CHAPTER LXVI *(continued)*

IRON *(continued)*

§ 18. The Mechanical Properties of Iron and Iron-Carbon Alloys (1); § 19. Thermal Properties of Iron and Iron-Carbon Alloys (130); § 20. Optical Properties of Iron and Iron-Carbon Alloys (169); § 21. Electrical Properties of Iron and Iron-Carbon Alloys (189); § 22. Magnetic Properties of Iron and Iron-Carbon Alloys (244); § 23. The Chemical Properties of Iron (297); § 24. The Corrosion of Iron and Steel (403); § 25. The Valency and Atomic Weight of Iron (494); § 26. The Passivity of Iron (498); § 27. Alloys and Intermetallic Compounds of Iron (526) § 28. Ferrous Oxide and its Hydrate (701); § 29. Ferrosic Oxide; or Magnetic Oxide of Iron (731); § 30. Ferric Oxide (774); § 31. Hydrated Ferric Oxide—Hydrosol (831); § 32. The Hydrated Ferric Oxides—Hydrogels (859); § 33. The Ferrites and Perferrites (905); § 34. Iron Trioxide.—Ferric Acid and the Ferrates (929).

INDEX 939

ABBREVIATIONS

aq. = aqueous
atm. = atmospheric or atmosphere(s)
at. vol. = atomic volume(s)
at. wt. = atomic weight(s)
T° or °K = absolute degrees of temperature
b.p. = boiling point(s)
$\theta°$ = centigrade degrees of temperature
coeff. = coefficient
conc. = concentrated or concentration
dil. = dilute
eq. = equivalent(s)
f.p. = freezing point(s)
m.p. = melting point(s)
mol(s) = $\begin{cases}\text{gram-molecule(s)}\\ \text{gram-molecular}\end{cases}$
mol(s). = $\begin{cases}\text{molecule(s)}\\ \text{molecular}\end{cases}$
mol. ht. = molecular heat(s)
mol. vol. = molecular volume(s)
mol. wt. = molecular weight(s)
press. = pressure(s)
sat. = saturated
soln. = solution(s)
sp. gr. = specific gravity (gravities)
sp. ht. = specific heat(s)
sp. vol. = specific volume(s)
temp. = temperature(s)
vap. = vapour

In the **cross references** the first number in clarendon type is the number of the volume; the second number refers to the chapter; and the succeeding number refers to the "§," section. Thus **5**. 38, 24 refers to § 24, chapter 38, volume 5.

The oxides, hydrides, halides, sulphides, sulphates, carbonates, nitrates, and phosphates are considered with the basic elements; the other compounds are taken in connection with the acidic element. The double or complex salts in connection with a given element include those associated with elements previously discussed. The carbides, silicides, titanides, phosphides, arsenides, etc., are considered in connection with carbon, silicon, titanium, etc. The intermetallic compounds of a given element include those associated with elements previously considered.

The use of **triangular diagrams** for representing the properties of three-component systems was suggested by G. G. Stokes (*Proc. Roy. Soc.*, **49**. 174, 1891). The method was immediately taken up in many directions and it has proved of great value. With practice it becomes as useful for representing the properties of ternary mixtures as squared paper is for binary mixtures. The principle of triangular diagrams is based on the fact that in an equilateral triangle the sum of the perpendicular distances of any point from the three sides is a constant. Given any three substances *A*, *B*, and *C*, the composition of any possible combination of these can be represented by a point in or on the triangle. The apices of the triangle represent the single components *A*, *B*, and *C*, the sides of the triangle represent binary mixtures of *A* and *B*, *B* and *C*, or *C* and *A*; and points within the triangle, ternary mixtures. The compositions of the mixtures can be represented in percentages, or referred to unity, 10, etc. In Fig. 1, pure *A* will be represented by a point at the apex marked *A*. If 100 be the

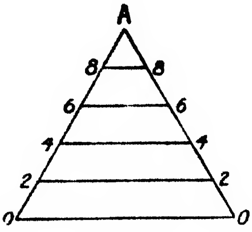

FIG. 1.

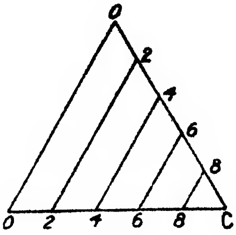

FIG. 2.

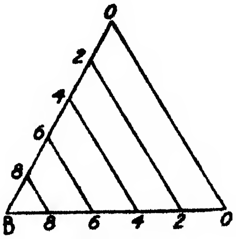

FIG. 3.

standard of reference, the point *A* represents 100 per cent. of *A* and nothing else; mixtures containing 80 per cent. of *A* are represented by a point on the line 88, 60 per cent. of *A* by a point on the line 66, etc. Similarly with *B* and *C*—Figs. 3 and 2 respectively. Combine Figs. 1, 2, and 3 into one diagram by superposition, and Fig. 4 results. Any point in this

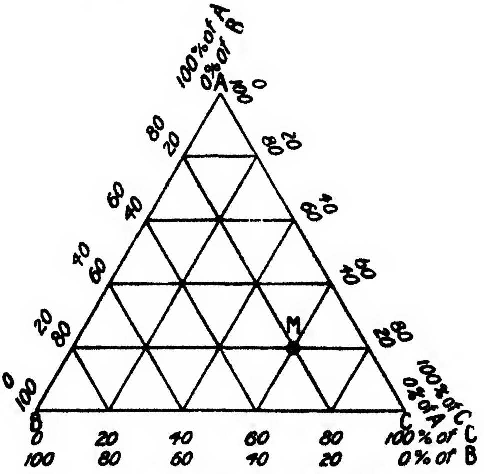

FIG. 4.—Standard Reference. Triangle.

diagram, Fig. 4, thus represents a ternary mixture. For instance, the point *M* represents a mixture containing 20 per cent. of *A*, 20 per cent. of *B*, and 60 per cent. of *C*.

CHAPTER LXVI (*continued*)

IRON (*continued*)

§ 18. The Mechanical Properties of Iron and Iron-Carbon Alloys

The Arabic manuscript of Abu-r-Raihan, *The Book of the Best Things*, written about the tenth century, and described by H. C. Bolton,[1] and J. J. C. Mullet, gave 7·74 for the **specific gravity** of iron, and this value is near the 7·85 accepted to-day. The Arabic manuscript, *Book of the Balance of Wisdom*, by Al-Khazini, written about A.D. 1122, and described by H. C. Bolton, and N. Khanikoff, also gave 7·74 for the sp. gr. of iron. D. G. Fahrenheit gave 7·817; R. Boyle, 7·645—and for soft steel, 7·738, hard steel, 7·704, and spring temper-steel, 7·809; and J. C. . . ., 7·643 for iron, and 7·852 for steel; P. von Muschenbrock, and L. B. G. de Morveau made observations on the sp. gr. of iron. G. Pearson gave values for the sp. gr. of thirty-five different samples of iron and steel, and, for wootz steel, found 7·181 to 7·403; for wootz steel which had been forged, 7·503 to 7·647; for wootz steel which had been melted, 7·200; and for wootz steel which had been quenched from a white-heat, 7·166; Huntsman's hammered steel, 7·826 to 7·916; the same steels quenched from a white-heat, 7·765 to 7·771; soft and tough hammered iron, 7·780 to 7·787; and cast iron, 7·012. T. Bergman gave for steel, 7·643 to 7·784; and for wrought iron, 7·798 to 7·829. Collections of data were published by R. Böttger,[2] E. F. Dürre, and F. W. Clarke.

G. Broling found that the sp. gr. of bar-iron is 7·8439, whereas the same iron in very thin sheet had a sp. gr. 7·6, and that these anomalies may seem to proceed from repulsion between the surface of the iron and the water used in measuring the sp. gr., since the sp. gr. decreased in proportion to the extent of the surface of the metal. The surface, however, had been freed by means of potassium hydroxide from all foreign matters which might prevent adhesion between the metal and water. J. Percy found electrodeposited iron had a sp. gr. of 8·1393 at 15·5°. M. J. Brisson gave 7·788; C. J. B. Karsten, 7·790; A. Baudrimont, 7·6000 to 7·7312, for iron wire in different conditions, and 7·7433 for hammered wire; J. J. Berzelius, 7·8650 to 7·8707; J. A. Poumarède, 7·50 to 7·84 for iron reduced by the vapour of zinc; C. Stahlschmidt, 6·03 for iron obtained by heating the nitride not over 327°; L. Playfair and J. P. Joule, 7·130 for the sp. gr. of iron reduced by carbon; H. Caron, 7·880 at 16° for forged iron fused in hydrogen; 7·847 for wire fused in hydrogen; 7·833 for iron fused in a crucible; and 7·852 for good commercial iron; and H. Schiff gave 7·998 to 8·007 at 10° for iron reduced by hydrogen. K. Ruf gave 7·876 at 20° for the sp. gr. of the metal with less than 0·02 per cent. of carbon; E. Madelung and R. Fuchs gave 7·8544; E. Gumlich gave 7·876; H. Tomlinson, 7·630 for hard drawn, and 7·259 for annealed iron wire; H. Hanemann and E. H. Schulz, 7·899; and R. von Dallwitz-Wegner, 7·86. Amongst

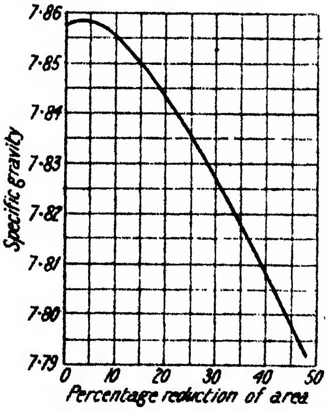

FIG. 179.—The Effect of Cold-work on Armco Iron.

the best results for the sp. gr. of purified iron there are those of J. H. Andrew and A. J. K. Honeyman, who gave 7·864 for the sp. gr. of annealed purified iron, and 0·12716 for the sp. vol.; C. Benedicks, 7·85 for the sp. gr. of purified iron and 0·12739 for the sp. vol.; M. Levin and K. Dornhecker, 7·871 for the sp. gr. of purified and annealed iron, and 0·12705 for the sp. vol.; T. Ishigaki, 7·880; K. Tamaru, 7·882; whilst H. C. Cross and E. E. Hill gave 7·867 for the sp. gr. of electrolytic iron fused in vacuo, and 0·12711 for the sp. vol., the corresponding data for the same iron hot-rolled are 7·8685, and 0·12709; for the same iron annealed at 775°, they are 7·8547 and 0·12731, and when annealed at 900°, 7·865, and 0·12714. R. L. Keynon's results are summarized in Fig. 179.

S. Kaya gave 7·8701 for the sp. gr. and 0·12706 for the sp. vol. of a single crystal where the possibility of intercrystalline pores or spaces is excluded; he said that the sp. gr. of the single crystal of iron may be taken to be about 0·42 per cent. greater than that of polycrystalline iron. W. P. Davey calculated from the X-radiogram data that the sp. gr. of iron is 7·93; L. W. McKeehan, 7·872; and A. Westgren and G. Phragmen, 7·878.

L. Zimmermann and H. Esser measured the sp. vol. of white cast iron at temp. between 0° and 1300°. From the thermal expansion data of K. Honda and H. Endo, and S. Sato, it follows that the sp. gr. of α-iron at 20° is 7·8685—the X-radiogram value is 7·8404; the value for α-iron at 906° is 7·5706—when the X-radiogram value is 7·55. Similarly, the value of γ-iron at 906° is 7·6327, and at 1400°, 7·4077; and the value for δ-iron at 1400° is 7·3900, and at 1535°, the m.p. of iron, 7·3550. The value for molten iron—*vide infra*—at 1535° is 7·0995 when calculated from the expansion data of S. Sato. A. Osawa extrapolated his values for nickel-iron alloys and obtained for γ-iron at 200°, 8·008.

The effect of carbon on the specific gravity of iron.—H. von Jüptner gave for the best representative values for iron alone 7·85 to 7·88; for wrought iron, 7·79 to 7·85; for steel, 7·60 to 7·80; for white cast iron, 7·58 to 7·73; and for grey cast iron, 7·03 to 7·13. S. Rinman, and C. J. B. Karsten gave 7·5 for the sp. gr. of white pig-iron, and 7·1 for that of grey pig-iron. Results were also given by T. Scheerer, B. Kerl, C. Karmarsch, F. Wüst and E. Leuenberger, J. Weisbach, A. Guettier, R. Mallet, E. Maurer, and C. F. Rammelsberg. E. F. Dürre showed the available sp. gr. data to indicate that the sp. gr. of spiegeleisen is diminished if it be melted and slowly cooled; if grey cast iron be melted and rapidly cooled, its sp. gr. is increased; if cast iron be melted under conditions where decarburization can take place, its sp. gr. is increased; and if rods of cast iron be subjected to compression, the sp. gr. is increased. J. E. Hurst gave for the sp. gr. of cast iron, 6·9 to 7·5—mean 7·217; wrought iron, 7·47 to 7·808—mean 7·698; and steel, 7·729 to 7·904—mean 7·852. L. Elsner found the sp. gr. of ordinary steel to be 7·795; hardened cast steel, 7·6578; unhardened cast steel, 7·9288; cast steel, once remelted and hardened, 7·647, and unhardened, 7·647. H. von Jüptner also gave for the sp. gr. of compact iron-carbon alloys:

Carbon . .	0·529	0·649	0·841	0·871	1·0005	1·078 per cent.
Sp. gr. . .	7·841	7·829	7·824	7·818	7·807	7·805

H. C. Cross and E. E. Hill gave for hot-rolled steels:

Carbon .	0·09	0·16	0·25	0·45	0·65	0·87	0·98	1·28 per cent.
Sp. gr. .	7·848	7·857	7·853	7·841	7·831	7·832	7·822	7·812

and for annealed steels:

Carbon .	0·25	0·59	0·73	0·85	0·98	1·15	1·28	1·39 per cent.
Sp. gr. .	7·852	7·836	7·838	7·824	7·823	7·809	7·813	7·816

The smoothed curve for the annealed steel is shown in Fig. 180, and that for the hot-rolled metal almost overlaps. J. H. Andrew and A. J. K. Honeyman's curve likewise is almost overlapping. The curve of M. Levin and K. Dornhecker for hot-rolled steel is shown dotted in Fig. 180, and there is a drop in the curve for the annealed steel which does not appear in the results of H. C. Cross and E. E. Hill, and J. H. Andrew and co-workers. W. Brown gave for the sp. gr. and sp. vol. of steels *A*-series with 0·02 to 0·17 per cent. of silicon, and 0·14 to 0·18 per cent. manganese; and *B*-series with 0·46 to 0·49 per cent. silicon, 0·58 per cent. manganese:

	A-series					*B*-series			
Carbon .	0·028	0·05	0·14	0·89	1·23	0·58	1·00	1·25	per cent.
Sp. gr. .	7·8771	7·8778	7·8638	7·8268	7·7897	7·8132	7·7587	7·7525	
Sp. vol. .	0·12695	0·12694	0·12716	0·12777	0·12827	0·12800	0·12890	·012900	

With up to 0·2 per cent. of carbon, the increase in sp. vol. is 0·0018 c.c. per one per cent. of carbon, and for higher proportions up to 1·25 per cent., 0·0015 c.c. B. Simmersbach made observations on this subject. According to E. Gumlich, if C denotes the percentage amount of carbon, then the sp. gr., D, of alloys with up to $C=1$, is $D=7·876-0·030C$ for slowly cooled alloys; and $D=7·876-0·17C$ for alloys quenched from 850°. H. C. Cross and E. E. Hill gave sp. gr. $=7·855-0·032C$, for the sp. gr. of hot-rolled iron-carbon alloys with up to 1·29 per cent. of carbon, and for the same steels with up to 1·4 per cent. of carbon, when annealed, $D=7·860-0·04C$. J. H. Andrew and A. J. K. Honeyman gave for the sp. vol., $0·12712-0·00052C$. F. Wever represented the at. vol. of austenitic steels by $v=0·1246+0·0004[\mathrm{Mn}]+0·0041[\mathrm{C}]$, where the bracketed symbols represent atomic percentages.

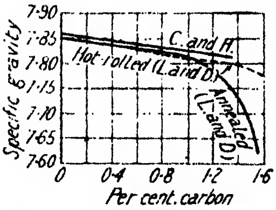

FIG. 180.—The Effect of Carbon on the Specific Gravity of Hot-rolled and Annealed Steels.

G. Hailstone found the effect of the *casting temperatures* on the sp. gr. of cast iron—*vide infra*—with about 1·90 per cent. silicon; 0·10, sulphur; 1·45, phosphorus; 0·27, manganese; and:

Carbon	Total .	3·258	3·246	3·261	3·256	3·281	3·283	3·291	3·295	3·305	3·312 per cent.
	Free .	2·830	2·840	2·862	2·891	2·915	2·926	2·951	2·987	3·012	3·126 ,,
	Comb. .	0·428	0·405	0·399	0·365	0·366	0·357	0·340	0·308	0·293	0·186 ,,
Sp. gr. . . .		7·281	7·262	7·240	7·225	7·201	7·158	7·123	7·085	7·012	7·936
Casting temp. .		1428°	1400°	1390°	1386°	1361°	1348°	1330°	1302°	1272°	1264°

W. H. Hatfield added that the reduction in sp. gr. is partly due to some influence other than the casting temp., and the results agree with H. A. Schwartz that free carbon has a greater influence than combined carbon. One per cent. of free carbon reduces the sp. gr. 0·17; 1 per cent. as free cementite, reduces the sp. gr. 0·025; 1 per cent dissolved in ferrite, 0·115; 1 per cent. of silicon, in soln. in ferrite, 0·060; and 1 per cent. manganese in soln. in ferrite, 0·003. One per cent. of phosphorus in the binary eutectic as Fe_3P reduces the sp. gr. 0·080; and 1 per cent. sulphur present as manganese sulphide reduces the sp. gr. of cast iron 0·2. C. Benedicks said that the addition of one per cent. of manganese increases the sp. vol. 0·00006; with the same proportion of phosphorus, 0·00089; of silicon, 0·00117; and of aluminium, 0·00200. The effects of various elements on the sp. gr. were discussed by H. M. Lane, etc.—*vide infra*, the corresponding alloys of iron.

The effect of mechanical treatment on the specific gravity of iron and of its alloys with carbon.—The early observations of G. Broling are in general agreement with those of later workers. The sp. gr. of the metal usually decreases with *cold-working*; a sample before rolling had a sp. gr. 7·8707, and after rolling 7·8650—the iron was impure since it gave off fœtid hydrogen when dissolved in acids. H. Hädicke found that the hammered metal had a sp. gr. of 7·843, and unhammered 7·838. The effect of cold-work on the densities of metals generally was studied by G. W. A. Kahlbaum and E. Sturm, T. Uêda, W. Spring, J. Johnston and L. H. Adams, and Z. Jeffries and R. S. Archer—*vide* **1**. 13, 18; and the effect of drawing, stretching, or twisting on the density of iron and steel was studied by

E. Heyn and O. Bauer, P. Goerens, H. O'Neil, etc. T. M. Lowry and R. G. Parker found that the sp. gr. of iron filings is less than that of the compact metal from which they were formed—compact iron, 7·8558, filings (cold-worked), 7·8172, decrease 0·0386. J. O. Arnold gave for forged steel, with 99·82 to 99·87 per cent. of iron, 7·8477, and for cast steel, 7·8478. F. Osmond observed that in drawing a wire with a diameter 5·4 mm. and sp. gr. 7·839, the sp. gr. was 7·791 when the diameter was reduced to 3·45 mm., and 7·796 to 7·781 when the diameter was reduced to 0·4 mm. H. M. Howe, W. H. Deering, H. Scott and H. G. Movius, H. E. Doerr, K. Heindlhofer and F. L. Wright, P. Goerens, etc., concluded that the sp. gr. of iron is reduced by cold-working. J. W. Landon found that a piece of wire whose sp. gr. was 7·7097 had a sp. gr. of 7·6160 after being twisted through an angle of 157°, and a sp. gr. of 7·5890 after being twisted through an angle of 228°. The subject was also investigated by E. Houdremont and E. Bürklin, M. Oknoff, K. Tamaru, and T. Uêda. F. C. Thompson and W. E. Millington studied the relations between the sp. gr. and deformation by cold-work with respect to the packing of the atoms of the crystals. They found that very little variation, 7·869 to 7·868, in the sp. gr. of mild steel, of sp. gr. 7·869, pulled in tension with a stress of 14·87 to 21·30 tons per sq. in., occurs until the last section commenced to yield; and with a piece of armco iron, of sp. gr. 7·8580, with the reduction in area in tension of 2·4, 17·8, and 47·5, the sp. gr. were respectively 7·8586, 7·8464, and 7·7927. No change in the sp. gr. occurred until about 5 per cent. reduction of area had occurred, and the decrease in sp. gr. continued until the reduction in area had fallen to 16 per cent. K. Honda, and K. Tamaru discussed the factors involved in the change of sp. gr. by cold-work—*vide supra*, tempering—and the effect is attributed to the closing of blow-holes, and to the weakening of the interatomic forces. H. Hanemann and R. Yamada studied the vol. changes of steel during elastic deformation, and observed that the vol. of mild steel with increasing stress, increases linearly until plastic flow begins; the vol. then increases more rapidly by regular increments, and the curve no longer follows a straight line. The vol. increase $(v-v_0)/v_0\times10^4$ gives a value which rises from zero under a stress of 3·18 kgrms. per sq. mm. to 7·85 under a stress of 41·38 kgrms. per sq. mm.

H. C. Cross and E. E. Hill observed that the effect of hot-rolling is also to decrease the sp. gr. The older observations, which indicate an increase in sp. gr. by cold-working, refer to cast metals in which small cavities are closed up under the hammer, etc. E. Piwowarsky and H. Esser found that the **gas permeability** of cast iron for hydrogen is largely due to microscopic flaws. The porosity of iron is discussed in connection with the corrosion of the metal—*vide infra.* H. O'Neil, B. Beer, J. E. Fletcher, G. Tammann and H. Bredemeier, and A. Marks discussed the **porosity** of cast iron. W. Thörner emphasized the fact that iron always contains pores, and that, where possible, the determinations should be made with the powdered metal. Thus, he obtained for the porosity of iron, in c.c. per kgrm.:

	Specific gravity		Porosity	
	Powder	Compact	Pores	Solid
Ordinary cast iron	7·142	7·042	2·00	140·00
Bessemer steels	7·921	7·826	1·530	126·24
	7·755	7·729	0·530	128·95
Thomas steels	7·968	7·813	2·500	125·50
	7·752	7·700	1·580	128·42

H. O'Neil found that by increasing cold-work in *tension* of armco iron very little alteration in the sp. gr. occurs at first, but the sp. gr. soon decreases about 0·17 per cent., a critical deformation is then reached, for afterwards the sp. gr. ceases to fall and may rise slightly. With further increments of cold-work, the sp. gr. decreases. The overall fall in sp. gr. is about 0·83 per cent. In marked contrast with metallic aggregates, the sp. gr. of single crystals of iron 7·747 was not altered after being subjected to a tensile stress producing a 65-per-cent. reduction of area. T. Ishigaki used a test-piece of armco iron which had been fractured by tensile stresses, and measured the sp. gr. at distances of one centimetre taken successively from the fracture to the lug. The results show that the sp. gr. was least at the point of fracture and increased at increasing distances away. T. Uêda found that the sp. gr. of iron and carbon steel, when stretched, decreases as the tensile stress increases, Fig. 181. If an elongation e be produced by an external force T, $T=eE$, where E is the elastic constant; and if v be the sp. vol., s, the density, and σ, Poisson's ratio, then $dv/v=-ds/s=e(1-2\sigma)$, and by substitution, $ds/s=-E/(1-2\sigma).ds/s$. For a metal with $\sigma=0{\cdot}29$, and $E=2{\cdot}2\times10^4$ kgrms. per sq. mm., $ds/s=-1{\cdot}909\times10^{-5}\ T$. Below the yield-point the sp. gr. decreases slightly and almost proportionally with the stress, but above this point the decrease is more rapid. With carbon steel, the decrease in the sp. gr. is discontinuous at the yield-point, and the magnitude of the decrease decreases with increasing proportions of carbon until, with 0·9 per cent. of carbon, the phenomenon does not occur.

