3+3H_2O$. No definite **manganese ferrate,** $MnFeO_4$, was obtained by the action of manganese nitrate on barium ferrate; and **ferrous ferrate,** $Fe(FeO_4)$, obtained by the action of ferrous nitrate on barium ferrate decomposes on drying; and similarly also with **ferric ferrate,** $Fe_2(FeO_4)_3$, obtained by the action of a soln. of ferric nitrate on barium ferrate. L. Losana prepared rose-violet **cobalt ferrate,** $CoFeO_4$, by the action of a soln. of cobalt nitrate on barium ferrate. The powder dried for 5 hrs. at 20° lost 2·18 per cent. when dried 5 hrs. at 25°, and 11·1 per cent. in 18 hrs. at the same temp. Similarly with **nickel ferrate,** $NiFeO_4$, which gives a greyish-green powder. The powder dried for 5 hrs. at 20° lost 1·88 per cent. when heated 3 hrs. at 30°, and 7·46 per cent. in 18 hrs. at the same temp.

O. Baudisch and P. Mayer[2] assumed that **perferric acid,** $FeO_3(OH)_2$, or H_2FeO_4, is produced when freshly precipitated ferrous hydroxide is oxidized by oxygen. D. K. Goralevich said that **iron tetroxide,** or **perferric anhydride,** FeO_4, or perferric acid, H_2FeO_5, is probably formed as a volatile, unstable compound when barium perferrate, $BaFeO_5$, is treated with an excess of dil. sulphuric acid, at a low temp. Perferric anhydride is insoluble in water, but soluble in dil. acids. He prepared bright green **potassium perferrate,** $K_2FeO_5.nH_2O$, by fusing ferric oxide with potassium hydroxide and an excess of potassium nitrate, or, better, chlorate. The salt can be purified by sublimation; it decomposes very slowly when kept in air; explosively, when warmed, on treatment with conc. sulphuric acid, or on impact if mixed with sulphur, phosphorus, or charcoal. It is quite stable in alkaline soln., but acids readily decompose it, with evolution of oxygen and, in the case of hydrochloric acid, chlorine. Oxidizing agents like chlorine and hydrogen peroxide give a deep red soln. of potassium ferrate, with evolution of oxygen. Neutral soln. of the perferrate give no reaction for ferric ions until, on the addition of acid, decomposition has commenced. Similarly with **sodium perferrate,** the alkaline earth perferrates were obtained as white precipitates on adding a soln. of a salt of an alkaline earth to a soln. of potassium perferrate; with barium salt, **barium perferrate,** $BaFeO_5.7H_2O$, is produced; and with a strontium salt, **strontium perferrate,** $SrFeO_5.7H_2O$. These salts are white and insoluble in water, alcohol, and ether.

Alum, 615
Aluminium - chromium - molybdenum - iron alloys, 626
—— —— steels, 616
—— -copper-iron alloys, 557
—— ferrate, 936
—— ferrite, 919
—— -iron alloy, 549
—— —— -manganese alloys, 667
—— -magnesium-iron alloys, 557
—— -silicon-iron alloys, 570
—— sulphate, 615
—— -zinc-iron alloys, 557
Ammonia, 608, 612, 615
—— -alum, 609
Ammonium carbonate, 613
—— chloride, 609, 615
—— nitrate, 615
—— sulphate, 609, 615
Apples, 615
Argillaceous hæmatite, 775
Aventurine, 877
—— glazes, 775, 780

B

Barium ferrate, 934
—— ferrite, 914
—— -iron alloy, 541
—— perferrate, 936
—— perferrite, 926
Barophoresis, 837
Bean ore, 886
Beer, 615
Benzene, 615
Benzol, 613
Berggeel, 885
Berggelb, 885
Beryllium ferrite, 914
—— -iron alloy, 542
Bismuth-tin-iron alloys, 579
Bixbyite, 816
Bleaching powder, 615
Bloodstone, 775
Blue brittleness, 32, 599
—— gold, 541
—— -heat, 32
Blutstein, 774
Bog ore, 886
Bohnerz, 886
Bole, 887
Boric acid, 613, 615
Boron-iron alloys, 548
Brauneisenstein, 877, 885, 886
—— ochriger, 885
Brittleness, 61
Bromine, 615
Burnt pig, 558
Bush sickness, 376

C

Cadmium ferrite, 918
—— -iron alloys, 545
Cæsium ferrate, 934
—— ferrite, 906
Calcium aluminatoferrite, 920
—— chloride, 615
—— dichlorometaferrite, 913
—— ferrate, 935
—— ferrite, 910
—— (di) hexaferrite, 911
—— (penta) hexaferrite, 911
—— -iron alloys, 541
—— magnesium aluminatoferrite, 921
—— metaferrite, 911
—— orthoferrite, 911
—— oxymetaferrite, 911
—— tetraferrite, 911
Caput mortuum, 781
Carbide tungsten steels, 634
Carbolic acid, 613, 615
Carbon disulphide, 613
—— -iron alloys (*see* iron)
—— tetrachloride, 615
Cassel brown, 887
Cast iron, non-magnetic, 257
Cerium-iron alloys, 557
Chileite, 877
Chinese red, 782
Chlorine, 615
Chlorosulphonic acid, 615
Chromic ferrite, 922
Chromitite, 923
Chromium - aluminium - molybdenum - iron alloys, 626
—— —— steels, 616