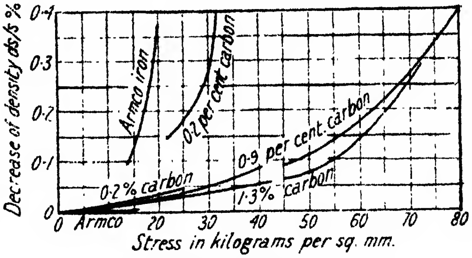

Fig. 181.—The Effect of Tensile Stresses on the Specific Gravity.

H. O'Neil found the sp. gr. of armco iron, between 14° and 16·5°, varied between 7·8393 and 7·8586; and that of single crystals of iron, between 13·3° and 17·5°, varied between 7·747 and 7·754 with *compression* loads up to 45·83 tons per sq. in. After 26 per cent. reduction by compression, the sp. gr. had fallen only 0·07 per cent., and with further work it actually rose above its original value. This is in marked contrast with the behaviour of aggregates of crystals. T. Ishigaki observed the effect of compressing iron and steel at different press., p kgrms. per sq. cm. The results were:

Armco iron		p	0	4,930	7,040	11,970	16,200
		Sp. gr.	7·868	7·866	7·866	7·867	7·867
Carbon	0·3 per cent.	p	0	4,500	7,890	11,830	16,900
		Sp. gr.	7·846	7·844	7·845	7·845	7·844
	0·6 per cent.	p	0	7·040	10,560	12,680	16,900
		Sp. gr.	7·837	7·833	7·835	7·835	7·834
	0·9 per cent.	p	0	5,630	10,700	14,370	16,900
		Sp. gr.	7·828	7·824	7·825	7·826	7·826

The results show that with increasing press. up to about 7000 kgrms. per sq. mm., there is a steady fall in the sp. gr.; an increase then occurs which soon attains a maximum, when it again begins to decrease. The maximum sp. gr. is always less than its initial value. The effect of annealing is gradually to lower the sp. gr. until a tempering temp. of 550° has been obtained when the sp. gr. begins to increase.

J. W. Landon observed a maximum decrease in the sp. gr. of iron, with 0·68 per cent. of carbon, when the iron is subjected to overstrain by *torsion* through various angles:

Angle of twist	0°	70·5°	150°	225°	262°
Sp. gr.	7·7149	7·6678	7·6136	7·5802	7·5757

The results show that the sp. gr. decreases generally as the result of cold-working by twisting. F. C. Lea and W. N. Thomas measured the changes in the sp. gr., D, of steel produced by compressive stresses, S, beyond the yield-point expressed in tons per sq. in. calculated on the original area, and summarized the results by $d=D=0{\cdot}9984+0{\cdot}0_929(250-S)S$. The sp. gr. tends to recover with the lapse of time.

G. Tammann assumed that the decrease in sp. gr. produced by cold-work is due to the production of minute gaps in the slip-planes of the crystal grains; and K. Honda, to the deformation of the space-lattice by internal strain. T. Ishigaki said that the first decrease may be due to these two effects, but the subsequent increase is produced by the closing up of the minute gaps by the higher press. The value of the maximum sp. gr. being smaller than the initial sp. gr. is an effect of the distorted lattice; and the decrease of sp. gr. with higher strains is due to the formation of new intercrystalline gaps. S. Sekito found that the decrease in sp. gr. produced by quenching is due to an expansion of the space-lattice.

The effect of hardening by quenching on the specific gravity of iron and of its alloys with carbon.—Hardening by quenching also lowers the sp. gr., as in the case of cold-working; thus, H. Caron gave the following measurements of a steel rod:

	Before Hardening	Hardened		
		10 times	20 times	30 times
Length . . .	20·00	19·50	18·64	17·97 cm.
Breadth. . . .	0·94	0·96	0·96	1·00 ,,
Thickness . . .	0·93	0·96	0·97	1·00 ,,

and the sp. gr. before hardening was 7·817, and after hardening thirty times, 7·793. H. C. Cross and E. E. Hill's results are summarized in Table XIV. Observations were also made by H. J. French and O. Z. Klopsch. C. Fromme gave for the vol. changes of iron subjected to different heat treatments, original vol., 1·00000; glass-hard, 1·01000; tempered yellow, 1·00495; tempered blue, 1·00060; tempered grey, 1·00425; and annealed at a red-heat, 1·00175. C. Fromme's results show a maximum, or an expansion in volume on passing from the grey annealed to the soft state. C. Barus was unable to verify this, but added that with a more prolonged heating and cooling, it might be possible to obtain the maximum. In one series of observations he found for steel annealed at different temp.:

Annealing temp.	100°	190°	330°	460°	720°	900°	1100°	1300°
Sp. gr. . .	7·7102	7·7251	7·7441	7·7641	7·7793	7·7840	7·7865	7·7856
Sp. vol. . .	0·12970	0·12945	0·12913	0·12880	0·12854	0·12846	0·12843	0·12801

when the values for glass-hard steel are respectively 7·6817 and 0·13018; and for commercial soft steel, 7·81 and 0·1280.

W. Metcalf and J. W. Langley found that steel increases in vol., or decreases in sp. gr. during hardening. The sp. gr. were:

Carbon		0·529	0·649	0·841	0·871	1·005	1·079 per cent.
Ingot		7·841	7·829	7·824	7·818	7·807	7·805
Unhardened rolled steel .		7·844	7·824	7·829	7·825	7·826	7·825
Hardened at	dark redness	7·813	7·806	7·812	7·790	7·812	7·811
	red-heat .	7·826	7·849	7·808	7·773	7·789	7·798
	pale red-heat	7·823	7·830	7·780	7·758	7·755	7·769
	yellow-heat .	7·814	7·811	7·784	7·755	7·749	7·744
	white-heat .	7·818	7·791	7·789	7·752	7·744	7·690

J. H. Andrew and co-workers found that the effect of varying the temp. of quenching on the sp. vol. of steels with carbon up to about 75 per cent. is such that at 800°, the increase in sp. vol. is almost linear, as far as 0·75 per cent. carbon, and the increase is then slower. For a quenching temp. of 1100°, the curve shows a drop in the sp. vol. in the range 0·90 to 1·2 per cent. of carbon, and there appear to be analogous drops in quenching from 900° to 1000° steels with 1·20 to 1·60 per cent. carbon.

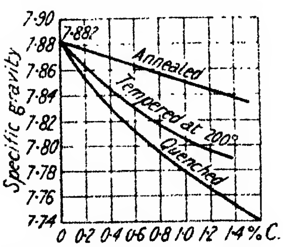

FIG. 182.—The Effect of Annealing, Tempering, and Quenching on the Specific Gravity of Carbon Steels.

K. Tamaru's results for the sp. gr. of quenched, annealed, and tempered steels are summarized in Fig. 182. S. Sekito found that the X-radiograms of quenched steels with different proportions of carbon show that the distances, 2*b*, of the lines (110) with different proportions of carbon, are:

Carbon .	0·12	0·32	0·40	0·51	0·73	0·80	0·90	1·08 per cent.
2*b* . .	56·34	56·33	56·22	56·24	56·14	56·16	56·01	56·17 mm.

so that the lattice expands 0·45 per cent. for 1 per cent. of carbon; the value calculated from K. Tamaru's values for the sp. gr. is 0·44 per cent. This shows that the expansion is mainly due to the expansion of the crystal lattice. The internal stress corresponding with the broadening of the lines is 192 kgrms. per sq. mm., which is of the same order of magnitude as the tensile strength—C. Grad gave 200 kgrms. per sq. mm. The plane at right angles to the plane of maximum at. density—*i.e.* the plane of easiest slip—has the greatest internal stress.

H. Hanemann and E. H. Schulz obtained for steels with 0·16 per cent. C, 0·33 Si, 0·38 Mn, 0·015 S, 0·017 P, and 0·07 Cu:

	Annealed	Quenched at					
		1200°	1105°	1005°	930°	820°	765°
Sp. gr. .	7·863	7·854	7·855	7·861	7·853	7·851	7·855

for steel with 0·51 C, 0·33 Si, 0·62 Mn, 0·023 S, 0·045 P, and 0·07 Cu:

Sp. gr. .	7·854	7·804	7·798	7·801	7·795	7·804	7·844

for steel with 0·86 C, 0·23 Si, 0·25 Mn, 0·033 S, 0·010 P, and 0·020 Cu:

Sp. gr. .	7·857	7·774	7·769	7·772	7·762	7·779	7·839

and for steel with 1·17 C, 0·21 Si, 0·31 Mn, 0·020 S, 0·010 P, and traces of copper:

Sp. gr. .	7·847	7·752	7·759	7·771	7·761	7·810	7·834

The effect of annealing on the specific gravity of steel hardened by mechanical work or quenching.—The effect of annealing is to restore the original sp. gr. diminished by the cold-work. Thus, P. Goerens found a steel wire in which the sp. gr. 7·806, rose to 7·822 on annealing. G. W. A. Kahlbaum and E. Sturm gave 7·7970 for the sp. gr. of annealed piano-wire, and 7·7772 for the same wire cold-drawn—decrease 0·0198. The original sp. gr. was restored on annealing. E. Maurer, E. H. Schulz, B. D. Enlund, and K. Tamaru discussed the subject in connection with the tempering of steels (*q.v.*). C. Chappell and M. Levin found the sp. gr. of cold-worked specimens of steel is about 0·3 per cent. less than that of the annealed metals. Observations were also made by M. Levin and K. Dornhecker, who found that for the sp. gr. of annealed and unannealed iron-carbon alloys:

Carbon .		0	0·11	0·35	0·63	1·00	1·54	2·69	3·05	3·75 per cent.
Sp. gr.	unann.	7·8718	7·8523	7·8422	7·8297	7·8159	7·7957	7·7591	7·7522	7·7343
	ann. .	7·8748	7·8519	7·8425	7·8277	7·8166	7·6422	—	—	—

W. Fraenkel and E. Heymann followed the course of the annealing of quenched steels by the change in the sp. gr. They also observed that with an austenitic steel, having 2·65 per cent. of manganese, and 0·82 per cent. of carbon, at 200°, the sp. gr. rises during the first hour from 7·7801 to 7·8080, and falls to 7·7926 in the first 50 hrs., and rises to 7·7940 in the next 150 hrs. With annealing at a red-heat, the sp. gr. rose to 7·8197. With a steel having 0·50 per cent. of manganese and 0·80 per cent. of carbon, there was only a difference of 0·004 between the maximum and minimum, whilst with the other steel there was a difference of 0·015.

A. Osawa observed that a sample of armco iron, annealed at 1150°, had a sp. gr. of 7·8787 at 20°, and a sp. gr. of 7·8795 after being dipped in liquid air at about −185°, and brought back to 20°. Iron can thus become more compact by cooling to a low temp., possibly owing to the elimination of some pores by the contraction of the metal. H. Hanemann observed the sp. gr. of an unannealed 1·79 per cent. carbon alloy quenched from 1120°, 1130°, and 1140°, before cooling in liquid air, to be respectively 7·7842, 7·6923, and 7·8214, and after cooling in liquid air, respectively 7·6866, 7·8117, and 7·6828; and for alloys quenched from 1100° to 1130°, aged or annealed at 100° to 395°, before and after cooling in liquid air:

Tempered at .		100°	150°	210°	260°	287°	306°	435°	375°	395°
Sp. gr.	Before .	7·8758	7·8979	7·8314	7·7331	7·7084	7·7714	7·7728	7·7794	7·7536
	After .	7·6942	7·7146	7·6993	7·7186	7·7032	7·7560	7·7686	7·7810	7·7485

The observations of H. C. Cross and E. E. Hill, H. A. Dickie, P. Goerens, R. Hay and R. Higgins, E. Heyn and O. Bauer, and F. C. Lea and co-workers show that the effect of annealing on the sp. gr. of cold-worked steel is appreciable in some cases at temp. so low that recrystallization has not commenced. K. Tamaru's results are summarized in Fig. 182—*vide supra*, the tempering of steel. T. Ishigaki observed that with armco iron the sp. gr. 7·862 was reduced by hammering to 7·855. The recovery of the sp. gr. by annealing did not here commence until nearly 700°; in fact, a decrease in the sp. gr. occurred at 500°. This has not been explained. The decrease was also observed in the annealing of specimens which had been subjected to tensile and compression stresses. B. D. Enlund observed a contraction in the sp. vol. during the annealing of quenched steel beginning near 100° and ending about 210°. Thereafter, a pronounced expansion occurs between 250° and 300°. The expansion was also observed by G. E. Svedelius, G. Charpy and L. Grenet, and P. Chévenard. The contraction is attributed by B. D. Enlund to the formation of troostite and the coagulation of cementite, while the expansion corresponds with the decomposition of retained austenite. The subject was discussed by K. Tamaru—*vide supra*, tempering.

E. Heyn and O. Bauer measured the influence of annealing mild steel wire at different temp. on the sp. gr., and found for wires of diameter *d* mm., and the ratios *n* of the elongations due to cold stretching, the sp. gr. before and after annealing:

d	5·22	3·65	3·10	2·65	2·25	1·90	1·60	1·40	1·25
n	—	2·045	2·835	3·88	5·38	7·55	10·65	13·91	17·43
Sp. gr. Before .	7·861	7·840	7·832	7·835	7·828	7·838	7·836	7·841	7·825
Sp. gr. After .	7·862	7·845	7·8405	7·849	7·843	7·8415	7·843	7·847	7·8575

They also found for the cold-drawn wire, 1·25 mm. diameter, annealed at various temp.:

	0°	100°	200°	300°	400°	500°	600°	700°	800°	900°
Sp. gr. .	7·825	7·8275	7·829	7·834	7·836	7·836	7·834	7·8385	7·850	7·8575

The sp. gr. increases with rising temp. E. Maurer observed that cold-worked steels with 0·14 and 0·40 per cent. of carbon attained their maximum sp. gr. when annealed respectively at 150° and 250°. H. C. Cross and E. E. Hill's observations are summarized in Table XIV.

TABLE XIV.—THE SPECIFIC GRAVITY OF QUENCHED AND TEMPERED CARBON STEELS.

Carbon per cent.	Temp. Quenching	Specific Gravity								
				Tempering Temperature						
		Hot-rolled	Water-quenched	150°	225°	300°	375°	460°	525°	600°
0·09	910°	7·848	7·823	7·829	7·809	7·830	7·838	7·845	7·839	7·841
0·28	865°	7·850	7·829	7·837	7·833	7·839	7·842	7·846	7·846	7·844
0·35	865°	7·839	7·802	7·811	7·816	7·829	7·830	7·828	7·829	7·829
0·44	820°	7·839	7·802	7·805	7·809	7·824	7·833	7·834	7·834	7·831
0·47	820°	7·833	7·795	7·796	7·801	7·818	7·825	7·828	7·828	7·831
0·60	810°	7·838	7·785	7·794	7·797	7·818	7·827	7·829	7·828	7·832
0·68	810°	7·832	7·776	7·788	7·789	7·809	7·821	7·824	7·826	7·827
0·87	795°	7·832	7·769	7·784	7·784	7·810	7·824	7·826	7·826	7·830
0·98	795°	7·828	7·762	7·780	7·776	7·804	7·818	7·821	7·823	7·823
1·05	795°	7·825	7·770	7·795	7·792	7·814	7·818	7·821	7·821	7·822
1·12	795°	7·819	7·757	7·781	7·770	7·785	7·805	7·809	7·807	7·813
1·29	795°	7·812	7·758	7·780	7·767	7·787	7·802	7·805	7·807	7·808

H. A. Schwartz measured the sp. gr. of annealed and unannealed white cast iron with different percentages of carbon. E. Maurer determined the sp. gr. of a 0·83 per cent. carbon steel, hardened by quenching from 800°, and annealed at different temp. J. H. Andrew and A. J. K. Honeyman found for carbon steels with 0·08 to 0·25 per cent. of manganese, and 0·08 to 0·175 per cent. of silicon the values shown in Fig. 183 for the sp. vol. (corrected for silicon) for steel quenched from 900° and tempered for an hour at different temp. Tempering at 160° affects only the martensite. At 250°, both austenite and martensite are tempered, but in the higher-carbon steels the tempering of austenite predominates although it is not completed. The tempering at 350° completes the austenite transformation, but some martensite still remains. Tempering is complete at 620°, but this would probably be obtained at a lower temp. For furnace-cooled nickel-chromium steel, with 3·46 per cent. of nickel, 1·80 per cent. of chromium, 0·13 to 0·19 per cent. of silicon, the critical temp., sp. vol. corrected for silicon, and the scleroscopic hardness were :

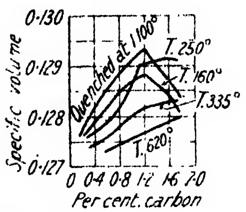

Fig. 183.—The Effect of Annealing and Tempering on the Specific Volume of Carbon Steels.

Carbon .	0·51	0·51	1·28	1·28	1·28	1·50	1·50	1·50 per cent.
Critical temp.	600°	400°	600°	400°	150°	600°	400°	150°
Sp. vol. . .	0·12757	0·12774	0·12781	0·12768	0·12788	0·12790	0·12778	0·12794
Hardness .	30	57	38	48	67	36	47	70

For the same steel, quenched from 1200° and tempered for an hour at the temp. named :

Per cent. C.	Quenched	Tempered				Annealed
	1100°	190°	260°	365°	600°	780°
Sp. vol. . .	0·12843	0·12814	0·12814	0·12790	0·12763	0·12763
Hardness . .	65	65	65	60	52	34
Sp. vol. . .	0·12626	0·12626	0.12626	0.12716	0·12798	0·12788
Hardness . .	29	34	34	49	56	36
Sp. vol. . .	0·12650	0·12647	0·12647	0·12763	0·12803	0·12791
Hardness . .	31	34	34	57	63	40

No change in the sp. vol. occurs until 365° is reached ; the slight increase in hardness is a surface effect. Tempering at 365° results in an incomplete transformation of austenite, but most of the transformation is completed between 350° and 600°. The tempering at 600° is not complete. Heating to 780°, followed by slow cooling, brings the steels back to the fully annealed state.

The energy equivalent of the changes in volume.—As indicated below, E. Heyn and O. Bauer found the sp. gr. of cold drawn mild steel wire to be 7·825, and when annealed at 700°, the sp. gr. becomes 7·838 ; and this corresponds with a decrease of 1·66 mm. per 1000 in a wire 1·25 mm. diam. E. Heyn and O. Bauer explain the reduction in sp. gr. by cold-work, and the increase in sp. gr. by subsequent annealing as follows : E. Rasch has shown that in stretching a metal bar, heat is absorbed so long as the stress is elastic in character ; but on passing the yield-point the heat of the action changes sign, and heat is evolved. In compressive tests, however, E. Rasch found that the heat of the action is positive from the beginning, and on exceeding the yield-point a sudden increase in the heat of the action occurs, but the sign is not changed. From this it might be inferred that the elastic change of form of metals follows a law similar to that which governs the elastic change of form of gases. That is to say, expansion is accompanied by the absorption of heat and a reduction in density ; and compression, by the liberation of heat and increase in density. In contradistinction to this purely elastic change of form stands the purely plastic change of form, which occurs when the internal friction of the metal particles is overcome ; it is accompanied by the conversion of work into heat. This process, as in all cases where work is converted into heat by friction, is not reversible. No change in the sp. gr. would be expected to take place, so long as there were no hollow spaces in the body before undergoing deformation. That is, as long as the change of sp. gr. can be taken as zero and the movement of the particles of the body is not prevented by very high press. Such a deformation of a purely plastic nature cannot be produced in practice, because it is always accompanied by an elastic change of form, even though this, so far as can be judged from the extent of deformation, is very minute in comparison with the former. Since an elastic change of form, as in the case of gases, is accompanied by a storing up of potential energy, a certain amount of potential energy remains stored in metals when deformed in the cold state. Thus, in the cold-drawing of wire, the individual particles become plastically, but also partly elastically, stretched. When the stress is no longer applied, the material partially recovers from the elastic change of form; but this change of form may be partially retained in the material in consequence of the resistance due to friction, which opposes the return to a state of equilibrium; and this remanent elastic tension reveals itself in the reduction of the sp. gr. of the metal. By heating the cold-drawn material the internal friction is moderated, and the elastic tension of the particles is thereby released so that a new state of equilibrium corresponding to the temp. is attained. The sp. gr. must therefore correspondingly increase, as has been already proved by G. W. A. Kahlbaum and E. Sturm for a great number of metals. E. Heyn and O. Bauer obtained an approximate estimate of the remanent elastic stress—namely 33 kgrms. per sq. mm.—from the differences in the sp. gr. before and after annealing.

Let d, l, and s respectively denote the thickness (1·25 mm.), length, and sp. gr. of the annealed wire, and D, L, and S the corresponding values for the cold-drawn wire. Then $dls = DLS$, but the difference in the thickness of the two wires is small enough to be neglected, and then $L = ls/S$; and the elongation $L - l$ becomes $l\{(s/S) - 1\} = 0{\cdot}00166l$, since the sp. gr., s, of the cold-drawn wire is 7·825, and the sp. gr., S, of the wire annealed at 700° is 7·838. This means that the wire, 1·25 mm. diameter, has been shortened $0{\cdot}00166l$—*i.e.* 1·66 mm. per 1000—during annealing. Let E denote the modulus of elasticity, nearly 20,000 kgrms. per sq. mm., and δ the elastic stress in kgrms. per sq. mm. Then, $0{\cdot}001661 = l\delta/E$; or δ, the remanent elastic stress, is nearly 33 kgrms. per sq. mm.—*vide supra*, annealing.

The specific gravity and specific volume of the constituents of the carbon-iron alloys.—O. C. Ralston found that the mean values for the sp. gr. and sp. vol. of the constituents of steel are respectively as follow: Ferrite, 7·864 and 0·1271; cementite, 7·670 and 0·13038; pearlite, 7·778 and 0·12856; austenite, 7·843 and 0·1275; martensite, 7·633 and 0·1310; α-martensite, 7·581 and 0·1319; and β-martensite, 7·800 and 0·1282. This shows that when an austenitic steel is converted into martensite, there is an expansion in vol. The transition from martensite to pearlite involves a decrease in volume although pearlite has a smaller sp. gr. than austenite. G. Tammann and K. Ewig found that at the A_0-arrest, about 210°, the dilation of cast iron corresponds with an expansion of 0·0795 c.mm. per gram of Fe_3C. A. Westgren found the sp. gr. of austenite with 12·1 per cent. of manganese and 1·34 per cent. of carbon to be 7·82; and G. Tammann and E. Scheil gave 7·83 for the sp. gr. of a steel with 1·72 per cent. of carbon. These austenites are impure. A. Osawa obtained 8·008 for the sp. gr. of austenite calculated by extrapolation from the X-radiogram data for nickel steel. S. Sato's value for the thermal expansion gave 8·12 for the sp. gr. of austenite at room temp.; F. Wever's value is 8·04; and K. Tamaru's value 8·097.

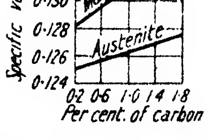

FIG. 184.—The Effect of Carbon on the Specific Volume of Martensite and Austenite.

C. Benedicks said that troostite, sorbite, and pearlite all have the same sp. vol., and that the sp. vol. of austenite is less, and that of martensite greater than that of pearlite. H. von Jüptner gave 7·82 for the sp. gr. of pearlite, and 0·1279 for the sp. vol. J. H. Andrew and A. J. K. Honeyman observed that, as indicated by the sp. vol., the tempering of martensite begins at or below 150°, but it is not complete at 360° in an hour. The sp. vol of fully tempered martensite is the same as that of the corresponding pearlite, indicating that in both conditions of steel, the cementite possesses the same crystalline form. E. Maurer represented the effect of carbon on the sp. vol. of martensite and austenite by the curves Fig. 184. The changes in sp. gr. or sp. vol. during the transformation of austenite to martensite were studied by W. Fraenkel and E. Heymann, H. Hanemann and L. Träger, E. Scheil, M. Levin and K. Dornhecker, K. Honda, F. Wever and P. Rütten, A. Westgren and G. Phragmen, K. Heindlhofer and F. L. Wright, and W. L. Fink and E. D. Campbell. L. Zimmermann and H. Esser studied the sp. vol. of cast iron. K. Honda found that the sp. vol. of austenite, and of the α- and β-martensites, depend on the carbon contents, thus:

	Carbon	0·4	0·7	1·0	1·2 per cent.
Sp. vol.	Austenite .	1·1252	0·1256	0·1260	0·1263
	α-martensite .	0·1276	0·1283	0·1294	0·1300
	β-martensite .	0·1265	0·1268	0·1270	0·1272

and for the sp. vol. of cementite at room temp. and at 1130°, K. Honda and co-workers gave respectively 0·1304 and 0·1350; and for iron, respectively 0·1271 and 0·1331.

The changes in volume during tempering.—The observations of K. Tamaru, and others have been discussed in connection with tempering. According to H. C. Cross and E. E. Hill, carbon steels, with up to 1·30 per cent. of carbon, decrease in density when quenched due to the formation of martensite. The magnitude of this decrease rises with increasing carbon content, reaching a maximum at about 1 per cent. carbon, and then falls off slightly. Upon tempering, the quenched steels gradually increase in density. A decrease in density is noted in the hyper-eutectoid steels when tempered at 225° and this may be ascribed to the tempering of retained austenite. Upon further tempering above 225°, the density of all samples increased, ultimately approaching the density of the annealed steel upon tempering at 600°. The greatest increase in density occurs upon tempering at 300°, the rate of increase then gradually falls off as the tempering temp. is raised to 600°.

Quenched austenite is more stable than martensite at room temp. and up to 200°, so that on tempering up to 200°, martensite needles may be converted into troostite; and if a sample be then cooled in liquid air, needles of martensite appear in a ground mass of unaltered or super-cooled austenite. Water-quenched steel contains martensite mixed with some austenite. On tempering, martensite alters to troostitic and sorbitic pearlite with an increase in vol. The change is at about 100°, and is nearly complete at 200°; and austenite begins to pass into sorbite at about 250°, so that as the temp. rises to 300° to 500°, the sp. vol. decreases by the passage of what G. Tammann and E. Scheil call *distended pearlite*, or troostitic pearlite, into normal pearlite. Any austenite converted at or below 250° furnishes this distended or troostitic pearlite, and any converted above 250° furnishes normal sorbitic pearlite. The pearlite is distended at 100° to 300° because it has a smaller sp. vol. than the martensite from which it was derived. The solid is not sufficiently mobile at these temp. to allow it to contract and fill the spaces that tend to form. Hence, tempered steels have usually a high sp. vol. Ordinary pearlite formed by the slow cooling of austenite has a sp. vol. of 0·12856, whereas the distended pearlite has a sp. vol. 0·1303. O. C. Ralston suggested that if the distended pearlite is sorbite or troostite, the sp. vol. 0·1303 corresponds to a real vol. and is not due to a distortion of the pearlite lattice as a result of its rigidity at the low temp. of the tempering.

According to G. Tammann and E. Scheil, water-quenched steel has about 50 per cent. martensite embedded in a matrix of super-cooled austenite; and steel quenched in liquid air has a sp. vol. of 0·12965 corresponding with about 80 per cent. martensite. K. Honda and H. Endo found that by repeated cooling in liquid air, and warming back to ordinary temp., the sp. vol. could be brought to 0·1303, very nearly the value 0·1310 for martensite. Hence, quenching in liquid air did not completely eliminate the austenite.

The changes in volume on solidification or melting.—H. Moissan found that iron with but little carbon contracts on solidification, but when saturated with carbon, the metal expands on solidification. O. C. Ralston gave $dv/v=0·036$ for the best representative value of the expansion per unit volume for purified iron on melting at 1535°. According to W. C. Roberts-Austen and T. Wrightson, the sp. gr. of solid iron, near its m.p., is 6·95, whilst that of the liquid metal, a little higher in temp., is 6·88. R. Mallet made observations on this subject. T. Wrightson gave for the sp. gr. of cold, solid grey Cleveland iron, 6·95; molten iron, 6·88; and iron in the plastic state, 6·50. C. Benedicks and co-workers found the sp. gr. of liquid iron holding 0·10 per cent. of carbon, which was estimated to increase to 0·2 or 0·3 per cent. of carbon during the experiment, to be 6·92±0·07 at 1550°. This corresponds roughly with a linear shrinkage of $\frac{1}{35}$th in passing from the m.p. to ordinary temp. K. Honda and co-workers obtained the results summarized in Fig. 185. The sp. gr. curve of liquid iron containing different proportions of carbon, and, for comparison, the liquidus curve, are given in Fig. 185. Both curves are of the same general type. At 1600°, the sp. vol., v, and the increase in the sp. vol., δv per 100°, are:

Carbon	0	0·5	1·0	1·5	2·0	3·0	4·0 per cent.
Sp. vol.	0·1397	0·1445	0·1461	0·1471	0·1487	0·1518	0·1566
δv	0·0020	0·0023	0·0025	0·0028	0·0030	0·0035	0·0038

The effect of additions of various elements on the sp. vol. is indicated in Fig. 186.

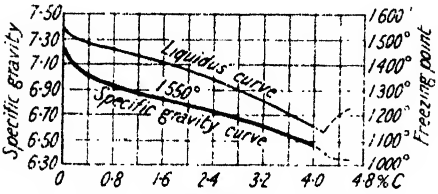

FIG. 185.—Specific Gravity Curve of the Liquid Alloys of Carbon and Iron.

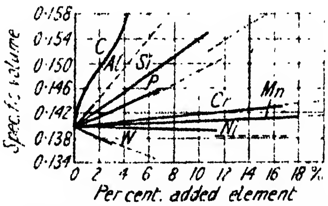

FIG. 186.—The Effect of Various Elements on the Specific Volume of Iron.

According to F. Wüst, the contraction of purified iron from the solidifying temp. is 2·39 per cent. It is diminished by carbon, the addition of 1·7 to 2 per cent. giving a minimum of 1·9 per cent., but then slowly increases as the carbon is further increased. Phosphorus diminishes the contraction to 1·3 per cent. at 1·7 per cent. phosphorus, but further addition increases the contraction. In both series of alloys the formation of mixed crystals diminishes the contraction, but when the limit of solubility is exceeded and iron carbide or iron phosphide is formed, the contraction increases. Silicon diminishes the contraction of iron from 2·37 per cent. to 1·7 per cent. at a content of 18·24 per cent. silicon. Manganese was the only element investigated which increased the contraction, which rose to 2·89 per cent. at 15·5 per cent. manganese. Sulphur diminishes the contraction rapidly up to a content of 1 per cent., afterwards more slowly, but with no minimum value as in the case of phosphorus. Nickel diminishes the contraction of iron very little, with a minimum at about 25 per cent. nickel. Chromium diminishes the contraction uniformly to 1·80 per cent. at a content of 21·4 per cent. chromium. Iron alloys free from graphite show an elongation at the beginning of solidification, the magnitude of which corresponds roughly to that of the solidification period of the alloy. C. Benedicks and N. and G. Ericsson, and C. H. Desch and B. S. Smith gave for iron with 0·03 to 0·04 per cent. of carbon, and for alloys with 3·12 to 3·65 per cent. of carbon:

	0·03 to 0·04 per cent. C				3·12 to 3·65 per cent. C			
	1530°	1545°	1550°	1560°	1300°	1355°	1405°	1465°
Ericsson.	7·18	7·17	7·16	7·17	7·26	7·23	7·23	7·17
D. and S.	6·79	6·05	6·97	6·95	6·93	6·90	6·82	6·77

The mean values for 0·04 per cent. carbon are respectively 7·00 and 7·17 at 1545°, and for 3·40 per cent. carbon respectively 7·25 and 6·86 at 1355°. H. A. Schwartz found the sp. gr. of liquid iron between 1375° and 1500° varies 0·02 grm. per c.c. per degree; and that at 1450°, sp. gr.$=7·16-0·1[Si]-0·7[C]$, where the symbols represent parts per 100. D. W. Berlin gave for carbon-free iron, and iron with 1·2 per cent. of carbon:

	m.p.	1550°	1600°	1650°	1700°
Carbon-free . .	7·4	7·3	7·2	7·0	6·9
1·2 per cent. C.. .	—	7·0	6·9	6·8	6·7

F. Sauerwald and co-workers found the sp. vol. and sp. gr. of grey cast iron—with 3·32 per cent. total carbon; 2·72 per cent. graphite; 2·76, Si; 0·56, Mn; 0·126, S; and 0·492, P:

	700°	800°	840°	900°	1000°	1100°	m.p.		1200°	1300°
Sp. vol. . . .	0·1460	0·1478	0·1484	0·1476	0·1457	0·1444	0·1444	0·1435	0·1445	0·1477
Sp. gr. . . .	6·85	6·77	6·73	6·78	6·86	6·92	6·92	6·97	6·92	6·77
	Solid						Liquid			

The results are plotted for the sp. vol. in Figs. 187 and 188; there is a maximum on the curve at 840°. H. A. Schwartz represented the sp. gr., *D*, of liquid iron, at 1450°, by $D=7·16-(0·1\ Si+0·07\ C)$. Observations were made by G. Dearth and F. Sauerwald, W. Krause and F. Sauerwald, W. Biltz and K. Meisel, and J. J. Saslawsky. According to F. Sauerwald and E. Widawsky, the sp. vol. of molten iron-carbon alloys does not follow the mixture rule, and hence they infer that the liquid metal contains the tritacarbide, Fe_3C. Their results are summarized in Table XV. W. Biltz and K. Meisel calculated 1·05 for the at. vol. of α-iron at absolute zero.

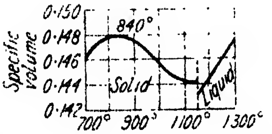

Fig. 187.—The Effect of Temperature on the Specific Volume of Iron.

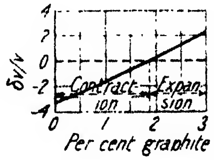

Fig. 188.—The Effect of Carbon on the Specific Volume of Iron.

TABLE XV.—THE SPECIFIC VOLUME OF THE IRON-CARBON ALLOYS.

Carbon per cent.	Liquidus	Specific Volume		Temp. Coeff. $\frac{dv}{dT}\times 10^4$	Specific Gravity	
		at Liquidus	at 1600°		at m.p.	at 1600°
0·0	1533°	0·1402	0·1405	0·05	7·13	7·12
0·5	1480°	0·1408	0·1411	0·06	7·10	7·08
1·0	1458°	0·1412	0·1417	0·06	7·08	7·05
1·5	1422°	0·1416	0·1425	0·07	7·065	7·02
2·0	1382°	0·1418	0·1432	0·07	7·05	6·98
2·5	1341°	0·1419	0·1438	0·08	7·05	6·95
3·0	1290°	0·1419	0·1445	0·08	7·05	6·92
3·5	1232°	0·1418	0·1452	0·09	7·05	6·88
4·0	1170°	0·1415	0·1459	0·10	7·06	6·86
4·2	1150°	0·1414	0·1462	0·10	7·07	6·84

K. Honda and co-workers found for the increase in volume, $\delta v/v$, which occurs during the solidification of cast iron with *Gr* per cent. of graphite, and *C* per cent. of decomposed cementite:

Gr . . .	3·10	2·86	2·38	1·90	1·00	0·22	0·12	0·00
C . . .	46·40	42·80	35·60	28·40	14·95	3·02	1·79	0·00
$\delta v/v$ . . .	2·74	2·22	1·98	0·82	−1·60	−3·07	−3·54	−4·00

The volume changes at the eutectic temperature.—K. Honda and H. Endo estimated that pure iron on freezing at 1530° contracts 4·4 per cent. in volume. The sp. vol. of α-iron at 1450° is 0·1366; and of δ-iron at 1530°, 0·371, and the sp. gr., 7·29. They gave for the sp. vol. of white cast iron with 4·1 to 4·3 per cent. total carbon, and 2·8 to 3·0 per cent. graphite:

	1130° (m.p.)	1150°	1200°	1250°	1300°
Sp. vol.	0·1433	0·1435	0·1445	0·1460	0·1480
Sp. gr.	6·97	6·96	6·91	6·85	6·75

The increase in vol., $\delta v/v$, decreases as well, becoming zero with 2·06 per cent. of graphite (4·1 per cent. of total carbon and 0·38 per cent. of silicon). When no graphite is precipitated, and the metal is 100 per cent. white cast iron, extrapolation shows that the contraction during solidification is 3·6 per cent. The results show the relation between the change of vol. and the liberation of graphite during freezing; and they agree with the assumption that the graphite present in cast iron is a decomposition product of the cementite which is precipitated from the molten alloy during solidification—*vide supra*. F. Sauerwald and co-workers gave for pig-iron of a eutectic composition, 6·85 for the sp. gr. and 0·1460 for the sp. vol. at 700°, the sp. vol. rose to a maximum of 0·1484 (or sp. gr. 6·73) at 840°, and then decreased steadily to the m.p. where a sharp decrease occurred followed immediately by a rapid increase on liquefaction. The abnormal contraction at the m.p. is attributed to the formation of large quantities of cementite in the melt, and the maximum in the sp. vol. curve to the formation of cementite and γ-iron. F. Sauerwald and J. Wecker found the sp. vol., v, and sp. gr., D, of white cast iron before and after melting, to be $v=0·1398$ and $D=7·15$ for the solid, and $v=0·1418$ and $D=7·05$ for the liquid; and for grey cast iron, $v=0·1449$ and $D=6·90$ for the solid, and $v=0·1435$ and $D=6·97$ for the liquid. Consequently, while grey cast iron contracts on melting, white cast iron expands. F. Sauerwald and E. Widawsky found that the contraction of solid grey iron is due to the dissolution of graphite, and that cementite is formed when the grey iron is melted. The data for grey cast iron, and white cast iron are:

		700°	900°	1000°	1150°	1155°	1155°	1160°	1250°	1300°
Grey	Sp. vol. .	0·1456	0·1480	0·1455	0·1450	—	—	0·1455	—	0·1478
	Sp. gr. .	6·87	6·75	6·87	6·90	—	—	6·97	—	6·77
White	Sp. vol. .	0·1340	0·1352	0·1360	—	0·1391	0·1415	—	0·1440	—
	Sp. gr. .	7·46	7·39	7·35	—	7·18	7·07	—	6·92	—
		Solid					Liquid			

L. Zimmermann noted a break in the sp. vol. curve at about 700° with white cast iron, and found that the expansion which occurs on melting is between 1·33 and 1·41 per cent. J. J. Saslawsky studied the atomic volume. W. L. Bragg[3] calculated for the **atomic radius,** 1·40 A.; W. P. Davey, $1·236\times10^{-8}$ cm.; C. Benedicks, $1·26\times10^{-8}$ cm.; M. L. Huggins, 1·23 A. for bivalent iron; and G. Natta, 0·83 A. G. Natta and L. Passerini found that if the radius of oxygen is 1·32 A., that of iron is 0·82 A. Observations were also made by A. M. Berkenheim, E. J. Cuy, V. M. Goldschmidt, H. G. Grimm, E. Herlinger, M. L. Huggins, L. Pauling, J. C. Slater, and E. T. Wherry from which it follows that for tervalent iron atoms, the effective radius is 0·49 to 1·45 A. A. Kapustinsky investigated the effect of solvation on the ionic radius; and F. Wever, the effect of polymorphic transformations. C. Benedicks discussed the sphere of activity of the atoms; P. Vinassa, the mol. number; and J. A. M. van Liempt, the atomic constants.

J. B. A. Dumas[4] observed that iron is scratched by glass of **hardness** 5·6 on Mohs' scale. F. C. Calvert and R. Johnson said that iron is the hardest of all the ductile metals—the hardness of Staffordshire iron being 6 to 7 on Mohs' scale, and that of steel 6. J. R. Rydberg gave 4·5 for the hardness of iron on the same scale. H. F. E. Lenz also reported the results of some tests on the hardness of metals. Actually, P. P. Cioffi found the hardness of iron of a high degree of purity to be about the same as that of annealed copper, that the hardness of iron on Mohs' scale is 5·5, and after heating in vacuo, 4·5. T. Turner observed that the hardness of iron is 1375 when that of copper is 1360, and that of the diamond 3010. These statements serve to illustrate how simple a property hardness was considered to our predecessors; a marked contrast to what the term means to-day. There is also little to indicate the marked change in the hardness which occurs with modifications in the thermal treatment. Hardness may be defined as the resistance of a body against permanent change of shape; or, less rigorously, as T. Turner expressed it, hardness is the property of resisting penetration, so that a hard body is one which under suitable conditions readily penetrates a softer material. The phenomenon is really a complex one, so that hardness varies in kind. The manifestations of hardness vary with the form of stress to which a metal may be subjected, so that phrases like tensile hardness, cutting hardness, abrasive hardness, and elastic hardness have been employed. The usual tests for hardness are *static* in character, but, as T. Turner pointed out, the conditions are different when the penetrating (or other) body is moving with a greater or less velocity. *Dynamic* hardness is exemplified by resistance to the action of a sand-blast, to the pounding of a heavy locomotive on a steel rail, to a projectile, or to a cutting tool in a lathe. The subject has previously been discussed from one point of view—**2**. 20, 7.

S. Bottone assumed that, in general, the closer the atoms are packed, the greater the hardness; hardness varies inversely as the at. vol. Hard metals have a low at. vol., and soft metals a high at. vol. G. Wertheim made a similar observation with respect to tenacity about 1844; and W. C. Roberts-Austen, with respect to the influence of foreign elements on the tensile strength of gold; and F. Osmond, with respect to the influence of various elements on the critical temp. of iron. C. Benedicks pointed out a certain analogy between the atomic volume rule and the gas law that the press. of a gas at a given temp. is proportional to the number of molecules in unit space, for the hardness or the resistance offered by a solid to the entry of another body will increase as the number of atoms in unit vol. is increased. The subject was discussed by L. Gruardet, and C. H. Desch. M. Hanriot observed that iron with a hardness of 57·7 units acquired a hardness of 62·3 after being compressed by a press. equivalent to 10,000 kgrms. per sq. cm.—*vide infra*, the influence of cold-work.

The parallelism between hardness and at. vol. is not rigid, and might be better if the metals were tested under like conditions. P. Ludwik said that the comparison should be made at temp. bearing some relation with the m.p. G. Mars illustrated the idea by calculating the atomic concentrations of a number of steels of known composition and hardness. According to K. Honda, for a given substance having a definite molecular force, its hardness increases with the fineness and strained state of the structure, and for the same structure, and the same degree of strain, the hardness of a substance increases with the strength of its molecular force. C. A. Edwards found that there is an even closer parallelism between the hardness and the m.p. of the metals than with the at. vol. P. Lasareff said that the proportionality between hardness and at. concentration—the reciprocal of the at. vol.—follows from the assumption that the mutual attractive forces of the atoms of different elements is the same function of the distance between them. I. Traube observed a close parallelism between the hardness and internal press.; and C. Benedicks, between hardness and osmotic press.

The various methods for measuring hardness have been summarized by the nomenclature committee of the Iron and Steel Institute in 1902; and reports were issued by the Institution of Mechanical Engineers in 1916, and 1929. The study of the so-called absolute hardness by H. Hertz, F. T. Trouton, etc., was discussed **2**. 20, 7. The summary with some modifications is as follows:

I.—The hardness of a body is determined by the penetration into it of another body.

A.—When the respective positions of both bodies remain unchanged during the operation of testing.

(*a*) The penetration of the foreign body is effected by means of a steady press.
- (1) The depth of penetration, press., constant—*e.g.* J. A. Brinell's indentation test.
- (2) Press. required to produce a fixed depth of penetration.

(*b*) The foreign body is driven in by means of a falling weight.
- (1) The depth of penetration produced by a constant blow—*e.g.* the diamond indentation test, and S. P. Rockwell's test.
- (2) The force of blow is required to produce a fixed depth of penetration—*e.g.* E. G. Herbert's pendulum.

B.—The respective positions of both bodies vary during the operation of testing.

(*a*) By scratching the surface with normal substances of various hardness—*e.g.* T. Seebeck's proposal, and F. Mohs' mineralogical test.

(*b*) By pressing the harder substance against the body to be tested.
- (1) The press. required to plough a way through a certain distance, or in a certain time, a definite portion of the test body—*e.g.* W. J. Keep's drill test.
- (2) The weight of material removed from the test body by a definite press. in a definite time.
- (3) The press. necessary to produce on the test body a furrow of definite width —*e.g.* T. Turner's sclerometer.
- (4) The width of furrow cut in the test body by a definite loading of the cutting agent—*e.g.* A. Martens' sclerometer.
- (5) The number of rotations required to cut a definite depth into a substance by a diamond-tipped borer under a definite load—*e.g.* T. A. Jaggar's and W. J. Keep's processes. The dynamic tests, however, introduce complications which obscure the development of the difficult concept of hardness. H. P. Hollnagel found that soft wrought iron may appear hard when rotated fast enough. Thus, at a speed of 30 ft. per sec., a soft wrought iron disc was cut by a steel tool; at 100 ft. per sec., it cuts the steel tool; and at 300 ft. per sec., it cuts quartz.
- (6) The abrasive hardness discussed by F. Robin, etc.

(*c*) By measuring the height of rebound of a hard body dropped from a given height on to the surface to be tested—*e.g.* A. F. Shore's scleroscope.

II.—The hardness of a body is deduced from the properties of tenacity of the material—*vide infra.*

G. D. Bengough pointed out that the hardness measured by these tests involves two or more variables; and that hardness alone cannot be measured directly. This was also the opinion of W. C. Unwin. The different kinds of hardness are the resultants of different groups of component forces. Thus, according to G. D. Bengough, T. Turner's sclerometer gives readings probably proportional to tenacity and density; A. F. Shore's scleroscope gives readings proportional to the elastic limit, and the elastic hardness so measured would be more accurately called *resilience*; J. A. Brinell's test measures resistance to compression which is nearly proportional to tenacity, the reciprocal of compression; and T. A. Jaggar's test depends on tenacity, density, and elongation. The term *hard* is also applied to metals with a high tensile strength and a low elongation, but the term *coherent* would be more appropriate; metals with a low tensile strength and high elongation could then be called *viscid* instead of soft; metals with a high tensile strength and high elongations could then be called *ductile*; and metals with a low tensile strength and low elongation could be called *weak*.