Chromium-copper steels, 616
—— ferrate, 936
—— -iron alloys, 586
—— —— carbide, 591
—— —— tungsten carbide, 629
—— -manganese steels, 667
—— molybdenum carbide, 620
—— —— -iron alloys, 626
—— -silicon steels, 616
—— tetritacarbide, 592
—— -titanium steels, 616
—— -tungsten steels, 642
—— —— -vanadium-iron alloys, 643
—— —— —— steels, 642
—— -vanadium-molybdenum-iron alloys, 626
—— —— steels, 617
—— -zirconium steels, 616
Chromoferrite, 591
Cider, 615
Citric acid, 613, 615
Clay ironstone, 775
Cobalt ferrate, 936
Cobaltic ferrite, 925
Cobaltous ferrite, 924
Coercive force, 246
Coercivity, 246
Coffee, 615
Colchotar, 782
Colcothar, 781, 782, 783
Coldshare iron, 61
Coldshore iron, 61
Coleshire iron, 61
Cologne earth, 887
Colsar, 61
Colshire iron, 61
Columbium-iron alloys, 586
Copal, 615
—— varnish, 615
Copper-aluminium-iron alloys, 557
—— carbonate, 615
—— chloride, 609, 615
—— -chromium steels, 616
—— ferrate, 934
—— -iron alloys, 527
—— —— -manganese alloys, 666
—— —— -silicon alloys, 570
—— —— -zinc alloy, 545
—— -lead-iron alloys, 579
—— -molybdenum-iron alloys, 626

—— —— films, 781
—— —— Graham's solution, 831
—— —— Grimaux' solution, 832
—— —— hemitrihydrated, 887
—— —— hydrated, 831, 859
—— —— —— allotropic forms, 863
—— —— —— hydrosol, 831

Ferric oxide, hydrogel, 831, 859, 862
—— —— hydrosol, negative, 836
—— —— —— positive, 836
—— —— jellies, 862
—— —— monohydrated, 878
—— —— —— colloidal, 887
—— —— preparation, 776
—— —— properties, chemical, 805
—— —— —— physical, 782
—— —— St. Gilles solution, 831
—— —— tetrahydrated, 895
—— —— trihydrated, 893
—— —— tritapentahydrate, 890
—— oxyhydroxide, 878
—— paraoxide, 864
Ferrites, 702, 905
Ferrochromium, 586
Ferromagnetism, 244
Ferromolybdenum, 617
Ferropicotite, 732
Ferrosic oxide, 702, 731, 732
—— —— hydrated, 761
Ferrosilicon, 558
Ferrotitanium, 571
Ferrotungsten, 626
Ferrous ferrate, 936
—— ferrite, 732, 923
—— hydroxide, 718
—— —— hydrosol, 720
—— lead ferrite, 924
—— orthoferrite, 732
—— oxide, 702
—— —— hydrated, 718
—— peroxyhydroxide, 725
—— suboxide, 702
—— triferric oxide, 807
Ferro-vanadium, 579
Ferrum liquidum, 831
Fixing solution, 615
Flèches d'amour, 877
Flux density of magnetism, 245
Food-pastes, 615
Formaldehyde, 615
Formic acid, 613, 615
Franklinite, 917
Fruit juices, 613
Fullonite, 877

G

Gallium-iron alloys, 557
Garrisonite, 629
Gelbeisenstein, 886
Germanium-iron alloys, 576
Glanzeisenstein, 886
Glasköpfe, 774, 775
Glaskopf, 877, 885
Glazed pig, 558
Goethite, 877
—— α-, 880
—— γ-, 880
—— colloidal, 887
Gold-iron alloys, 540
Graphititis, 445
Graphitization, 445
Greases, 613
Gres de Thiviers, 783
Grey gold, 541

H

Hæmatite, 774, 874
—— brown, 886
—— columnar, 775
—— compact, 775
—— fibrous, 775, 785
—— hemisphœricus, 885
—— micaceous, 775
—— red, 774, 775
—— specular, 774, 775
Hæmatophanite, 922
Hardness, 14
—— abrasive, 26
Heat-resisting alloys, 457
Hematite, 775
Hercynite, 919
High-speed steels, 634
Horse-radish cream, 615
Hydrochloric acid, 609, 615
Hydrofluoric acid, 615
Hydrogen, 606
Hydrogoethite, 884
Hydrohæmatite, 874
Hydroquinone, 615
Hyposiderite, 886
Hysteresis, magnetic, 247

I

Igelströmite, 895, 916
Indian red, 782, 887
—— steel, 550