Observations on the testing of the hardness of iron and its alloys were made by A. H. d'Arcambal, G. Auchy, E. S. Ault, J. C. Ayers, G. W. Barr and co-workers, R. G. C. Batson, C. A. Bauer, C. Benedicks and V. Christiansen, V. Bernard, F. Bollenrath, C. A. Briggs, J. A. Brinell, R. C. Brumfield, D. K. Bullens, G. Charpy, H. le Chatelier and co-workers, J. Class, C. J. B. Cooke, R. H. Coolidge, I. H. Cowdrey, J. W. Craggs, A. E. Crisp, W. J. Crook and H. S. Taylor, N. N. Davidenkoff and G. N. Titoff, C. H. Davis, H. E. Degler, G. H. Denison, H. C. Dews, C. Dillner, P. W. Döhmer, J. W. Donaldson, F. W. Duesing, P. Dufour, J. Durand, H. K. Dutcher. C. A. Edwards and co-workers, J. V. Emmons, R. Esnault-Pelterie, G. S. Evans, A. B. Field, F. Figari, J. E. Fletcher, A. Föppl, M. F. Fogler and E. J. Quinn, A. V. de Forest, F. E. Foss and R. C. Bramfield, H. Fowler, E. Franke, C. de Fréminville, H. J. French and co-workers, T. Friesendorff, J. D. Gat, R. Genders, H. M. German, S. L. Goodale and R. M. Banks, S. H. Graf, C. Grard, R. H. Greaves, L. Grenet, R. Guillery, L. Guillet and co-workers, A. Haar and

Koerber and I. B. Simonsen, S. Kokado, F. Krau, R. Kühnel and co-workers, C. Kugler, W. Kuntze, E. F. Lake, O. H. Lehmann, R. M. Leslie, P. Lieber, P. Ludwik, V. E. Lysaght, D. J. MacAdam, A. McCance, R. Mailänder, A. Mallock, R. Malmström, F. S. Mapes, R. Mather, E. Maurer, E. Menzel, W. J. Merten, A. Mesnager, E. Meyer, H. Meyer and F. Nehl, G. A. A. Middelberg, H. Moore, R. R. Moore, G. Moreau, H. H. Morgan and J. R. Mooney, M. Moser, R. Mouillac, K. H. Müller and E. Piwowarsky, P. Nicolau, P. Nicollet, G. Nidecker, A. L. Norbury, A. L. Norbury and T. Samuel, A. Ohnstein, J. Okubo and M. Hara, T. Y. Olsen, H. O'Neil, A. R. Page, A. L. Parsons, J. G. Pearce, S. N. Petrenko, A. Picarelli, H. R. Pitt, M. Plant, A. Pomp, A. Pomp and H. Schweinitz, A. Portevin, A. Portevin and H. Berjot, L. Prandtl, H. S. and J. S. G. Primrose, G. W. Quick and L. Jordan, E. Rasch, H. S. Rawdon and co-workers, H. Redenz, P. Rehbinder, A. Reichelt, C. O. Reid, M. Retzow, L. Revillon, F. Ricolfi, F. Riedel, A. Ries and L. Zimmermann, F. Robin, S. P. Rockwell, P. le Rolland, A. Rosiwal, P. Rossi, P. Roudie, G. A. Rousch, O. C. Rudolph, G. Sachs, R. Sancery, D. A. N. Sandifer, F. Sauerwald and co-workers, A. Sauveur, N. N. Sawin and E. Stachrowsky, M. Schandt, J. J. Schneider, E. Schüz, M. von Schwarz, F. Schwerdt, G. Sellergren, J. Shaw, G. A. Shires, A. F. Shore, I. G. Slater and T. H. Turner, R. L. Smith and G. Sandland, S. C. Spalding, M. Spindel, A. Stadeler, B. Stoughton and J. S. McGregor, R. Stribeck, M. Suzuki, K. Takahasi, K. Taniguchi, F. C. Thompson, F. S. Tritton, L. B. Tuckerman, T. Turner, F. T. Turpin, W. C. Unwin, F. Waizenegger, L. Waldo, F. Walker, A. Wallichs and H. Schallbroch, A. Wallichs and co-workers, H. L. Whittemore, L. W. Wild, A. Wildometz, S. R. Williams, and F. Wüst and P. Bardenheuer.

E. Meyer showed that in Brinell's test, if P denotes the load in kgrms., and d the diameter of the indentation in mm., $P=ad^n$, where a and n are constants for a given material; or a may be regarded as the load required to give an indentation of unit diameter, and n, the hardenability or capacity of the metal for becoming strain-hardened, either by increased indentation, or by other cold-working operations. n is very nearly 2, and the results are often represented $a=P/d^2$. The subject was discussed by H. Moore, H. O'Neil, T. Baker and T. F. Russell, C. A. Edwards and F. W. Willis, J. J. Schneider, A. Kürth, R. G. C. Batson, B. P. Haigh, etc. According to O. Keune, if B denotes Brinell's hardness of iron; B_1, Brinell's hardness of the standard; S_1, the scleroscopic hardness of the standard; and S_2, the scleroscopic hardness of the specimen, then $B=B_1+(S_2-S_1)B_1/S_1$. Since the different tests for hardness measure different groups of properties, they might be correlated through their components—density, tenacity, etc. As it is, a close agreement is not to be expected, although T. Turner found that the results with his sclerometer, A. F. Shore's scleroscope, and J. A. Brinell's penetration test, are either in agreement with, or proportional to one another. Thus, taking one-sixth of the value of J. A. Brinell's numbers:

	T. Turner's	A. F. Shore's	J. A. Brinell's
Lead	1·0	1·0	1·0
Softest iron	15·0	—	14·5
Mild steel	21·0	22·0	16 to 24
Soft cast iron	21·4	24·0	24·0
Rail steel	24·0	27·0	26 to 35
Hard cast iron	30·0	40·0	35·0
Hard white iron	72·0	70·0	75·0
Hardened steel	—	95·0	93·0

R. A. Hadfield gave the comparison, shown in Table XVI, of J. A. Brinell's ball test, and A. F. Shore's scleroscopic hardness. The subject was discussed by T. N. Holden, and S. N. Petrenko. There is some relation between hardness and tensile strength, as shown by R. A. Hadfield's comparison, Table XVI, of the hardness and the compressive strength, tensile strength, and elastic limit of a great variety of steels. R. H. Greaves and J. A. Jones measured the ratio: Tensile strength (tons per sq. in)/Brinell's number for over a thousand steels, and they observed:

	Ratio
Heat-treated steels with Brinell's number 250 to 400	0·21
Heat-treated steels with Brinell's number $<$ 250	0·215
Medium carbon steels—rolled, normalized, or annealed	0·22
Mild steels—rolled normalized, or annealed	0·23

but no satisfactory explanation of the constancy of the ratio has been given. W. H. Hatfield found that the relation between Shore's hardness and the elastic limit was not always proportional, since the curves sometimes crossed. R. R. Abbott gave a number of empirical factors for converting Shore's hardness, S, into Brinell's hardness, B, for carbon steels: $B=5\cdot6S+14$; for converting Brinell's number, B, into tensile strength in lbs. per sq. in., T, for carbon steels, $T=0\cdot75B-28$; and for converting Shore's number, S, into tensile strength in lbs. per sq. in., $T=4\cdot4S-28$. E. Schüz represented the relation between Brinell's hardness, H, and the tensile strength, T kgrms. per sq. mm., of cast iron by $E=k(H-40)$, where k is a constant. The deviations from the rule were due to the proportion of ferrite and pearlite, and to the size of the graphite flakes.

TABLE XVI.—COMPARISON OF HARDNESS WITH THE TENSILE STRENGTH AND ELASTIC LIMIT OF STEELS.

Hardness		Tensile strength (tons per sq. in.)		Compression (tons per sq. in.)	
Shore's	Brinell's	Yield-point	Maximum stress	Elastic limit and 0·25 per cent. compression	Compression per 100 tons per sq. in.
—	150	20	36	17	49·0
—	175	26	41	19	40·0
34	200	32	46	21	35·0
38	225	38	51	23	31·0
42	250	44	56	26	27·0
46	275	50	61	30	23·0
50	300	56	66	34	19·0
54	325	61	71	38	15·2
57	350	67	76	43	11·3
61	375	73	81	49	8·0
64	400	79	86	55	5·6
68	425	84	91	61	3·8
71	450	90	96	67	2·4
75	475	96	101	74	1·3
78	500	102	106	81	0·6
80	525	107	111	87	0·23
84	550	113	116	94	0·21
86	575	—	121	101	0·20
89	600	—	126	108	0·18
92	625	—	131	115	0·16
95	650	—	136	122	0·14
99	675	—	141	129	0·13
101	700	—	—	136	0·12
—	725	—	—	144	0·11
—	750	—	—	151	0·09
—	785	—	—	159	0·08
—	800	—	—	166	0·07

R. R. Abbott also gave for nickel steels, $T=0\cdot71B-32$; $T=3\cdot5S-6$; and $B=5\cdot0S+48$; for chromium-vanadium steels, $T=0\cdot71B-29$; $T=4\cdot2S-21$; and $B=5\cdot5S+27$; for low chromium-nickel steels, $T=0\cdot68B-22$; $T=3\cdot7S-1$; and $B=5\cdot4S+33$; for high chromium-nickel steels, $T=0\cdot71B-33$; $T=3\cdot7S-3$; and $B=4\cdot8S+58$; and for all steels grouped together, $T=0\cdot70B-26$; $T=4\cdot0S-15$; and $B=5\cdot5S+28$.

J. S. G. Primrose recalculated these results; and J. E. Stead represented the relation between Brinell's number, B, and tenacity by: Tenacity (tons per sq. in.) $=\frac{1}{5}B+6$, or tenacity (kgrms. per sq. mm.) $=\frac{1}{3\cdot2}B+10$. J. Navarro represented the relation between the hardness, B, and the coeff. of the resistance to bending, or the transverse breaking stress, S kgrms. per sq. mm., of cast iron, by $B=3{\cdot}23S+42$. T. Friesendorff studied the mathematical theory of Brinell's test. The relations between the hardness and the other mechanical properties of iron and steel were discussed by T. Baker and T. F. Russell, R. Baumann, G. S. Bell and C. H. Adamson, G. Berndt, H. Bohner, H. M. Brayton, I. H. Cowdrey, H. A. Dickie, P. W. Döhmer, P. Goerens, R. H. Greaves, R. H. Greaves and J. A. Jones, H. Hencky, K. Honda and K. Takahasi, F. Hugueny, E. J. Janitzky, H. von Jüptner, F. Kick, B. Kirsch, A. Kürth, A. Leon, E. Meyer, W. Müller, A. L. Norbury and T. Samuel, J. Okubo, H. O'Neil, V. Pöschl, A. Portevin, F. Reiser, T. F. Russell, F. Sauerwald and K. Knehans, F. Sauerwald and H. Viessen, E. Schüz, O. Schwarz, W. K. Shepard and C. T. Porter, A. F. Shore, T. Swinden and G. R. Bolsover, J. J. Thomas, A. Vierendeel, F. Wüst and P. Bardenheuer. B. D. Saklatwalla and H. T. Chandler applied the probability law of the frequency of errors to the choice of the results of Brinell's test.

F. Auerbach, in applying H. Hertz's method of measuring absolute hardness —**2**. 20, 7—showed that hardness and elasticity are associated quantities in that variations of the one are attended by corresponding variations of the other independent of the body operated upon. His method of calculation is based on the assumption that when the total pressure between a sphere and a plane of a given body is increased up to the elastic limit, the time of yielding is sharply marked either by a permanent set, or by rupture at the area of contact, and the hardness is then determined by the total pressure and the diameter of the impressed area for the time in question. The electrical resistance and hardness also appear to be related in some way, because when one increases, the other also increases. As the temp. falls, the electrical resistance also falls, but usually the hardness is considered to increase as the temp. falls. C. Barus and V. Strouhal, and C. A. Casperson, indeed, estimated the hardness from the electrical resistance of steels (*q.v.*), and K. Heindlhofer, from the magnetic hardness (*q.v.*).

H. O'Neil found that the scratching hardness of single crystals of iron is greatest in a direction parallel to the lobes of the pressure figures; and the hardness is greatest in a direction at right angles to that of the elongation due to cold-work. In aggregates of crystals, the hardness becomes greater in the region of the boundaries of the crystal grains; and in cold-worked metals, etch bands are also super-hardened. H. Gries and H. Esser also measured the hardness of single crystals of iron. W. R. D. Jones and K. G. Lewis, W. Schwinning and E. Strobel, E. Greulich, and F. Sauerwald and co-workers discussed the hardness induced by the cold-work, or cold-deformation—*i.e.* **work-hardening.** Hot-deformation does not have a hardening effect in the same sense, but it causes the metal to recrystallize. M. Mikhailoff and I. Churbanoff studied the hardness of iron broken by tension. B. Stoughton's results for the scleroscopic hardness of cold-rolled, electrolytic iron are shown in Fig. 189; the hardness increases up to a constant value with an increase in the work performed on the iron. The subject was discussed by R. Jonson, M. Guichard and co-workers, and B. Garre.

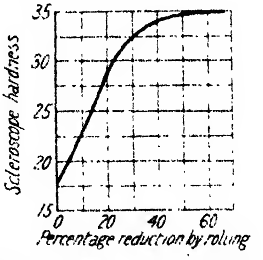

FIG. 189. — The Scleroscopic Hardness of Cold-Rolled Iron.

G. P. Fuller gave 14 to 16 for the scleroscopic hardness of 99·965 per cent. electrolytic iron annealed to remove hydrogen. T. D. Yensen found Brinell's hardness of electrolytic iron, melted in vacuo, to be 60 to 70. D. J. MacNaughtan showed that the hardness of electro-deposited iron is dependent to some extent on the conditions of deposition. Thus, with the pH-value for the H'-ion concentration 4·5 to 4·2, the Brinell's hardness varied from 167 to 195; with pH=3·6 to 3·8, 225 to 244; and for pH=3·3 to 3·5, 256 to 281. Again, with current densities of 5, 10, 15, and 20 amps. per sq. ft., the Brinell's hardnesses of the deposits were respectively 182, 229, 283, and 354. A rise in temp. tends to soften the deposits.

The hardness of electro-deposited iron was attributed to the dissolved hydrogen as such, or as hydride, by L. Cailletet, H. Lee, J. Cournot, A. J. Allmand, H. O'Neil, and N. B. Pilling. D. J. MacNaughtan suggested the proportion of hydrogen in solid soln. is insufficient to explain the high hardness attained ; he also thought that the assumption that the deposit is largely amorphous iron is not a likely explanation ; nor does he favour the assumption that the crystal lattice is distorted by the electrical forces acting during the deposition producing a hardening effect analogous to that of cold-work. The fine-grained character of the crystalline structure, due in part to the action of hydrogen in interfering with crystalline growth, may be a partial explanation of the phenomenon. E. J. Mills found that the electro-deposited iron, cobalt, and nickel are in a condition of tensile stress, whilst with cadmium and zinc, the stress is compressive. G. G. Stoney, W. Kohlschütter and E. Vuillemnier, and R. H. D. Barklie and H. J. Davis made observations on the subject—*vide supra*, theories of hardness, and *vide infra*, electrostriction. The hardness produced by cold-work, etc., was discussed by D. J. MacNaughtan and A. W. Hothersall, C. A. Edwards and K. Kuwada, F. Sauerwald and F. Rakosky, M. Guichard and co-workers, R. H. Greaves, R. Hay and R. Higgins, E. G. Herbert, P. Nicolau, E. A. Ollard, W. P. Sykes and A. C. Ellsworth, and G. Tammann. A. Sauveur and D. C. Lee gave the results summarized in Fig. 190. For J. H. Andrew and A. J. K. Honeyman's observations, *vide supra*, sp. gr. ; and for those of C. Nusbaum and W. L. Cheney on the effect of different rates of cooling eutectoid-carbon steels, *vide* Table XVI, magnetism.

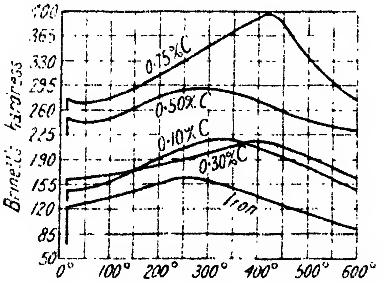

FIG. 190.—Brinell's Hardness of Steel after being Strained at Different Temperatures.

The hardness of steel and cast iron is largely determined by the condition of the carbon. As shown by G. Neumann, the hardness of grey cast iron is more sensitive to the ground mass than to the form of the graphite than is the case with the tensile and bending tests. The subject was studied by T. Klingenstein. The maximum hardness of cast iron occurs when all the carbon is in the combined state ; and also by the particular constituent which predominates in the metal. This is largely determined by the heat treatment to which the metal has been subjected. The exterior of a casting, for instance, is usually harder than the interior. This is due to the chilling of the metal which comes in contact with the mould. For the increase in hardness accompanying the change of austenite into martensite, and the decrease in hardness as the martensite passes into troostite or pearlite, *vide supra*, martensite ; and the hardening and tempering of steel.

The different constituents of steel have their own specific hardness, and H. C. Boynton gave the following relative numbers for Brinell's hardness :

Ferrite	Electrolytic iron	1
	Electrolytic iron quenched	2·15
	Wrought iron	1·5 to 3·6
Pearlite	Steel with 0·13 to 1·52 per cent. C.	1·8 to 10·3
	Steel with 0·35 to 0·86 per cent. C.	3·8 to 4·2
Sorbite	Steel with 0·48 to 0·58 per cent. C.	5·2 to 53·6
Troostite	Steel with 0·58 per cent. C.	88·2
Martensite	Steel with 0·20 to 1·52 per cent. C.	38·9 to 261·6
Austenite	White cast iron with 3·24 per cent. C.	103·4
Cementite	Grey cast iron with 3·24 per cent. C.	272·8

The average values for the sclerometer hardness (calcite, 158 ; quartz, 46,103 ; corundum, 84,809) were :

Ferrite	Pearlite	Sorbite	Troostite	Austenite	Martensite	Cementite
460	2000	2400 to 24,000	40,500	48,000	110,000	125,000

J. A. Brinell found the hardness of Swedish pale grey cast iron to be 179; white cast iron, 460; and mottled cast iron in the grey part, 202, and in the white part, 375. He also found the hardness of Swedish steel with:

Carbon .	0·1	0·2	0·3	0·4	0·5	0·6	0·7 per cent.
Hardness .	97	107	145	156	185	215	232

P. Oberhoffer's results for the influence of carbon on the hardness of steel are summarized in Fig. 191. A. Wahlberg's results are similar, and include those represented by the dotted line. E. Schüz found that the relation between Brinell's hardness and the percentage of combined carbon follows almost a linear law. The results were very little affected by the size of the graphite plates. M. Levin and K. Dornhecker, P. Saldau, and I. G. Slater and T. H. Turner also obtained analogous results. F. Fettweis observed singular points in the hardness of iron at about 600°.

K. Tamaru gave 40 for Brinell's hardness of normalized armco iron; 155 for austenite; 225 for normalized 0·9 per cent. carbon steel; 270 for strained sorbite in 0·9 per cent. carbon steel; 400 for strained troostite in 0·9 per cent. carbon steel; 720 for martensite; 820 for strained cementite, and 640 for natural cementite. According to C. Grard, the hardness of troostite is about 400, and that of sorbite, 270—both are subjected to an internal strain. A. Portevin estimated the Brinell's hardness of cementite to be 400; and K. Tamaru gave the results indicated in Fig. 192, where the unannealed sample is under strain, and amounts to 820 on Brinell's scale; while annealed, or the so-called natural hardness, amounts to 64 on Rockwell's scale, or 640 on Brinell's scale. N. T. Belaiew found that if Δ_0 denotes the distance in microns; μ, pearlite lamellæ—**12**. 66, 15—the Brinell's hardness, H, can be represented by $\Delta_0 H=80$. Hence, for lamellæ with $\Delta_0=0{\cdot}28\mu$, $H=280$ approximately.

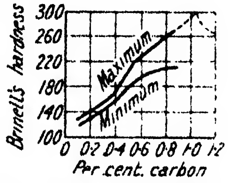

FIG. 191.—The Effect of Carbon on the Hardness of Steel.

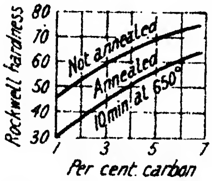

FIG. 192.—The Hardness of Cementite.

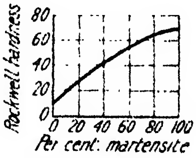

FIG. 193.—The Effect of Martensite on the Hardness of Austenite.

K. Tamaru found that the hardness of austenite in quenched carbon steels depends on the proportion of contained martensite, as indicated in Fig. 193. A similar maximum at about 600° to 630° was observed in the austenite of manganese and nickel steels. The change in hardness which attends the transformation of austenite to martensite was discussed by L. Demozay, W. P. Sykes and Z. Jeffries, etc.—*vide supra.* F. Koerber observed a maximum at 600° in the impact hardness. The observations of R. A. Hadfield and J. Hopkinson, J. O. Arnold and A. A. Read, and E. E. McKee show that there is a separation of carbides in annealing these steels, but K. Tamaru attributed the maximum to the blue shortness of steel—*vide infra,* tensile strength—which, according to K. Honda, is due to the cold-work undergone by the steel during the application of the load. The plastic deformation due to cold-work always lags behind the applied load, and this lag diminishes with rise of temp. Consequently, as the velocity of loading increases, the maximum hardening is displaced towards a higher temp. F. Wüst and E. Leuenberger, W. Köster, O. Reinhold, E. L. Dupuy, H. J. French, Z. Jeffries, T. Matsushita and K. Nagasawa, K. Honda, and T. Inokuty observed a maximum at 200° to 300° in the statical test, and F. Fettweis found that the maximum is displaced to a higher temp. as the velocity of loading is increased. The decreasing hardness with increasing carbon of austenitic manganese steel is attributed to the presence of martensite which increases with decreasing proportions of carbon and manganese. The general results show that Brinell's hardness of austenite is 155 in carbon steels at room temp. A. Sauveur gave 175 to 180; and R. A. Hadfield and J. Hopkinson, 200. K. Tamaru found that Brinell's hardness of martensite in a 1·69 per cent. carbon steel, quenched from 1120°–1130°, is 720. The hardness of the inner portion of a piece of steel quenched in water, and also after immersion in liquid air. The hardness increases with carbon-content up to 0·8 per cent., and then gradually decreases; below 0·7 per cent. of carbon, the outer portion is harder since, owing to the low proportion of carbon, the martensite is well developed; and above 0·8 per cent. of carbon, the outer portion is softer because, in virtue of the high carbon content, more austenite is formed than in the centre. The decrease in hardness with steel with over 0·8 per cent. of carbon is due to the increasing proportion of retained austenite. A. Wahlberg observed that the hardness gave 652 for the maximum hardness of a quenched 0·65 per cent. carbon steel. Observations were made by E. Maurer. A. Katto measured the effect of repeated quenching on the hardness of steel. W. R. Chapin, C. R. Hayward, T. Kase, S. Idei, and K. Honda and S. Idei studied the distribution of the hardness in quenched carbon steel, and M. A. Ammon, and G. Charpy and L. Grenet, the relation of hardness to the depth of carburization of case and hardened steels. C. Y. Clayton, F. J. Walls and A. Hartwell, C. A. Edwards and K. Kuwada, and O. Bauer and W. Schneider found that Brinell's hardness of electrolytic iron is not affected by quenching from 650° to 1258° in iced water, although H. C. Boynton said that there is a 100 per cent. increase in the scratching hardness.

The effect of heat treatment determines to some extent the nature of the dominant constituents of the metal, and these, as just shown, are in a large measure responsible for variations in the hardness of the carbon-iron alloys. J. A. Brinell employed a steel with about 0·01 per cent. of sulphur and 0·026 per cent. of phosphorus, as well as the proportions of carbon, silicon, and manganese shown in Table XVII, and obtained the values for Brinell's hardness shown in the same Table XVII, for steel when subjected to different heat treatments. The effect of the hardening temp. on some steels is indicated in Table XVII.

TABLE XVII.—THE EFFECT OF HEAT TREATMENT ON THE HARDNESS OF STEEL.

Percentage composition			Brinell's hardness			
Carbon	Silicon	Manganese	Direct from rolling-mill	Cooled in charcoal from dull redness	Cooled in charcoal from a white-heat	Quenched from red-heat in water at 20°
0·10	0·007	0·10	109	97	94	149
0·20	0·018	0·40	126	115	109	196
0·25	0·30	0·41	161	143	132	311

J. A. Jones found that when an annealed bar of armco iron containing 0·05 per cent. of carbon, is reheated to 600° for an hour, the Brinell's hardness with a 10 mm. ball of 1000 kgrms., after various rates of cooling, 8 : slow cooling, 75 ; air-cooled, 87 ; quenched in water and tested after 10 min., 96 ; 1½ hrs., 100 ; 7 days, 107 ; 28 days, 120 ; and 63 days, 136 ; quenched in water and aged for 50 days, 130 ; and then reheated to 100° for an hour, 116 ; or to 200° for one hour, 100. M. Sauvageot and H. Delmas studied the hardness of steels quenched from a high temp. ; and L. Grenet, the hardness of tempered steels. T. Turner gave for the percentage loss of quenching hardness for steel with nearly 0·9 per cent. of carbon when the steel was quenched at different temp., and the hardness measured in different ways :

Percentage loss	100°	200°	300°	400°	500°	600°
Brinell's hardness .	—	13	38	68	94	100
Martens' ,, .	2·5	14·0	41·0	70·6	87·5	95·7
Jaggar's ,, .	1·8	5·4	9·1	23·6	64·0	94·5
Shore's ,, .	3·7	2·7	11·1	33·0	92·5	100

E. Heyn and O. Bauer measured the effect of tempering on the scratching hardness of a 0·95 per cent. carbon steel, quenched from 900°. R. Hay and R. Higgins found that if H_0 denotes the hardness of martensitic steel, and H the hardness on tempering at $\theta°$, then $H=H_0e^{-a\theta}$, where a is a constant. A. Martens obtained a hardness of 277 on a special scale for forged steel with 0·95 per cent. of carbon, this rose to 2775 when the steel was heated to 900° and quenched in water, and on tempering the hardness fell in the following way :

	100°	200°	275°	400°	500°	700°
Hardness . .	2775	2285	1060	595	446	277

The hardness of 0·89 per cent. carbon steel quenched from 850° in water, and then tempered for an hour at various temp. is indicated in Fig. 194—*vide supra*, tempering. The hardness of a sample tempered at 112° is greater than that of the quenched steels, but as the tempering temp. rises still farther, the hardness decreases. The abnormal change at 150° to 200° corresponds with α-martensite, that at 350° to 400°, with β-martensite ; and that at 430° to 450°, with the re-crystallization of the steel. C. Grard found an increase at 100°. Above 450°, the internal stress is removed, and the grain-size increases, and the hardness decreases by tempering—*vide supra*, tempering.

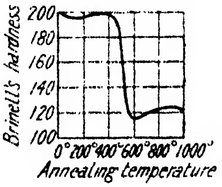

FIG. 194.—The Effect of Tempering on the Brinell's Hardness of Iron.

C. Barus, and L. C. Brant found that hard steel became appreciably softer when kept under ordinary conditions for thirty years ; and C. Barus added that if glass-hard steel tools had been preserved from the beginning of the Christian era they would now be soft as to need re-tempering to be efficient. This statement has probably given rise to the impression that hard and tempered steel will not retain its qualities, and that hard steel is in a metastable state which is afterwards more or less alleviated by tempering. The observations of H. C. H. Carpenter and J. M. Robertson on the hardened and tempered steels of ancient Egypt show that both hardened and tempered steels can retain their mechanical properties and hardness for many thousands of years.

L. Guillet and J. Cournot showed that there is an increase in hardness as the temp. falls, and that there is a fairly large increase in passing from −80° to −190°. The fall in the resilience as the temp. drops is greater the higher the proportion of contained ferrite. Austenite, containing enough nickel, does not show fragility at low temp. ; but pearlitic steels, containing nickel, are fragile in liquid air, but the nickel retards the lowering of the fragility with a decrease in temp. P. Dejean discussed the effect of compression on the resilience or elastic properties of steel. The effect of ageing on the tensile properties of mild steel was discussed by G. Masing and L. Koch, G. Tammann and V. Caglioti, G. Masing, R. S. Dean and co-workers, E. Heyn, and W. Köster—*vide infra*, the tensile strength of iron. L. B. Pfeil found that work-hardened metals are liable to increase in hardness as a result of ageing.

F. C. Thompson examined the effect of grain-size on the hardness of Swedish iron and found that the Brinell's hardness could be increased about 50 per cent. by grain refinement. H. Hanemann and R. Hinzmann found only slight differences in the hardness of steel with grain-sizes ranging from 90 to 20,000μ^2. A. Pomp's data for soft iron with 0·08 per cent. of carbon gave an increase of 15 per cent. with grain refinement. He observed that

Grains per sq. mm. .	68	827	1350	2310	3970
Brinell's hardness .	83	87	89	96	95

W. A. Wood also found that Brinell's hardness, H, increases as the grain-size, $G \times 10^{-6}$ cm. diameter decreases:

$G \times 10^6$.	28·9	8·3	3·9	3·0	2·6	1·9	1·5	1·1
H . .	290	300	313	326	333	361	404	495

A linear curve is obtained from the relation $H = kG^{-2}$, where k is constant; since G^2 is proportional to the surface area of the grain, S, then $H = k'A^{-1}$, where k' is constant. H. S. Rawdon and E. Jimeno-Gil decided that with iron containing 0·07 per cent. of carbon the grain-size has little influence on the hardness; but in general, fine-grained samples had the greater Brinell's hardness; whilst T. Ishigaki observed that with armco iron, the Brinell's hardness decreased as the size of grain increased. S. Shimura and H. Esser showed that with 0·6 to 1·75 per cent. carbon steels, the hardness decreased almost linearly with an increase in the time of annealing, or with an increase in the grain-size of the carbide. The final hardness of all the steels after a prolonged annealing was approximately the same, viz. 121 to 142 on Brinell's scale. The results with a 0·97 carbon steel are summarized in Fig. 195. L. B. Pfeil concluded that neither the grain-size nor, in the case of single crystals, the crystallographic face of the indented plane had any perceptible influence on its Brinell's hardness; although F. Osmond and G. Cartaud had previously reported that the octahedral face has a Brinell's hardness greater than is the case with the cubic-face, and the hardness of the (011)-face is intermediate between the two. H. O'Neil found that the Brinell's hardness of normalized armco iron is lowered considerably by annealing in vacuo; Brinell's hardness is also independent of the grain-size, and different faces of single crystals have the same hardness as aggregates, but the scratch-hardness in different directions on the crystal faces is different. The strain hardening of vacuum-hardened, decarburized iron, shown by the scratch-tests, indicated that the strain-hardening increased somewhat as the temp. is raised from $-185°$ to $+100°$; and similarly also for cold-rolled iron. The results from 100° to 130° are variable. There is a small increase in the scratch-hardness of ferrite at 120°; but the effect with single crystals is small although there are indications of an inflection between 110° and 125°. The subject was discussed by S. V. Belynsky.

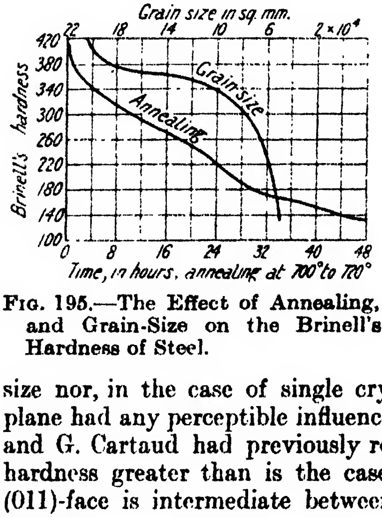

Fig. 195.—The Effect of Annealing, and Grain-Size on the Brinell's Hardness of Steel.

The hardness of cold-drawn steel and iron is greater than that of the annealed material, and the term "hard drawn" has long been applied to unannealed wire. P. Goerens found the Brinell's and the Shore's hardness of wrought iron with 0·11 per cent. of carbon to be:

Reduction area .	0	10·8	25·4	39·8	43·6	48·3 per cent.
Brinell's . .	118	157	176	181	189	201
Shore's . .	24	33	31	39	45	46

and of steel with 0·98 per cent. of carbon to be :

Reduction area .	0	9·1	14·2	22·6	28·3	32·8 per cent.
Brinell's . .	285	325	349	352	350	361
Shore's . .	59	60	56	62	53	52

T. Ishigaki measured the Rockwell hardness of steel before and after it had been subjected to cold-work by tensile straining, and found :

Carbon . .	0·1	0·3	0·3	0·7	0·9	1·1 per cent.
Before cold-work .	65·0	78·0	90·0	95·0	96·0	97·0
After cold-work .	73·2	93·1	95·6	101·5	109·2	106·7

Hence, the hardening effect increases as the proportion of carbon increases, and it attains a maximum with eutectoidal steel. The subject was discussed by W. P. Sykes and A. C. Ellsworth, and W. Broniewsky and J. Krol. M. Hanriot observed that metals are hardened by hydrostatic press., and T. Ishigaki obtained for armco iron, subjected to a compression of p kgrms. per sq. cm., the Rockwell hardness :

p . . .	0	2800	5200	7320	12,400	16,500
Hardness .	40·0	48·0	53·2	56·6	59·0	59·4

The change in the hardness produced by tempering is illustrated by Fig. 196. Assuming that the hardness produced by cold-working depends on internal stress, the latter cannot be increased beyond the yield-point, and consequently the hardness will attain asymptotically a certain maximum value. Thus, the hardness of iron increases rapidly at first, but then gradually tends towards an asymptotic value. The effect of tempering work-hardened armco iron, between 250° and 350°, is to increase slightly the hardness as shown in Fig. 196, and then to decrease somewhat rapidly towards about 470°. A slight hardening occurs in the range 470° to 570°, and the hardness then falls suddenly near 600°. The second hardness is attributed to the development of crystal nuclei occurring immediately before the re-crystallization of cold-worked metals sets in. The sudden softening about 600° is supposed to be due to the release of internal strains attending re-crystallization. The slight hardening of iron and steel between 250° and 350° is explained thus :

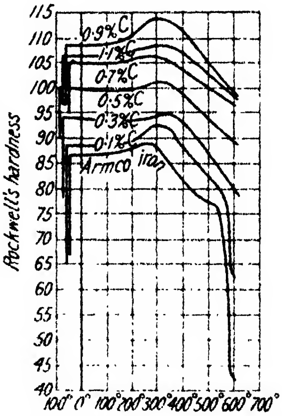

FIG. 196. — Hardness of Tempered Iron and Steel.

> In a severely cold-worked metal some internal strain remains after an applied stress has been released, and thus the metal is considerably hardened, that is, its resistance to slip is greatly increased by the cold-working; but at the same time, it is in a somewhat unstable condition. Consequently, by tempering between 250° and 350°, which results in a violent thermal motion of the atoms, some portions of the internal strain are released at the point of its greatest instability, most of the strain remaining unaffected. Thus the metal becomes a little stable, or becomes more resistant to slip ; that is, the hardness is increased by tempering. The slight hardening in a range between 250° and 350° is probably explained in the same way as above, the only difference being that in the present case, the release of the greatest instability takes place during the stretching at these high temp.

According to R. A. Hadfield, a specimen of steel with 0·045 per cent. carbon had a Brinell's hardness of 90 when tested at ordinary temp., but when tested at −182°, its hardness was 266, that is, about equal to that of a 0·8 carbon steel at normal temp. F. Robin found that the hardness curves of carbon steels show a minimum at about 100°, and a maximum at about 250° ; and that these points coincide with the minimum and maximum resistance to tensile stress. The maximum hardness is followed by a marked and regular fall only in the case of hard steels; with soft steels, there is a downward peak, and the hardness falls rapidly only at about 400° to 450°. Similar effects are encountered in connection with the tensile strength. The presence of phosphorus lowers the variations in the curve, for with 1 per cent. of that element, the curve is almost constant at 215° up to 400°, after which it falls to about 130° at 600°. Abrupt variations in hardness, resistance to tensile stress and crushing, occur only in the case of α-iron. Austenitic steels, with α-iron, give regular and continuous curves like copper and nickel. Observations were made by J. Vietorisz, G. Delbart, F. C. Lea, O. W. McMullen, A. R. Page, H. E. Publow, and H. J. Tapsell and W. J. Clenshaw. The *red hardness* or *hot hardness* of alloy steels was studied by E. G. Herbert, and F. Sauerwald and co-workers.

According to H. M. Howe, M. Rudeloff, and C. Bach, the resistance of cast iron to tensile stresses does not alter up to 300°, but from 300° to 400°, the resistance decreases; and A. Kürth showed that the hardness diminishes slowly with a rise of temp., then rises a little between 200° and 300°, and ultimately falls rapidly above 300°. The tenacity of hard cast iron falls suddenly above 400°, while that of annealed castings falls slowly. F. Robin made observations on cast irons. W. Melle, J. B. Kommers, R. Hugues, P. Goerens and H. Jungbluth, etc., discussed the hardness of cast iron; and H. A. Schwartz, that of malleable iron.

K. Ito found Brinell's hardness, H, of cast iron at different temp. to be:

	−40°	−24°	0°	16°	35°	56°	75°	115°	130°	150°
H . .	159·5	158·0	154·6	150·6	148·2	146·1	146·1	142·2	142·2	139·2

and he represented the relation between hardness and temp., θ, by $\log H_2 - \log H = \alpha(\theta_2 - \theta_1)$, where $\alpha = 0{\cdot}00030$ is the inclination of the straight line, the temp. coeff. of Brinell's hardness. For rolled steel with 0·1 per cent. of carbon:

	−43°	−21°	0°	20°	40°	55°	75°	115°	130°	148°
H . .	114·5	113·2	113·2	111·8	109·2	109·2	108·4	107·2	104·6	104·6

where $\log H_2 - \log H_1 = 0{\cdot}00020(\theta_2 - \theta_1)$. For rolled steel with 0·7 per cent. of carbon:

	−40°	−21°	0°	10°	40°	55°	75°	115°	129°	145°
H . .	239·0	237·2	229·9	225·8	223·7	223·7	221·8	217·8	216·2	212·6

where $\log H_2 - \log H_1 = 0{\cdot}00025(\theta_2 - \theta_1)$. For rolled steel with 1·5 per cent. of carbon:

	−42°	−26°	1°	16°	35°	55°	75°	95°	115°	147°
H . .	302·0	293·5	285·8	283·0	274·4	274·4	267·4	261·8	259·8	255·5

where $\log H_2 - \log H_1 = 0{\cdot}00040(\theta_2 - \theta_1)$. The hardness thus increases considerably with a fall of temp. The hardness and temp. coeff. of rolled steel are greater than with cast specimens. The relation between the coeff. of hardness, α, and the m.p. T_m, on the absolute scale, of a number of metals can be represented by $T(\alpha + 0{\cdot}000145) = 2{\cdot}5$. This is similar to A. Mallock's relation between the temp. coeff. of Young's modulus, and C. Schaefer's relation for the temp. coeff. of the torsion modulus. G. Mahoux studied the effect of electromagnetic waves on the hardness of steel.

F. Robin compared the **abrasive hardness**, or abrasive wear of steels by rubbing the metal against abrasive paper, at a given speed, under a definite pressure, for a given time, and finding the loss in weight. He observed that carbon steels do not wear inversely proportionally to their percentage of carbon. They show a minimum of resistance to wear on emery-paper at about 0·4 per cent. of carbon. Purified and fine-grained metals offer most resistance. Phosphorus greatly increases the resistance to wear. Small quantities of manganese and silicon diminish the resistance to wear in the case of carbon steels, which is the opposite to what is found in regard to lubricated wear on a polished surface. Cast iron is more resistant to wear if it contains phosphorus or is composed largely of cementite. Its wear on abrasive paper reveals the peculiarity of being very high to commence with and subsequently falling to a very low value. Basic pig-iron and chilled castings offer the highest amount of resistance, although this does not apply to their penetrative hardness. Quenched and annealed steels (martensite, osmondite, and sorbite) possess a very high degree of resistance to wear in the vicinity of the eutectoid. This resistance does not increase with higher percentages of carbon. Austentite is specially resistant to wear. With a relatively low penetration hardness, the wear is comparatively inconsiderable. The austenitic alloy steels especially reveal this property. Steels containing nickel and manganese in high percentages are exceedingly resistant. Manganese steel offers a high degree of resistance which varies with the speed and with the pressure of the test. Pearlitic chromium steels similarly wear but little, particularly in the case of annealed steels. Annealed steels containing a double carbide wear with the greatest ease, and pearlitic steels containing tungsten and molybdenum show the same property. Vanadium considerably improves the resistance of steels to wear with emery-paper.

The subject was discussed by C. B. Dudley, J. E. Howard, S. J. Rosenberg, and A. Stadeler. The abrasive hardness was discussed by A. L. Boegehold, A. M. Cox, L. Guillet, G. A. Hankins, K. Honda and R. Yamada, L. Jannin, H. M. Kerscht, T. Klingenstein, G. L. Norris, W. H. Phillips, F. Robin, S. J. Rosenberg, S. Saito, E. H. Saniter, and M. Suzuki; and the endurance of rail steels, etc., in service, and the wearing qualities of iron and steel, by J. M. Blake, J. A. Brinell, A. Capron, N. N. Davidenkoff, T. G. Digges, A. Dormus, J. R. Freeman and co-workers, C. Frémont, H. J. French, H. J. French and H. K. Herschman, H. Friedrich, M. Füchsel, A. Hasch, F. Heimes and E. Piwowarsky, F. P. Hitchcock, L. Jannin, L. Jordan, J. F. Kayser, R. Kühnel, O. H. Lehmann, L. Lubimoff, P. Lucchini and M. Ros, M. Marqueyrol and M. Merklen, P. Mast, H. Meyer and F. Nehl, F. K. Neath, W. H. Parker, E. Piwowarsky, G. Ranque, C. O. Reid, S. J. Rosenberg and co-workers, J. Seigle, R. Spazier, M. Spindel, A. Stadeler, H. W. Swift, L. Thibaudier and H. Viteaux, A. A. Timmins, and A. K. Zaitzeff. M. Fink discussed the wear of steel rails as a result of oxidation associated with sliding friction. J. O. Arnold, E. G. Coker and K. C. Chakko, R. E. Crompton, C. Frémont, H. J. French and T. G. Digges, H. Friedrich, E. G. Herbert, K. Honda and K. Takahasi, J. E. Hurst, A. J. Langhammer, W. J. Merten, M. Okochi and M. Okoshi, W. H. Phillips, R. Poliakoff, H. Pommerenke and R. Dewert, W. Ripper and G. W. Bailey, W. Rosenhain and A. C. Sturney, H. D. Smith and I. Hey, T. E. Stanton, T. E. Stanton and R. G. C. Batson, T. G. Digges, and P. V. Vernon discussed the cutting properties of tool steels, and the cube law of cutting speed as used to develop the heat theory of durability; and A. Kessner, the drilling test.

I. Traube [5] represented the **internal pressure** of solid iron by 239,000 megabars. F. C. Thompson gave 323,900 for annealed, normalized, and quenched and tempered iron. R. von Dallwitz-Wegner calculated 336,837 atm. for the internal press. of wrought iron. S. Sekito calculated 192 kgrms. per sq. mm. for the value of the internal stress, and this is the same order of magnitude as the tensile strength. T. W. Richards gave 587 kilomegabars. Observations on the subject were made by J. H. Hildebrand and co-workers—*vide supra*, for internal strains and stresses. R. F. Mehl gave 587 kilomegabars for the internal press. and for the maximum disruptive internal press. 1884 kgrms. per sq. mm. R. von Dallwitz-Wegner gave 336,837 atm. for the internal cohesion at 0°, and 309,881 atm. at 100°.

G. Quincke gave 949·7 to 997 dynes per cm. for the **surface tension** of molten iron, and 25·8 to 27·1 sq. mm. for a^2, the **specific cohesion.** F. C. Thompson gave 1350 dynes per cm. for the surface tension between tempered iron and cementite. W. Krause and F. Sauerwald measured the surface tension and sp. cohesion of grey cast iron :

C : Mn : Si : P	.	1225°	1250°	1300°	1350°	
3·32 : 0·56 : 2·76 : 0·49	a .	826	846	880	926	$da/d\theta=0{\cdot}80$
	a^2.	12·01	12·37	13·09	13·84	
		1150°	1200°	1250°	1310°	
3·52 : 2·1 : 0·36 : 1·6	a .	1054	1071	1088	1108	$da/d\theta=0{\cdot}34$
	a^2.	14·6	15·17	15·68	16·39	
		1245°	1300°	1350°	—	
1·4 : 0·29 : 1·27 : 7·44	a .	957	1013	1065	—	$da/d\theta=1{\cdot}04$
	a^2.	13·79	14·92	16·02	—	

G. Drath and F. Sauerwald obtained for cast iron at 1267°, 1277°, 1310°, and 1318°, respectively, the surface tensions $\sigma=936$, 938, 917, and 914 dynes per cm., and the sp. gr. 6·81, 6·80, 6·75, and 6·74. The surface-tension forces between the crystal grains of a metal were discussed by G. T. Beilby, F. L. Brady, M. Brillouin, P. Curie, C. H. Desch, G. Quincke, G. Tammann, and F. C. Thompson; and F. C. Thompson attempted to correlate these forces with other properties of the metals, particularly the elastic limit. M. Born and O. F. Bollnow estimated the cohesive force of the atoms on the lattice to be $6{\cdot}25\times10^{11}$ dynes per sq. cm. W. B. Hardy discussed the range of cohesion at the surface of iron and steel. F. Sauerwald and E. Jänichen found that the force of adhesion of compressed iron powder increased with temp., but at high temp. a decrease occurs owing to crystallization. The tensile strength depends on the degree of compression and the grain-size of the powder. The **diffusion** of the different elements in iron is discussed in connection with alloys of the respective elements and iron, and in connection with cementation; M. Ballay studied the Ludwig-Soret phenomenon in liquid and solid alloys.

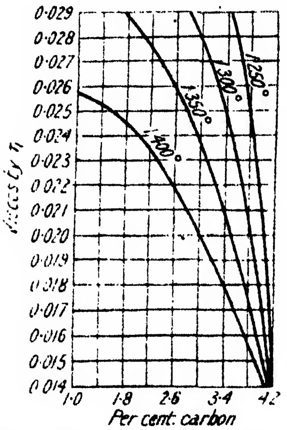

Fig. 197.—The Viscosity of Cast Irons with Different Proportions of Carbon.

K. Honda and S. Konno found the coeff. of normal **viscosity**, at 20°, of steel with

Carbon		0·18	0·38	0·67	1·17	1·75 per cent.
$\eta\times10^{-8}$	Not annealed	4·94	5·12	5·93	5·06	7·20
	Annealed at 850°	2·68	3·51	4·30	4·27	—

and K. Iokibe and S. Sakai gave for iron, and iron-carbon alloys:

Carbon	—	0·55	0·90	1·30 per cent.
$\eta\times10^{-8}$	12·89	12·90	7·70	9·82

Observations were also made by O. Boudouard, P. Chevenard, N. N. Feigin, O. Holz, J. E. Hurst, C. Johns, J. J. Porter, M. Riddell, D. Saito and K. Hayashi, and A. Wimmer; while H. Thielmann and A. Wimmer measured the influence of temp. on the viscosity of cast iron, Fig. 197. B. Gutenberg and H. Schlechtweg gave $1{\cdot}4\times10^{8}$ c.g.s. units for the inner friction of iron. Taking the fluidity of aluminium at about 800° as unity, D. Saito and K. Hayashi said that the fluidity of crucible steel at about 1600° is 46. G. Subrahmaniam gave 14×10^{8} for iron, and K. Iokibe and S. Sakai, 13×10^{8}—*vide infra*, plastic flow. A. L. Kimball and D. E. Lovell gave $4{\cdot}16\times10^{15}$ c.g.s. units for the internal friction of annealed Swedish iron, and $2{\cdot}33\times10^{15}$ c.g.s. units for cold-rolled mild steel.

The **internal or molecular friction** of a solid is measured in terms of the diminution in amplitude, or rather the logarithmic decrement of the amplitude, calculated for conditions where the friction of air is eliminated, when a metal wire, suitably loaded and supported is set in torsional oscillation, when the amplitudes of the vibration decrease more or less gradually until finally rest ensues. With small deformations, H. Tomlinson observed that the logarithmic decrement is independent of the amplitude, and independent of the vibration of the period when the wire has been allowed to rest for a considerable time after any change has been made in the arrangements, and when a large number of oscillations have been executed previous to the testing. H. Tomlinson said that the internal friction cannot resemble fluid friction because, for such velocities as are here employed, the internal friction of fluids is proportional to the velocity, nor can it resemble the extent friction of solids because the latter is not nearly so independent of the velocity as is the internal friction, nor would the logarithmic decrement be independent of the amplitude. The term viscosity applied by W. Thomson (Lord Kelvin) to what is here called internal friction is rather metaphorical. It is true that a substance which is infinitely viscous is a solid, for the component parts are held so tenaciously as to prevent permanent deformation; but, as emphasized by C. Barus, the impression conveyed in speaking of a very "viscous body" and of a "solid body" are very different. The conception of the viscosity of liquids, as well as the hypothetical proportionality between frictional resistance and velocity, was introduced by Isaac Newton in his *Philosophiæ naturalus principia mathematica* (London, 2. 9, 1687). He said: *resistentia quæ oritur ex defectu lubricitatis.* The theory of the "viscosity" of solids was discussed by F. Auerbach, W. Hallock, A. L. Kimball and D. E. Lovell, E. M. Horsburgh, R. H. Canfield, F. Braun, E. Cohn, J. A. Ewing, J. Hopkinson, F. Kohlrausch, F. Neesen, M. Brillouin, W. Thomson (Lord Kelvin), E. Warburg, W. Weber, R. Clausius, O. E. Meyer, J. C. Maxwell, L. Boltzmann, T. Nissen, E. Butcher, and J. Pernet.

C. Barus found that the viscosity of solid steel decreases as the hardness of the metal increases; or the internal or molecular friction of steel is greater in proportion as the metal is softer, and he said, in illustration, that as regards hardness and viscosity, hard steel may be compared with sealing-wax, and soft steel with tallow. C. Barus said that the relationship between viscosity and hardness is as follows:

> Suppose a stress to be so distributed in a solid that its application at any interface is nowhere sufficient to produce rupture. Then that property of a solid in virtue of which it resists very small forces (zero-forces) acting through very great intervals of time (∞-times) may be termed the viscosity of the solid. That property in virtue of which it resists the action of very large forces (∞-forces relatively) acting through zero-time may be termed the hardness of the solid. Since the application of forces in such a way as accurately to meet either of these cases is rare, we have in most practical instances mixtures of viscous resistance and hardness to encounter. We may reasonably conceive that in the case of viscous motion the molecules slide into each other or even partially through each other by interchange of atoms, so that the molecular configuration is being continually reconstructed; that in the other case (hardness) the molecules are urged over and across each other and that therefore the intensity of cohesion is in this case more or less thoroughly impaired. In most cases of scratching, the action is indeed accompanied by physical discontinuity of the parts tangentially strained. The interpenetration of the molecules of a viscous substance is necessarily favoured by temperature.

C. E. Guye and E. Mintz found that the internal friction of steel increases up to about 100°, then falls, and passes through a minimum value at about 200°, it then increases very rapidly. The changes are reversible because they can be observed on a rising or on a falling temp. The influence of temp. on the viscosity is diminished by previous annealing, and it increases when the load on the vibrating wires is increased. H. Tomlinson observed two critical points in the internal friction one about 550°, and one about 100°. M. Ishimoto found in the internal friction curves a minimum near 65° on both the heating and cooling curves; there was a maximum at 183° on the heating curve, and one at 173° on the cooling curve. There is a bend in the curve at 260°, and anomalous changes cease up to 500°. H. Tomlinson found the logarithmic (base 10) decrement of a torsionally oscillating hard-drawn wire to be 0·001214, and of an annealed wire, 0·000914. Observations were made by G. Subrahmaniam, A. G. Hill, P. Oberhoffer and A. Wimmer; and K. Iokibe and S. Sakai—*vide infra*—noted the change in the logarithmic decrement produced by heat-treatment.

The viscosity of steel varies with the character and amount of twist it has received. Fig. 198, by C. Barus, represents the angular distortion in radius as a function of the time in hours when wires of all degrees of hardness are exposed to temp., θ, of 100°, 190°, and 300°, respectively. The annealing temp. is indicated in brackets. Curves are included for the angular distortion for 100° when the rate of twist, $\tau=3°$; and likewise for a rate of twist $\tau=6°$ when the values for the angular distortion have been divided by 2. For $\theta=190°$, values are given for both $\tau=3°$ and $\tau=6°$. Each curve consists of two parts, an anterior ascending branch showing the motion at the high temp. θ, and a descending branch showing the elastic effect of cooling from θ to the temp. of the room. The results show that the viscous deformation is much more influenced by temp. when the steel is hard than when it is soft; that is, the viscosity decreases with temp.—*cæteris paribus*—at greater rates in hard steel than with soft steel. At the same temp. θ, the differences in viscosity are very large when the temper lies between glass-hard and annealed at 350°; intermediate differences within this interval are larger in proportion as the hardness is greater. When the temper lies between annealed at 350° and soft, differences of viscosity at the same temp. are relatively small. Consequently, the variations in viscosity due to temper are very pronounced during the first stage of annealing, and nearly vanish during the second stage. The effect of tempering on the viscosity is thus analogous to its effect on the electrical resistance, and the thermoelectric force.

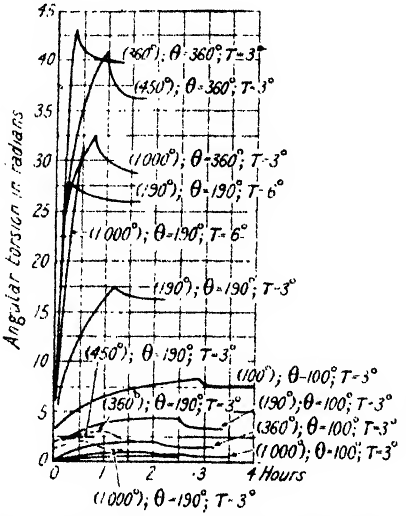

FIG. 198.—Viscous Deformation Increasing with Time for Different States of Temper and Temperature.

For the same degree of hardness, the viscosity increases at an accelerated rate with temp. In Fig. 198, for $\theta=100°$, the large viscous interval between the results of the metal annealed at 100° and at 360° is in striking contrast with the smaller viscous interval for metal annealed at 360° and at 1000°; for $\theta=190°$, the interval between the results with metal annealed at 190° and at 360° is greatly increased, but the increase is not so great for the interval between the metal annealed at 360° and at 1000°; and for $\theta=360°$, the interval in the second phase of annealing—360° to 1000°—is largely increased. Hence, steel wire annealed from hardness at $\theta°$ has a marked tendency to suffer viscous deformation at $\theta°$; and this tendency decreases with great rapidity in proportion as the temp. of exposure falls below $\theta°$.

C. Barus added that since at a depth of 10 miles below the surface of the earth the temp. is at least as high as 450°, it follows that if the earth were made of steel, in the state of maximum viscosity, the rigidity 10 miles below the surface would be *nil*, so far at least as the action of a continuous shearing press. is concerned.

The viscous deformation of steel increases much more rapidly than the rate of twist, and it is as much as 3 in the case of steel annealed at 190°, and more than 10 in the case of steel annealed at 1000°. It is therefore probable that the viscous relations of soft steel to hard steel vary enormously, and even change sign as the stress producing viscous motion passes from high to low values. For rates of twist less than 3°, steel is less viscous, and the viscosity is more susceptible to the influence of temp. in proportion as it is harder; and for rates of twist exceeding 6°, steel is less viscous and more susceptible to the influence of temp. in proportion as it is softer.

The effect of strains of whatever kind applied in sufficient intensity to homogeneous soft steel results in a marked decrease in the viscosity of the originally soft metal. The diminution increases with the intensity of the strain. The viscous effect of a tensile strain applied in any degree to the same originally soft metal is, after straining, almost *nil* in comparison. F. Kohlrausch, F. Streintz, and H. Tomlinson have studied these phenomena. C. Barus measured the time-variation of viscous deformation in the case of soft steel transformed by temper, drawing strain, traction, and torsion, with intense and moderate values of stress. In all cases, a given loss of viscosity is attended by a simultaneous increase in hardness.

Repeated torsional oscillation was shown by G. Wiedemann, and Lord Kelvin to reduce the internal friction, and they found that a large influence is exerted by a long rest, either with or without oscillation, and that a considerable diminution, both temporary and permanent, can be produced by raising the temp. of the wire to 100°. Thus, according to H. Tomlinson, a well-annealed iron wire, when tested 10 min. after suspension, had a logarithmic decrement, due to internal friction, of 0·003011, after an hour, 0·001195, and after a day, 0·001078. After the last period, the friction became sensibly constant, and remained the same after 4 days, so that the wire had accommodated itself to the conditions. F. Streintz, G. Wiedemann, and F. Kohlrausch called the period during which the diminution occurs, *the period of accommodation.* H. Tomlinson added that the reduction of the internal friction by oscillation and rest had not reached a minimum, because, on repeatedly heating the wire to 100°, and allowing it to cool, the logarithmic decrement rapidly diminished, until, after 6 days, on each of which the wire was heated to 100° and allowed to cool slowly, it became 0·000412 when further repetition of the process no longer affected the friction sensibly. The greater part of the diminution occurred after the first heating and cooling, but several repetitions were needed to produce the minimum. A temporary rise of temp. not exceeding 100° had a marked effect on the internal friction: for instance, the logarithmic decrement at 0° was 0·000412 and about one-fourth this value or 0·000112 at 98°. At this temp., the internal friction was a minimum, because with a further rise of temp., the logarithmic decrement increased. The internal friction in iron at 98° is thus very small, and this is shown by the fact that only about 3000 vibrations are required before the amplitude is reduced to one-half of its initial value by internal friction. Consequently, if a wire and its appendages be made to vibrate in vacuo, and the temp. be kept constantly at 98°, with a vibration period of 10 secs., more than 8 hrs. would elapse before an initial amplitude of 100 would be reduced to 50. The internal friction under these conditions is only one-thirtieth of its original amount. When the wire is fully accommodated, a small change in the conditions will produce a disturbance; thus, a mechanical shock, a change of load, a slight rise of temp., or a rotation of the molecules by magnetic stress, will require fresh oscillations to be made before the friction reaches its minimum. The time taken by a wire to re-accommodate itself when the accommodation has been disturbed by a change of temp. depends considerably on the direction of the change. Thus, if a wire be re-heated from room temp. to 100°, re-accommodation is effected in a much shorter time than when the accommodation has been disturbed by lowering the temp. from 100° to room temp.

O. E. Meyer referred viscosity to partial molecular rotation, and this view was adopted by F. Kohlrausch. These rotations are similar to those postulated by R. Clausius in developing a theory of shear. L. Boltzmann assumed that the elastic forces are dependent on the present and preceding deformations of the body. The effect of the earlier states of stress on the existing stress diminishes with intervening time, but is independent of intervening states of stress. Different viscous deformations are superposable. T. Nissen modified L. Boltzmann's theory to suit the atomic theory, and he distinguished forces producing and retarding motion, and the purely elastic forces which obtain when viscous motion has subsided. F. Braun concluded that elastic and viscous deformations are the result of the action of forces of different origin, and he refers viscous motion to the partial rotations postulated by W. Weber, and F. Kohlrausch. E. Warburg referred viscosity to the partial rotations of molecules of a form other than spherical. T. Nissen based a theory on the conditions under which æther enters the intermolecular spaces when a body is deformed by stress.

C. Barus employed J. C. Maxwell's theory in which the effect of twisting is to be referred to the motion of molecules which accompanies it. The molecules, together with their component atoms, are thus placed in new relative positions; therefore unstable configurations during the course of such motion are continually broken up into configurations of smaller potential energy and greater stability. Hence, finally, the observed decrease of viscosity. By reversing the sign of the twist the original configurations can be only partially restored, even for small permanent set, such as is here in question; and the effect of prolonged and repeated twisting is stiffness and constant viscosity, because all the molecules have collapsed into configurations of minimum stability, and the intrinsic molecular energy is the potential minimum compatible with the given conditions. Again, the molecular condition of iron at its recalescence temp. may be regarded as almost chaotic; the number of configurations made unstable because they are built up of disintegrating molecules is therefore a maximum, so that the viscosity will here be a maximum. C. Barus regarded glass-hard steel as a stage of temper which is undergoing incipient annealing at ordinary temp. Annealing is attended by chemical decomposition of the carbides, so that the molecular configuration of glass-hard steel is in a state of incipient change, and it contains more unstable configurations than steel in other states of temper. Hence, on J. C. Maxwell's theory, glass-hard steel, despite its extreme hardness, is the least viscous of the whole group of tempered and soft steels. According to C. Barus, viscosity and hardness can be clearly distinguished as follows:

> Imagine a round harder body sliding tangentially along the plane of a softer body without rotation. Let there be sufficient pressure on the round body normal to the plane of the softer body to insure cohesion at the point of contact. Then the softer body is subjected to a *simple shear* along the line of scratching. If the motion is sufficiently slow, the soft body may yield viscously and there will be no scratching. If the motion is sufficiently fast, the soft body will generally be scratched. Hence hardness and viscosity are each resistances against simple shearing, according as the tangential motion of the hard body is sufficiently rapid or sufficiently slow, respectively. The conditions for the occurrence of quiescent friction may therefore be stated thus: if there is sufficient time given for the molecules of two bodies to react on each other at the point of contact, the friction is quiescent. If the time be insufficient, friction is kinetic.

H. Tomlinson considers that both the temporary and permanent alterations of the internal friction of iron produced by raising the temp. not above 100°, are partly due to mere agitation of the molecules, but the permanent effects are probably not wholly an effect of molecular agitation because maintaining the temp. at 100° for some time does not bring down the friction anything like so much as repeated heating and cooling. The slow shifting backwards and forwards of the molecules induced by repeated heating and cooling, is, in a great measure, responsible for the permanent decrease of the internal friction. Similarly, the shifting backwards and forwards of the molecules caused by torsional oscillation produces a permanent diminution—*vide infra* for the effect of magnetization on viscosity. A. Guillet, and H. le Chatelier discussed the effect of the physical properties of iron on the damping down of the oscillations of a bar.

The **plastic flow** or **plasticity** of metals was discussed by E. N. da C. Andrade,[6] R. Becker, R. H. Canfield, H. and F. le Chatelier, J. Dejmek, J. H. S. Dickenson, R. Eisenschitz and co-workers, W. Fahrenhorst and E. Schmid, J. E. Fletcher, H. J. French, H. J. French and W. A. Tucker, N. P. Goss, J. N. Greenwood, B. P. Haigh, H. Hencky, E. Heyn, H. Hoff and G. Sobbe, E. M. Horsburgh, H. M. Howe and A. G. Levy, Z. Jeffries, Z. Jeffries and R. S. Archer, E. Kieft, F. Körber and co-workers, W. Kuntze, C. E. Larard, W. Lode, P. Longmuir, H. V. Loss, P. Ludwik, O. Manfred, H. Meyer and F. Nehl, H. F. Moore, A. Nadai, A. Nadai and co-workers, E. B. Norris, J. T. Norton and B. E. Warren, J. Orland, J. Puppe, R. L. Peek and D. A. McLean, L. B. Pfeil, W. Prager, H. Preussler, C. Ranque and P. Henry, M. Ros and A. Eichinger, W. Rosenhain and J. McMinn, G. Sachs, F. Sauerwald, F. Sauerwald and co-workers, F. Schleicher, E. Schmid and co-workers, A. Schob, J. Seigle, H. Shoji, E. Siebel and co-workers, F. T. Sisco, W. Tafel, G. I. Taylor and H. Quinney, F. C. Thompson and W. E. W. Millington, P. A. Welikhoff and N. P. Stchapoff, W. M. Wilson, and J. K. Wood. According to H. Shoji, if P denotes the plasticity of a metal, and dv/dw the final velocity per unit length caused by a load w_0 exceeding the elastic limit, then $P=(1/w_0)(dv/dw)$. The laws of flow were discussed by H. Meyer and F. Nehl, and E. N. da C. Andrade; and by W. Rosenhain, the behaviour of crystals under plastic deformation—*vide supra*, slip-bands. The effect of plastic deformation on the crystal structure was discussed in connection with the X-radiograms, and with slip-bands. A. Robertson and G. Cook studied the transition from the elastic to the plastic state. If the applied stress exceeds the elastic limit, the metal begins to flow perceptibly; and the rate of this flow expressed as a percentage elongation represents the ductility of the metal. The definitions were discussed by A. E. H. Love, and W. C. Unwin; H. Shoji said: "Suppose a metal be loaded by a constant weight so slightly beyond its elastic limit that the cross-section of the metal is not altered by the tension. Let V be the velocity of the elongation per unit length, w_0 the intensity of the stress corresponding to the elastic limit, when $V=0$, and w the intensity of the applied stress diminished by w_0; then the plasticity P can be defined by the equation $P=(1/w_0)(dV/dw)$." The theory of the subject was discussed by K. Bennewitz, A. E. H. Love, L. Boltzmann, A. A. Michelson, H. V. Wartenberg, G. Masing, H. Lorentz, R. Becker, V. Volterra, and H. Shoji. P. Kreuzpointer found that steel with granular structure flows less readily than steel with a "mushy" structure although both may have the same tensile strength and percentage elongation. He devised an arrangement which rang a bell when a test-piece was pulled by the hands showing that a force so slight suffices to cause an elongation of the test-piece. A. le Chatelier found that a metal may be broken by a tensile stress above a certain temp., with loads that produce permanent elongation. With a constant temp., the deformation under a given load has a decreasing value tending towards equilibrium; the deformation increases more rapidly than the loads, whilst the stress increases and the strain decreases with the speed of loading; deformation under shock is inversely proportional to the shock; under an increase in temp., the deformation increases, and the resistance decreases. Cast iron at 15° can support the following loads in tons per sq. in. for the time stated in the number of minutes without breaking:

Time .	0·5	1·0	5·0	15	60 mins.
Load .	25·21	24·63	23·87	23·49	22·86 tons per sq. in.

According to J. Cournot and K. Sasagawa, the time-elongation curves of metals at 600° show that the following increases in load were needed to pass from the viscosity limit to a rate of flow eq. to 16×10^{-4} mm. per hour with wires 100 mm. long: mild steel, 4·2 to 5·2 kgrms. per sq. mm.; semi-mild steel, 4·3 to 5·6 kgrms. per sq. mm.; high-speed steel, 14·0 to 19·0 kgrms. per sq. cm.; nickel-chromium alloy, 32·0 to 36·0 kgrms. per sq. mm.; and silicon-chromium steel, 30·0 to 35·5 kgrms. per sq. mm. J. J. Kanter and L. W. Spring found that steels which have undergone small amounts of flow do not seem to have deteriorated, the tensile properties, including elongation and reduction of area, remaining approximately what they were before the flow tests. Since little or no deterioration occurs or should be expected (unless through oxidation), and since with ductile metals at temp. above 315°, 10 per cent. or more of flow or elongation are necessary before the material starts out on its final stretching preceding rupture. Any slight flow or deformation brought about by stresses below the proportional limit are not seriously objectionable unless the distortion interferes with service. Carbon increases the resistance to flow. At low temp. where grain-size is a prime factor governing the strength, carbon increases the strength by refining the grain; at low temp., deformation is accompanied by great strain hardening, and continuous flow sufficient to rupture is observed only at loads approaching the tensile strength. At temp. above 425°, the grain-size is still small, but the grains themselves are not so brittle as at strain-hardening temp.; they are plastic enough to change their form under stress without splitting, and without forming slip-bands. In this plastic state, strength by mere virtue of number or multiplicity of grain does not obtain. The subject was studied by C. L. Clark and A. E. White, and J. L. Cox.

L. Klein discussed the **friction** between wood and iron; P. E. Shaw and

E. W. L. Leavey, and B. S. Hedrick, the friction of iron in vacuo against iron, nickel, aluminium, silver, and copper; J. S. Rankin, the friction of iron against glass, and brass; G. A. Tomlinson, the friction of copper, aluminium, iron, nickel, and glass; and O. H. Lehmann, the friction of ordinary cast iron against steel and against hard and soft cast iron. J. S. Stevens discussed the molecular contact during friction of one surface on another. F. Sauerwald and E. Jänichen studied the cohesion of the compressed powder.

A. Masson [7] observed the **velocity of sound** in iron to be 5015·9 to 4940·2 metres per sec.; A. Kundt, 5092·9 metres per sec.; and G. Wertheim gave 5123·8 metres per sec. between 15° and 20°, for iron wire, 4912·9 metres per sec. between 10° and 20°; for soft steel, 4982·0 metres per sec. between 15° and 20°; and for the same steel tempered blue, 4880·4 metres per sec. at 10°. G. Chrystal, and F. Robin noticed discontinuities at 120° and 250°; and G. Wertheim at 100°. G. Wertheim inferred that the velocity of sound in iron and steel is increased by a rise of temp. not exceeding 100° because of the increase in the longitudindal elasticity. He found that the percentage *increase* in longitudinal elasticity between 15° and 100° is 4·90 for annealed iron, 6·91 for annealed iron wire, 2·79 for annealed cast steel, 23·20 for annealed steel wire, and 5·18 for steel tempered blue. H. Tomlinson, however, found that both the torsional and longitudinal elasticities of iron and steel are *decreased* by about 2·5 per cent. when the temp. is raised from 0° to 100°. True, the longitudinal elasticity may be greater at 100° than it is at 0° provided a start be made from 0° and the wire has not been previously heated to 100°, but the apparent temporary increase is really a permanent one, and if the wire be repeatedly heated to 100° and then cooled, the elasticity is less at the higher temp. if sufficient rest after cooling has been allowed. The pitch of the musical note produced by a steel wire or steel tuning-fork is lower as the temp. is raised, and this more than corresponds with the mere change in dimensions. G. Tammann and co-workers studied the formation of Chladni's figures.

F. Robin examined the **acoustic properties** of iron. When the dry metal is heated, the duration of the sound diminishes slowly from, generally speaking, 10° to 20°, then more rapidly, and finally very rapidly, between 50° and 100°. At 90° the curve falls rapidly, and attains a minimum at about 120° to 130°, when the sound is hardly more than a confused murmur. On continuing the heating, the curve is seen to rise again, and the duration of the sound increases rapidly from 150° onwards to about 220° or 250°, where it reaches a maximum. From this point the duration increases very slowly until 325° to 350° is reached, when the fall becomes more rapid and the sound dies away finally at about 540°. It should be noted that on reaching red-heat, at about 500°, the bar still gives out a sound at least four times greater, generally speaking, than the sound given at 120°. The duration of the sound decreases very rapidly in steels, starting from normal temp., and attains a minimum at about 120°, which may be measured in the case of hypereutectoid steels. The peaking of the curve of resonance decreases, and the minimum rises with the percentage of carbon. It is less accentuated in proportion as white iron is approached. As may be seen on inspecting the curves of the duration of the sound, complete extinction of sound only occurs in the case of the annealed hypo-eutectoid between 100° and 140°. Grey irons no longer display sonorousness, and the phenomenon is no longer distinctly observable. The maximum resonance on heating is in the vicinity of 250°; it approaches 200° when the proportion of carbon increases; its distinctiveness and its absolute value increase with the amount of combined carbon contained in the metal. The resonance gradually diminishes and finally becomes extinguished at a little below nascent red-heat. Slag reduces and a little carbon favours resonance; sulphur diminishes the sonorous properties, but at ordinary temp. phosphorus has very little influence. For alloy steels, *q.v.*, J. A. Anderson found the velocity of sound in iron vapour to be between 990 and 1650 metres per second.

Innumerable tests have been made on the **mechanical properties** of iron and steels. A selection for some of the alloy steels is made in connection with the different alloys. For industrial purposes, in different parts of the world, probably thousands of samples are tested every day; and metals are manufactured to satisfy certain specified mechanical tests.

The *elastic limit* is the greatest load per unit of original cross-section which does not produce a permanent set; the *proportional limit* is the load per unit of original cross-section at which the deformations cease to be directly proportional to the loads; and the *yield-point* is the load per unit of original sectional area at which a marked increase in the deformation of the specimen occurs without increase of load—*cf.* **1.** 13, 17. The definitions were discussed by J. E. Howard,[8] and T. D. Lynch.

In 1809, L. B. G. de Morveau made some observations on the **tensile strength** of the metals, and found that the weight in kilograms which could be supported by an iron wire 2 mm. in diameter was 250; a copper wire, 137; a silver wire, 85; etc. G. Wertheim measured the tenacity of some metals, in kilograms per sq. mm., and found for iron, 50·3; copper, 31·6; silver, 16·4; etc. G. Wertheim said that the tensile strengths of the metals vary as their at. wts.—*vide supra*, hardness. There are many collections of data. The following is based on that of F. Auerbach. In illustration of the values given for the **elastic modulus** of iron, E, in kgrms. per sq. mm., N. Katzenelsohn gave for forged iron, 19,024; G. Wertheim, 20,869; G. Pisati and G. Saporito-Ricca, 21,450; M. Baumeister, 20,500; H. Tomlinson, 19,810; K. F. Slotte, 19,385; for annealed iron, G. Wertheim gave 20,794; for cast iron, P. A. Thomas gave 21,740; O. Wagner, 21,300; W. Pscheidl, 11,713; W. Voigt, 12,800; and A. Gray and co-workers, 15,750. Similarly, for forged steel, G. Wertheim gave 18,810; for annealed steel, 17,280; and for cast steel, 19,555. For cast steel, G. Pisati gave 18,490; W. Voigt, 20,400; E. H. Amagat, 20,395; O. Wagner, 20,560; and for mild steel, A. Gray and co-workers gave 21,700; and C. P. Weston, 19,380; for soft steel, 20,705; for medium steel, 20,910; and for hard steel, 20,600. A. L. Kimball and D. E. Lovell gave for the elastic modulus of annealed Swedish iron $18{\cdot}9\times10^{11}$ dynes per sq. cm., and for cold-rolled mild steel, 21×10^{11} dynes per sq. cm. H. Tomlinson gave for hard steel, $21{\cdot}360\times10^{6}$ and 1862×10^{6} grms. per sq. cm. for hard drawn, and 198×10^{6} grms. for annealed iron wire; and G. Angenheister, for hardened steel, 18,206; and for soft steel, 18,875; and G. F. C. Searle, 19,810—*vide supra*, Table XVI. As indicated below, the actual values for any particular samples must obviously depend on the composition of the metal, and on its previous history. W. Sutherland gave for the best representative values for iron, in kgrms. per sq. mm., 20,000, with the extremes 18,610 and 21,440. Observations on the elastic limit were made by C. H. Desch, J. Galibourg, E. Goens and E. Schmid, J. E. Howard, A. Jaquerod and H. Mägeli, P. Kreuzpointer, H. K. Landis, G. Lanza, P. F. Lee and H. A. Schade, P. le Rolland and P. Sorin, K. Prosad, C. A. P. Turner, and L. B. Turner. The results of D. K. Froman, for Young's modulus with small stresses, are summarized in Fig. 199. A. Mallock observed that there is a similar relation between the temp. coeff. of the modulus of elasticity and the m.p. as that which obtains between the temp. coeff. of the hardness and the m.p. L. C. Tyte discussed the deviations from Hooke's law.

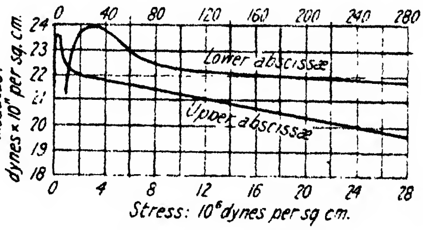

FIG. 199.—Young's Modulus with Small Stresses for Steel.

G. Wertheim gave for the elastic modulus of iron at 15°, 100°, and 200°, respectively 20,794, 21,877, and 17,700; and for that of cast steel, respectively 19,561, 19,014, and 17,926. N. Katzenelsohn found that with iron of elastic limit 19,024, the percentage decrease between 0° and 100° is 2·33. A. Wassmuth obtained a similar result. K. F. Slotte gave for the elastic limit of iron :

	8·4°	20·4°	30°	40°	50°	60°
E . .	19,687	19,385	19,226	19,137	19,037	19,004

A. Gray and co-workers gave $a = -0{\cdot}0_3136$ for the temp. coeff. of the elastic limit of iron. G. A. Shakespear obtained similar results, while M. C. Noyes obtained $0{\cdot}0_3460$ for steel; and G. Pisati obtained for iron, the following results for the elastic limit, E, and the temp. coeff., $a \times 10^5$:

	0°	20°	60°	100°	140°	180°	220°	260°	300°
E .	21,483	21,441	21,336	21,212	20,981	20,625	20,267	19,723	19,175
$a \times 10^5$.		10	12	27	34	41	47	60	69

and for steel :

	0°	20°	60°	100°	140°	180°	220°	260°	300°
E .	18,518	18,481	18,391	18,232	18,085	17,925	17,720	17,550	17,372
$a \times 10^5$.		10	13	26	18	24	28	25	26

K. Wimmer gave 7427 at 0°, 6298 at 100°, and computed 10,508 at −273°; and K. R. Koch and R. Dieterle, for steel with 0·0085 per cent. of carbon annealed at 620°, $1{\cdot}455 \times 10^{-6}$ kgrm. per sq. cm. at 12°; $1{\cdot}360 \times 10^{-6}$ at 200°; $1{\cdot}250 \times 10^{-6}$ at 400°; and $1{\cdot}0455 \times 10^{-6}$ at 600°; C. Schäfer gave $1{\cdot}835 \times 10^{-6}$ at 20°; and E. Grüneisen $2{\cdot}168 \times 10^{-6}$ at 18° for 0·1 per cent. carbon steel, and $2{\cdot}132 \times 10^{-6}$ at 18° for 1·0 per cent. carbon steel. J. R. Benton found the ratio of the elastic limit at −186° and at ordinary temp. to be 1·180; and C. Schäfer found a 0·02250 increase in the elastic limit per degree between 20° and −186°. K. Honda and T. Terada found that the coeff. of elasticity, E, of Swedish iron rose from $1{\cdot}802 \times 10^{12}$ with a load of 1689 grms. per sq. mm. to $1{\cdot}968 \times 10^{12}$ with a load of 11,700 grms. per sq. mm. H. Schlechtweg, and G. H. Kuelegan and M. R. Houseman studied the subject. W. Sutherland said that if E denotes Young's modulus at $\theta°$, and E_0 its value at the absolute zero, then, if θ_m denotes the m.p. of the metal, $E/E_0 = 1 - 0{\cdot}823\theta/\theta_m$, for temp. up to about 102°, but it is imperfect at the m.p., since it gives finite values at that temp., whereas the value ought to be zero. A. Gray and co-workers found for Young's modulus of mild steel $2{\cdot}1279 \times 10^{12}$ dynes per sq. cm., at 20·3°, and $2{\cdot}0939 \times 10^{12}$ at 80·3°—a diminution of 0·000247 per degree; for soft iron they gave $1{\cdot}5521 \times 10^{12}$ at 16° to 22°, and $1{\cdot}5321 \times 10^{12}$ at 94° to 96°—a diminution of about 0·000156 per degree. E. P. Harrison and S. K. Chakravarti observed that the elastic modulus does not reach a maximum as the temp. rises, but decreases continuously so that between 27° and 140° for annealed wires, $E = E_0\{1 - 0{\cdot}000934(\theta - 30) - 0{\cdot}0_6733(\theta - 30)^2\}$, when E_{30} is $18{\cdot}95 \times 10^{11}$ dynes per sq. cm. H. L. Dodge found the modulus of elasticity, E, of mild steel (0·162 per cent. carbon) in 10^{-11} dyne per sq. cm. :

	22°	142°	263°	398°	466°
$E \times 10^{-11}$ . .	19·3	18·9	18·2	16·9	14·6

A. Mallock gave 1·27 for the ratio of Young's modulus at −273° and at 0°. F. Sauerwald and co-workers attributed the brittleness of a-iron at the temp. of liquid air to the ready cleavage of the crystals at that temp.

K. Honda and T. Tanaka found that the effects of carbon on the modulus of elasticity, E, and modulus of rigidity, K, for iron alone are respectively $2{\cdot}087 \times 10^{12}$ and $8{\cdot}34 \times 10^{11}$; and for alloys with carbon :

Carbon . . .		0·10	0·20	0·40	0·59	0·81	1.02	1·19	1·48 per cent.
$E \times 10^{-12}$	Annealed .	2·045	2·025	2·070	2·040	2·030	1·906	1·981	1·930
	Quenched .	1·942	1·931	2·000	—	1·928	1·911	1·880	1·820
$K \times 10^{-11}$	Annealed .	8·13	8·11	8·21	8·19	8·15	8·17	8·06	7·97
	Quenched .	7·92	7·88	7·92	—	7·78	7·78	7·74	7·65

The presence of carbon in general decreases both moduli. The zig-zag character of the curves is attributed to impurities. Whilst the tensile strength of carbon steels is increased by quenching, the moduli of elasticity and rigidity are decreased in all cases. This fact was noted by K. Honda and H. Hasimoto.

H. Tomlinson observed that after a wire has suffered permanent extension, the temporary elongation which can be produced by any load becomes less as the interval between the period of permanent extension and that of applying the load becomes greater. This increase of elasticity is greater in proportion for large loads than for small ones. The increase of elasticity takes place whether the wire be allowed to remain loaded or unloaded between the period of permanent extension and that of testing for the elasticity. The rate of increase of elasticity varies considerably with different metals; with some, the maximum elasticity is attained in a few minutes, with others, as with iron and steel, not till some days have elapsed. The elasticity can be increased by heavily loading and unloading several times, the rate of increase diminishing with each loading and unloading. A more or less decided departure from Hooke's law—**1.** 13, 17—always attends recent permanent extension, even when the weights employed to test the elasticity do not exceed one-tenth of the breaking weight. L. C. Tyte found that all the metals he investigated deviated from Hooke's law over the whole range. The amount of deviation differed for the same material subject to different heat-treatments, and cold-working. For annealed metals, the deviations increased with an increase in the size of crystals. H. Tomlinson observed that the departure is diminished very noticeably in the case of iron and much less so in the case of other metals, by allowing the wire to rest for some time, either loaded or unloaded, it is also diminished by repeated loading and unloading. Permanent extension with all metals, provided the wire has not been kept heavily loaded for some time, produces a decrease of elasticity if the strain be not carried beyond a certain limit. If the extension be carried beyond this limit, a further permanent increase of length causes an increase of elasticity. In the case of iron, heavy loading for some time so increases the elasticity that even when the extension would have caused diminution of elasticity without such continued loading, the latter will, if sufficient time be allowed, change this diminution into an increase—but not so with copper. With iron which had been heavily loaded for some time, the ratio of the temporary elongation to the load producing it becomes less as the load employed becomes greater, until a certain limit is attained dependent on the extent of the previous heavy loading. With other metals, and with iron which has suffered permanent extension without allowing the load producing the extension to remain for any appreciable time on the wire, the elongation increases in a greater proportion than the load. This behaviour of iron, as well as the fact that this metal does not, until many hours have elapsed, attain its maximum elasticity, after having undergone permanent elongation, is attributed to the great cohesive force of the metal. When a fixed load is applied to steel at a constant temp., there is an initial flow which results in an elongation of the steel. This elongation ceases after a time, if the load is not too great. This indicates a strain hardening of the material. If the load be constant, there is a slower elongation, or *secondary flow*, which continues under a constant load of sufficient magnitude until it is followed by a *final rapid flow* which immediately precedes the fracture of the metal. H. F. Moore represents the phenomena as elastic deformation, slip, and fracture. The elastic deformation is represented by a slight stretching, or compression, or a lateral displacement (shear). This deformation disappears when the stress is released. As the stress is increased, some of the atomic bonds in the crystal-grains are broken along certain planes, the divorced atoms slide over other atoms, find new partners,

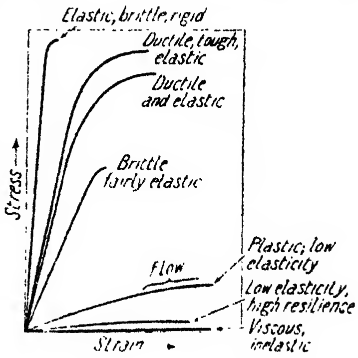

Fig. 200.—Some Types of Stress-Strain Curves.

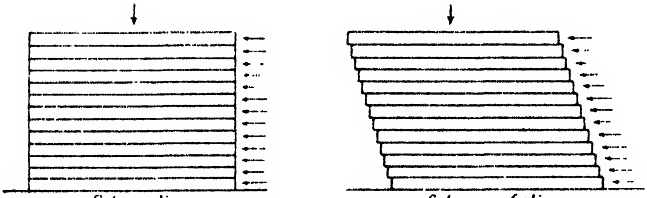
and form new bonds. It is remarkable that after a brief period of rest for readjustment, the new bonds seem to be stronger than the old—*e.g.* in cold-drawn steel the slip is attended by an increase in strength. The action at this stage is the phenomenon of slip discussed above. The planes of slip across the crystal grains appear microscopically as lines, or *slip-bands*. H. P. Hollnagel represented the different types of stress-strain curves by Fig. 200. H. F. Moore likens the slip to the action of an oblique pressure on a pack of cards—Fig. 201—and added : The slipping continues, some of the broken atomic bonds do not form new bonds, and minute cracks appear, until finally the cracks spread and a fracture occurs. The relations of stress to strain are illustrated by Fig. 202. *OE* represents the first stage of elastic deformation ; slip-bands begin to appear at *E* when the stress is *AE*, after that, the curve deviates from a straight line, and when the load is released, the material has acquired a small permanent set. *E* represents the proportional limit or elastic limit ; the yield-point is represented by *Y*, so that when the stress attains the value *BY*, a general slip occurs, and after that fracture. With very brittle materials, fracture may occur before the stress becomes large enough to show a well-marked yield-point. Under repeated loading a stress well below the ultimate tensile strength will start a fracture in metal which finally spreads to failure of the entire cross-section of a piece. This spread under repeated loading is very much slower that the spread under a single increasing load. Thousands or even millions of cycles of stress may be required to develop the final failure. This repeated stress fracture spreads slowly, like a minute hack-saw cut, but its rate of progress is accelerated, and just before fracture it is almost as rapid as is the spread of fracture under a single increasing load. In fact, a typical fatigue failure usually shows two distinct zones : (i) A smooth surface where the crack has spread slowly and the walls of the crack are battered smooth by repeated opening and closing, (ii) a rough " crystalline " surface indicating the very much more sudden fracture of the core of the piece. The subject was discussed by K. Yuasa.



Before slip

Side view of slip

FIG. 201.—Formation of Slip-bands (Diagrammatic).

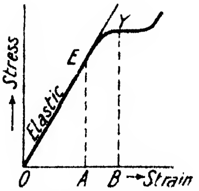


FIG. 202.—Relation of Stress and Strain.

According to Hooke's law, if S denotes the extension, and P the stress, $S=kP$, where k is a constant ; but, as just indicated, the results of accurate observations deviate a little from the rule. C. Bach said that F. A. Schulze's formula $S=kP^m$ gives better results when m is a constant greater than unity. For example, T. E. Stanton observed that in his tests, the relation between permanent strain, S, and stress, P, can be represented by $P=39{\cdot}37S^k$, where k is nearly 0·25 for some specimens of mild steel. R. Mehmke has made a collection of the formulæ which have been suggested in place of Hooke's law, in order to represent the observed results empirically. E. Hartig, and E. Grüneisen and F. A. Schulze assumed that the elastic modulus increases linearly with increasing stress, so that $dP/dS=E-cP$, where c is a constant ; and this can be written $S=E^{-1}(P+b_2P^2+b_3P^3+\ldots)$, where b_2, b_3, . . . are constants. This resembles I. O. Thompson's formula, $S=aP+bP^2+cP^3$. W. Voigt also supposed that the increase in the elastic modulus with increasing stresses is in accord with a power series. P. Debye assumed that the modulus of elasticity is a function of the interatomic distance. G. Wertheim made an assumption of this kind in 1848, for he gave the formula Ed^7=a constant when d denotes the mean distance apart of the atoms. P. Debye's hypothesis is not in accord with the behaviour of solid soln. where the change in the modulus is greater than can be explained by a small change in interatomic distances. According to H. von Wartenberg, every elastic deformation of a metal composed of grains is really made up of pure elastic deformation and of an elastic after-working, having a time factor. Single crystals do not exhibit elastic after-effect. The pure elastic deformation of a metal is independent of the previous treatment. The limit of proportionality of a metallic conglomerate is the stress at which the most unfavourably situated crystal slips, and it follows that there is no such limit for single crystals. The elastic limit is the stress at which the elastically deformed crystals fail to bring back the displaced crystals to their original position. The subject was discussed by A. Berliner, W. Geiss, G. A. Tomlinson, G. S. Meyer, M. Polanyi, G. Tammann, E. Goens and E. Schmid, P. Bechterew, G. Cook, G. Masing, H. Mark, L. Boltzmann, J. E. Wiechert, A. A. Michelson, J. Okubo, J. C. McConnel and D. A. Kidd, E. Heyn, M. Mesnager, F. Sauerwald and H. G. Sossinka, A. V. Stepanoff, and E. Houdremont and H. Kallen.

J. E. Stead worked out a theory for the relation between the cold-working of steel and the tensile strength. He stated that there are at least three stresses to consider: (i) the stress, S_1, required to destroy the cohesion between the atoms in the space-lattice of the crystal, and this is assumed to be constant: (ii) the stress, S_2, required to produce internal slip; it is a characteristic of each steel; it increases exponentially with the amount of slip, and depends on the amount of slip which has already taken place; and (iii) the stress, S_3, required to produce external slip; it is characteristic of each steel; and it increases linearly with the amount of slip that has taken place. He said:

> When a test-piece is stressed, the stress rises elastically until the initial value of S_2 is reached, and then internal slip takes place. The crystallites being in a state of unstable equilibrium owing to internal stresses, when slip takes place this equilibrium is upset and a position of stable equilibrium is attained, in which the internal stresses have disappeared. This necessitates considerable slip taking place, such slip constituting the yield-point slip. This is nearly all internal, but is accompanied by some slight external slip to conform with the movement that has taken place in the crystallites. While the crystallites are settling down into a position of equilibrium, the stress remains the same and the slip produces no hardening effect. That is to say, the piece cannot withstand any higher stress than S_2 without further slip. As soon as the equilibrium position is reached, any further slip produces an increase in S_2. That is to say, to produce further slip the stress must be increased, and with each increasing slip there is an increase in the value of S_2. However, the slip that takes place is partly internal and partly external, the proportion of external to internal increasing as the slip increases. Thus, hardening is due partly to the increase of S_2 and partly to that of S_3. Though the initial value of S_2 is less than that of S_3, the former increases with slip more rapidly than S_3, so that a point is reached when the value of S_2 is equal to the value of S_3. As the values of S_2 and S_3 approach each other, the ratio of external slip to internal increases until, when S_2 and S_3 are equal, the slip becomes wholly external. This continues until the breaking point is reached. The breaking stress may be equal to S_1, but of that there is no evidence one way or the other.

J. T. Bottomley noted the great difference between the tenacity of iron when loaded by slow degrees, and when loaded quickly; and this recalled the increase in the portative power of a magnet with gradual loading—*vide infra*. H. J. French and W. A. Tucker, and A. Michel and M. Matte showed that when a specimen of steel is subjected to a constant load, it passes through four phases: (i) an instantaneous extension; (ii) a slow extension; (iii) a constant increase; and (iv) a rapid increase accompanied by fracture. The permanent deformation and fracture was discussed by M. Malaval, and A. H. Leblond; and the expansion of cast iron under tension, by E. Piwowarsky and O. Bornhofen; and the change of dimensions under torsional stresses, by T. Uêda.

C. A. Edwards and L. B. Pfeil, working with single crystals of iron, containing 0·13 per cent. carbon, 0·023 Si, 0·44 Mn, 0·028 S, and 0·020 P, found that the limits of proportionality ranged from 1·725 to 2·69 tons per sq. in.; the tensile strength, from 9·38 to 15·38 tons per sq. in.; the modulus of elasticity, from 11,200 to 13,320 tons per sq. in.; and the elongation, from 30·5 to 53·65 per cent. With two exceptions, the tensile strengths fall within a range of 1·27 tons per sq. in., the average of 8 tests is 9·98 tons per sq. in. with maximum and minimum values, respectively, 10·65 and 9·38 tons per sq. in. H. C. H. Carpenter's values for the tensile strength ranged from 9·61 to 9·94 per sq. in. Observations were made by G. I. Taylor and C. F. Elam, F. Sauerwald and G. Elsner, P. Ludwik, A. B. Kinzel, J. Königsberger, A. Kroitzsch, W. H. Hatfield, R. L. Templin, O. Schwarz, J. Galibourg, J. Seigle, A. R. Page, F. G. Martin, J. A. Jones, F. W. Duesing, H. Poellein, P. Régnauld, R. Rimbach, C. H. Carus-Wilson, R. H. Graham, J. E. Howard, E. Bernardon, C. Cornut, J. H. Wicksteed, E. Marke, L. Tetmajer, W. P. Davey, A. Pomp, A. Vosmaer, J. W. Langley, K. Daeves, C. C. Schrott and G. M. Case, J. E. Howard, and T. B. Focke. The tensile strengths of small crystals were more variable than large ones. C. A. Edwards and L. B. Pfeil consider that the lowest value for the tensile strength in a single crystal will be obtained when two slip-planes make angles of 45° to the axis of stress, that is, when two planes coincide with a plane of maximum shear, and that higher values for tensile strength will be obtained when no planes make this angle. The important factor is the angle between the planes and the axis of stress, and not the relative position of the planes and the surface of the specimen. It is not clear whether an iron crystal during a tensile pull gives way upon the dodecahedral-planes or on the cube-planes. Slip in a crystal usually occurs most easily on the planes containing the greatest number of atoms per unit area, and in the case of α-iron, these are the rhomb-dodecahedral or (110)-planes. Observations, however, favour the assumption that slip in α-iron takes place on the cubic or (100)-planes. The limits of proportionality have an average of 2·19 tons per sq. in.; the results are all low when compared with that for crystalline iron where the value attains 8 tons per sq. in. No relation between the tensile strength and the limit of proportionality was observed. The elongation shows a tendency to vary in accord with the tensile strength; the data were very variable when compared with the tensile strength. The modulus of elasticity averages 12,016 tons per sq. in. There are no wide variations in accord with general observations that the condition of a metal—cold-worked, annealed, etc.—has but a small effect on the elastic modulus. F. Sauerwald and co-workers observed that single crystals of α-iron at the temp. of liquid air readily rupture along the face of the cube. According to F. Osmond and C. Frémont, the mechanical properties of single crystals are a function of the crystallographic planes in relation to the direction of stress. The extreme brittleness displayed along the planes of cleavage is associated with high plasticity in other directions. G. P. Fuller found that the yield-point of 99·965 per cent. electrolytic iron, annealed to remove hydrogen, is 23,000 lbs. per sq. in., and the tensile strength is 40,000 lbs. per sq. in. The metal can be annealed at a high temp. and quenched without affecting its properties.

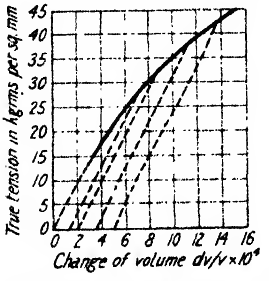

FIG. 203.—The Effect of Tensile Stresses on the Volume of Steel.

H. Quinney observed that the Ac_3-arrest with single crystals was not influenced perceptibly by strains; and the subject was studied by J. Seigle, and H. Griess and H. Esser. F. Sauerwald and T. Sperling observed that the Ac_1-arrest of iron is lowered by deformation; the Ar_1-arrest is raised about 1°; the Ac_3-arrest is lowered about 4°; and the Ar_3-arrest is raised about 4°. H. Hanemann and R. Yamada observed that the sp. vol. of steel is increased temporarily by elastic stress, and permanently if it be deformed when in a state of plastic flow. The dotted lines, Fig. 203, show that the vol. of a number of steels increases with increasing tension; and the continuous curve represents the increase in vol. which occurs when plastic flow begins. B. MacNutt and A. Concilio observed that when stressed in a testing machine, steel makes noises. The load at which the first noise is heard is constant for a given material, and it occurs in the neighbourhood of the yield-point.

The physical properties of steel are mainly dependent on (i) the previous history of the metal; (ii) the chemical composition, *i.e.* the relative proportions of the other elements present; (iii) the distribution of the different structural constituents, *i.e.* the relative proportions of ferrite, cementite, etc., present; and (iv) the size of the grains. F. Sauerwald and K. A. Pohle found that the brittleness of iron below 0° is not appreciably affected by the grain-size. L. Ljamin found that the tenacity of different steels varied as the size of the pearlite grains at the same finishing temp.; and A. Sauveur obtained the results indicated in Table XVIII,

TABLE XVIII.—THE RELATION BETWEEN THE GRAIN-SIZE AND TENSILE STRENGTH.

Size of grain in 0·0001 sq. mm.	Tensile strength (kgrms. per sq. mm.)	Elongation (per cent.)	Reduction of area (per cent.)
148	69·2	15·0	20
118	70·3	19·0	22
62	77·7	22·5	35

and found that if A denotes the average area of the grains in sq. mm., the tenacity, T, in kgrms. per sq. mm., is $T=75{\cdot}5-0{\cdot}004A$. Observations on the effect of the grain-size on the mechanical properties have been made by J. O. Arnold, F. C. Thompson, W. E. Dalby, W. H. Bassett and C. H. Davis, R. Arrowsmith, W. Rosenhain and J. C. W. Humfrey, R. E. Paine, E. Houdremont and co-workers, E. Schüz, H. von Jüptner, F. Osmond, O. von Keil and O. Jungwirth, and H. T. Angus and P. F. Summers. C. A. Edwards and L. B. Pfeil found that a test-piece with 28 crystal grains per sq. mm. had a tensile strength of 17·2 tons, and with decreasing grain-size the tensile strength remained steady until about 84 crystals per sq. mm. were present, after which, the strength increased rather rapidly to about 20 tons per sq. inch at a crystal-size of 145; with a crystal-size of 166, the tensile strength fell to 17 tons per sq. in.; and any further decrease in crystal-size had little effect since the tensile strength remained about 17 tons per sq. in. for all samples with a finer grain than 166. The curve thus shows a definite maximum which also corresponds with the maximum for the limits of proportion. The cause of the discontinuities has not been explained. It was not due to the contact of the metal with hydrogen or nitrogen.

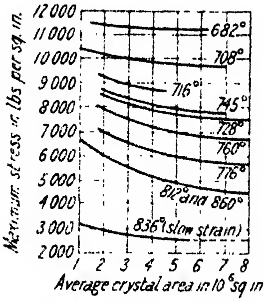

FIG. 204.—The Effect of the Grain-size of Crystals on the Tensile Strength at Different Temperatures.

C. A. Edwards and L. B. Pfeil observed that decarburized ferrite aggregates gave practically constant maximum stress and elongation values as the grain-size decreased from 27 to 307 grains per sq. mm. W. Rosenhain and J. C. W. Humfrey summarize their results, Fig. 204, as follows:

> Commencing with the material at the higher temp., that is, well above Ar_3, it possesses the mechanical properties and the microscopic behaviour of an aggregate of crystals, themselves relatively strong, embedded in a viscous fluid. Throughout the γ-range these characteristics are maintained although the actual fluidity of the intercrystalline cement no doubt diminishes steadily with decreasing temp. The allotropic modification which occurs at Ar_3 affects the crystals alone without altering the character and properties of the cement; as a consequence of the allotropic change, the crystals become very considerably weaker, so that the relative importance of crystals and cement from the point of view of strength is reversed after passing Ar_3; the crystals now being relatively weak, yield first, while the cement is relatively hard and stiff. This change makes itself felt in two ways: in the first place, the tenacity-temp. curve drops suddenly and follows a totally different course from that which governed its path in the γ-region, and in the second place, the strength of the material is now very largely dependent upon the crystal-size,

since the proportion of the harder and stronger cementing material is much higher in a fine-grained structure than in a coarse-grained one, and the presence of this harder material makes itself felt more directly, and also indirectly by acting as a stiffening which resists the tendency of the crystals to undergo plastic deformation. The fact that this influence of crystal-size is really due to the presence of an amorphous cement is further confirmed by the observations which show that if the rate of straining is extremely slow the influence of crystal-size practically disappears, this being in accordance with the view that at these slow rates of straining the cement even at this lower temp. will undergo viscous flow. The allotropic change at Ar$_2$, although clearly indicated by discontinuities in all tenacity-temp. curves, does not make itself felt very strongly in any of the observations, and beyond the fact of establishing the existence of a mechanical discontinuity the observations throw little light on the nature of the change from β- to α-iron. The bearing of the results of these observations on the allotropic theory of the hardening of steel is of some interest. An inspection of the temp.-tenacity curves clearly shows that the allotropic change at Ac$_3$, or Ar$_3$, brings with it the greatest change in mechanical properties. The question whether the β-modification of iron plays the principal part in the hardening of steel is still an open one. The shape of the curve does not justify any very definite extrapolation towards the ordinary temp., although it seems tolerably certain that if the γ- or β-curve could be produced down to the ordinary temp. it would correspond to material very much harder than α-iron. Whether, however, these two curves would retain their relative positions, thus making the γ-iron the harder at the ordinary temp., or whether the two curves may cross, cannot be concluded from these observations. All that can be definitely said is that at least one important transformation takes place in iron at a temp. near 900°, and that this transformation results in the formation of a considerably harder and stronger body, usually called γ-iron. A similar but much smaller change is indicated definitely at the temp. of Ar$_2$, and it is difficult to reconcile the occurrence of such a discontinuity with C. Benedicks' theory which regards β-iron as a soln. of γ-iron and α-iron. On the other hand, the observations, apart from the mechanical discontinuity, do not indicate any very striking difference between β- and α-iron.

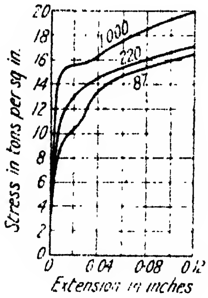

FIG. 205.—The Effect of Grain-size on the Stress - Elongation Curves.

R. Arrowsmith's observations on the effect of grain-size on the extension of armco iron at the yield-point are summarized in Fig. 205, for a sample annealed at 1050° for 7 hrs. when the number of grains was 87 per sq. mm., annealed at 920° for 90 min. when 220 grains per sq. mm. were present, and annealed at 770° for 19 hrs. when 1000 grains per sq. mm. were present. F. C. Thompson found that for a number of metals the elastic limit, E, is very nearly $E=1{\cdot}5n\sigma/d$, where n denotes the number of crystals per sq. cm., σ denotes the surface tension, and d denotes the thickness of the intercrystalline film. This expression assumes that the elastic limit is a measure of the strength of the intercrystalline junctions. Sufficient data are not available for satisfactory tests. The subject was discussed by W. von Moellendorff and J. Czochralsky, and T. W. Hardy. H. Hanemann and R. Hinzmann found only a slight variation in the tensile strength of steels with a grain-size ranging from 90 to 25,000μ^2.

W. S. Farren and G. I. Taylor found an increase in the internal energy of the metal in an overstrained state, and with mild steel they estimated an increase of 14 per cent. of the work done. Confirmatory results were obtained by H. Quinney. P. Lasareff said that the elastic limit of iron is proportional to $N^{5/8}$, where N is the number of atoms per c.c. The theoretical basis of the formula means that the intercrystalline forces can be neglected, the intermolecular force is proportional to the atomic concentration and a certain power, the same for all metals, of intermolecular distance—*vide supra*, hardness. E. Marke, T. Morris, W. E. Koch, T. H. Beare, W. M. Wilson and W. A. Oliver, and R. R. Kennedy and G. J. Oswald found that titanium, even in small proportions, considerably lessened the grain-growth, and H. Hanemann observed that with graphite present as coarse grains, the tensile strength of iron was 10 to 14 kgrms. per sq. mm., whilst it was 20 to 24 kgrms. per sq. mm. when present as fine grains. See hydrogen, for the effect of that element.

E. H. W. Tafel and H. Scholz discussed the distribution of the stresses in test-bars of different shapes. L. H. Appleby, W. Ast, C. Bach, C. Bach and R. Baumann, W. Bagshaw, J. Barba, T. H. Beare and W. Gordon, A. L. Boegehold, H. Bornstein, H. Brearley, P. Breuil, R. Buchanan, R. H. Cabena, R. C. Carpenter, F. J. Cook, A. H. Dierker, J. W. Donaldson, J. Durand, H. J. French, W. Gordon and G. H. Gulliver, W. Hackney, P. A. Heller, H. A. Holz, H. M. Howe and co-workers, H. Hubert, T. H. Johnson, B. Kirsch, P. Kreuzpointer, R. Kühnel, O. Leyde, J. T. Mackenzie, J. D. Mackinson, R. S. MacPherran, A. Martens, A. Mesnager, R. Moldenke, J. Muir, A. L. Norbury, P. Oberhoffer and W. Poensgen, D. A. Oliver, J. G. Pearce, A. Portevin and co-workers, A. Pouilloux, J. S. G. Primrose, P. Reusch, G. H. Roberts, E. V. Ronceray, W. H. Rother and V. M. Mazurie, M. Rudeloff, F. Sauerwald, H. B. Seaman, J. Seigle, J. Shaw, H. H. Shepherd, T. G. Staub, A. le Thomas and R. Bois, W. C. Unwin, E. R. Verity and A. Binns, G. B. Waterhouse, G. Welter, T. D. West, M. O. Withey, and W. Wood examined the influence of the form of the test-pieces on the results; E. P. Withrow and L. C. Niedner, and J. G. Pearce, the effect of machining and removal of skin; R. H. D. Barklie and H. J. Davies, the effect of films of electrodeposited metals; E. G. Coker, the effect of polishing; F. J. Cook, K. L. Zeyen, J. and L. Treuheit, and J. E. Stead, the mode of casting; J. E. Hurst, the effect of temp. of casting—*vide infra*; J. Bauschinger, B. Blount and co-workers, H. Stradtmann, J. T. Bottomley, H. Lebasteur, E. Maitland, the effect of the time of loading on the results; and O. Bauer, K. Hopfer, O. Knaudt, A. Pomp and S. Weichert, R. L. Templin, L. C. Tyte, H. Wald, and F. Wüst and W. C. Huntington, the degree of accuracy attainable in the tests.

A. Pomp measured the effect of cold-work on the tensile strength, in kgrms. per sq. mm., and Brinell's hardness of electrolytic iron, and of iron with 0·03 per cent. carbon; 0·01, silicon; 0·29, manganese; 0·028, sulphur; and 0·019, phosphorus. The results are indicated in Table XIX. F. C. Thompson and

TABLE XIX.—EFFECT OF COLD-WORK ON THE MECHANICAL PROPERTIES OF IRON.

	Thickness		Tensile strength		Hardness		Elongation per cent.
	mm.	Decrease per cent.	per cent.	increased		Increase—per cent.	
Electrolytic Iron	4·0	0·0	24·7	0·0	52	0·0	41·5
	3·5	12·5	28·8	16·6	78	50·0	34·2

	2·0	50·0	61·3	88·1	159	165·5	6·0

W. E. W. Millington studied the effect of varying diameters on the elastic constants of wires, and found the results indicated in Table XX. R. L. Sanford and co-workers also found that the effect of wear on steel wires is to increase the tensile strength per unit area.

TABLE XX.—THE EFFECT OF VARYING DIAMETERS ON THE ELASTIC CONSTANTS OF WIRES.

Diameter (inch)	Tons per sq. inch			Percentage elongation in $4\sqrt{\text{area}}$	Reduction of area (per cent.)
	Elastic limit	Yield-point	Maximum stress		
0·300	18·0	24·0	34·5	35·0	62·0
0·232	18·0	23·9	35·1	35·1	63·2
0·176	18·6	24·0	34·7	35·3	64·0
0·128	17·0	22·8	35·0	36·0	66·3
0·092	17·0	21·8	34·6	36·8	67·4
0·064	16·3	20·4	34·2	39·2	69·1
0·040	15·6	19·8	34·1	41·4	70·3
0·036	15·2	20·0	34·1	42·5	71·2

P. Goerens represented the effect of cold-work in terms of percentage reduction of area on the tensile properties of a soft basic Bessemer mild steel, on a medium steel, and on a hard steel, by Fig. 206—the dotted curves refer to percentage elongations, the others to tensile strengths. P. Goerens gave for the elastic modulus $E \times 10^6$ kgrms. per sq. cm. for drawn wire, and $E^1 \times 10^6$ for the annealed wire :

Carbon . .	0·07	0·12	0·27	0·55	0·62	0·78	0·98 per cent.
Drawn . .	96·5	70·4	70·4	86·5	44·3	58·5	32·8 ,,
$E \times 10^6$ . .	2·00	1·985	1·99	2·00	2·00	2·00	1·98
$E^1 \times 10^6$ . .	2·00	2·01	2·02	2·05	2·09	2·19	2·01

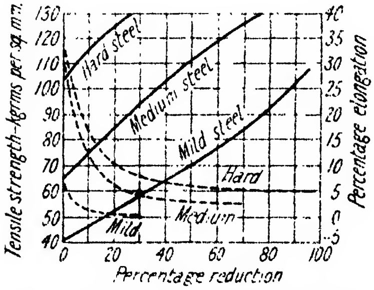

FIG. 206.—The Effect of Cold-work on the Tensile Strength of Steel.

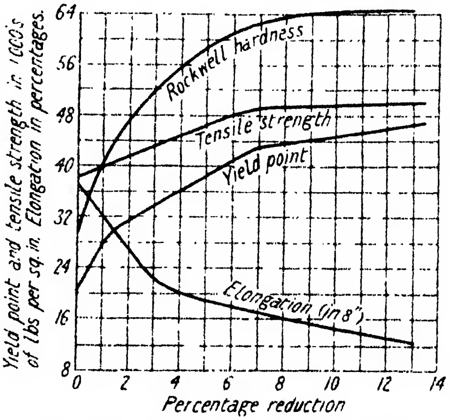

FIG. 207.—The Effect of Cold-work on Armco Iron.

R. M. Brown found that cold-drawing does not much affect the elastic modulus of iron and steel, but it may double the tensile strength. For mild steel, the limit of proportionality is increased by cold-drawing. H. Eicken and W. Heidenhain found that with a 0·26 per cent. carbon steel, with a 15 per cent. reduction in diameter, the tensile strength rose from 85 to 180 kgrms. per sq. mm. R. L. Keynon's results with armco iron are summarized in Fig. 207. Observations were made by I. Adachi, F. J. Cook, W. Broniewsky and J. Krol, C. A. Edwards and J. C. Jones, E. Fangmeier, J. Feilen, J. R. Freeman and A. T. Derry, R. Giraud, K. Honda and R. Yamada, E. J. Janitzky, W. Knackstedt, W. Köster and H. Tiemann, E. Marke, A. de Marneffe, F. S. Merrills, R. W. Miller, F. Pacher and F. Schmitz, L. B. Pfeil, A. Pomp, A. Pomp and W. Albert, W. Püngel, S. H. Rees, E. L. Rhead, W. Rosenhain, F. Sauerwald and co-workers, T. Swinden and G. R. Bolsover, and R. L. Templin. E. Grüneisen gave $E \times 10^6 = 1{\cdot}329$ for cast steel with 2·7 per cent. of graphite and 0·8 per cent. of combined carbon, and $E \times 10^6 = 1{\cdot}050$ for cast iron with 3·0 per cent. of graphite and 0·5 per cent. of combined carbon. For the relation between tensile strength and hardness, *vide supra*, Table XIX. L. Rürup examined the changes in composition of steel during mechanical treatment, and found :

	Total C	Combined C	Mn	P	Si
Crucible steel . . .	0·804	0·80	0·249	0·030	0·201
After rolling . . .	0·800	0·78	0·263	0·0465	0·0238
Annealed wire . . .	0·801	0·775	0·2625	0·0415	0·235

F. Schmitz gave for the averages of 200 basic steel bars, and 200 acidic steel bars, with carbon ranging from 0·45 to 0·54 per cent. :

	Elastic limit (kgrms. per sq. mm.)	Breaking stress (kgrms. per sq. mm.)	Elongation (per cent.)	Reduction area (per cent.)
Basic steel . .	38·46	71·73	16·83	40·58
Acidic steel . .	39·93	72·39	16·49	36·07

A. Sattmann studied the effect of the mechanical treatment of acid and basic steel ingots. The acid steel had 0·19 per cent. of carbon, a tensile strength of 26 tons per sq. in., an elongation of 24·5 per cent., and a reduction area of 59 per cent.; whilst the basic steel had 0·15 per cent. of carbon, a tensile strength of 22·8 tons per sq. in., an elongation of 28·5 per cent., and a reduction of area of 65 per cent. When reduced at different temp., by a rapid-striking hammer, from a thickness of 0·39 in. to one of 0·35 in., the mechanical properties were those indicated in Table XXI. The acid metal hammered at 200° could be bent double when cold, but showed small cracks at the bend; that hammered at 320° (blue-heat) broke when bent at an angle of 20°. The basic metal with a similar treatment could be bent double but showed slight cracks. The bars subjected to a temp. of —19°, had a lower tensile strength but a much greater elongation and reduction of area than the bars treated at slightly higher temperatures. The best temp. for the mechanical treatment of ingot metal would appear to be that of a bright red-heat. The effect of annealing the hammered bars is shown in Table XXII. The bars, which had been treated at a bright white-heat, became much softer and more ductile by this treatment; but those treated at somewhat lower temp. were not softened to so considerable an extent. The results show that heating the material to a yellow- or a blue-heat has no influence on the properties of the cooled-down bar. Heating

TABLE XXI.—MECHANICAL PROPERTIES AFTER HAMMERING AT DIFFERENT TEMPERATURES.

Temperature (degrees C.)	Acid metal			Basic metal		
	Tensile strength (tons per sq. inch.)	Elongation (per cent.)	Reduction of area (per cent.)	Tensile strength (tons per sq. inch)	Elongation (per cent.)	Reduction of area (per cent.)
− 19	26·3	15	59·8	25·2	19·5	64·0

1300	25·7	22	63·9	22·4	30·0	73·0
Not heated	26·0	24·5	59·0	22·8	28·5	65·0
Tested at −19°	25·8	19·0	63·9	23·1	26·5	80·8

to a white-heat affects the quality of the acid metal, but does not appear to have much influence on the basic metal. The effect of heating the hammered bars to various temp. and then plunging them into water at 6° is shown in Table XXIII.

TABLE XXIII.—THE EFFECT OF QUENCHING HAMMERED BARS FROM DIFFERENT TEMPERATURES.

Temperature (degrees C.)	Acid material			Basic material		
	Tensile strength (tons per sq. inch)	Elongation (per cent.)	Reduction of area (per cent.)	Tensile strength (tons per sq. inch)	Elongation (per cent.)	Reduction of area (per cent.)
200	24·3	22·5	65·3	23·9	26·0	65·5
320	24·2	24·6	65·6	23·6	28·0	69·4
600	26·5	16·0	62·7	24·9	22·0	67·3
800	36·4	13·0	54·8	38·3	14·5	56·6
1000	31·3	20·0	66·6	29·3	15·0	69·1
1100	32·2	20·0	61·1	29·6	15·0	63·6
1300	39·8	10·0	43·6	30·7	12·0	65·5

In both cases there is a first maximum tensile strength at 800°, followed by a drop and then by a further increase. The basic steel heated to a blue-heat gave much better results on testing than did the acid metal. With the exception of the bars heated to a white-heat, annealing softened the metal completely. Those heated to the temp. of 1300° still remained hard even after this annealing. J. Czochralsky, L. Guillet, Z. Jeffries and R. S. Archer, F. Körber, F. Körber and K. Wallmann, A. Lundgren, W. Püngel, T. F. Russell, F. Sauerwald, and C. W. Yearsley discussed the effect of cold-work on the tensile properties of steel; H. van de Loo, the effect of pickling and galvanizing; and K. Honda, the effect of the forging temp. on the tensile strength.

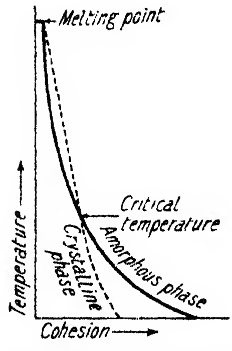

FIG. 208.—Idealized Tensile Strength Curves for Amorphous and Crystalline Materials.

Z. Jeffries and R. S. Archer assume that the effect of temp. on the tensile strength of metals agrees with the assumption that the cohesion depends on the relative magnitudes of (i) the intercrystalline cohesion, *i.e.* the cohesion of the assumed amorphous material between the grains, and (ii) the intercrystalline cohesion, *i.e.* the cohesion within the crystal grains. Analyzing the curves of the relation between the rupture strength and temp. with metals which suffer no allotropic change within the range of temp. considered, Fig. 208,. has shown that (i) at the higher temp., the intercrystalline cohesion is the smaller of the two, so that rupture occurs along the grain boundaries. Plastic deformation or viscous flow is characteristic of amorphous materials, and it resembles the flow characteristic of that of liquids, where the viscosity is very large at low temp. Whilst the rupture strength of a crystal depends on temp. and is independent of the duration of loading, the resistance to the deformation of an amorphous body varies with the rate and duration of loading. A large load exerted for a short time is equivalent to a smaller load applied for a longer time. Here, the tensile strength decreases linearly with temp., and can be represented by the relation: $S=S_0-a\theta$, where S_0 denotes the tensile strength at 0°, S, the tensile strength at θ°, and a is a constant showing the rate of decrease of S with temp. Again, (ii) at the lower temp., the intercrystalline cohesion is the smaller of the two, so that rupture occurs across the grains themselves. Here, the tensile strength increases very rapidly with temp. and the relation between temp. and tensile strength, S, was found by D. H. Ingall to be best represented by an exponential equation. There is a temp. at which the two forms of cohesion are equal—*the critical cohesion temperatures.* In accord with the suggestion that metals behave as if they are composed partly of a crystalline and partly of a viscous solid, and that the viscous flow occurs at the higher temp., and the critical cohesion temp. marks the minimum limiting temp. for viscous flow, D. H. Ingall said :

> For this reason it is suggested that the straight line or lower temperature curve is the all important one to the engineer, for, at a temperature beyond it, that is, beyond the critical inflection temperature which limits it, a metal or alloy will only be of mechanical use when it is subjected to a stress which is insufficient to overcome the resistance to flow due to friction, etc., or a cycle of stresses which do not give time for flow.

S. Dushman represented the relation between the tensile stress, S, and the absolute temp., T, by the exponential equation : $S=S_0e^{A/T}$, where, by analogy with numerous other chemical and physical reactions, the term A can be represented by Q/R, where R is the gas constant 1·986 cals., and Q denotes the heat, or may be energy, of the reaction per gram-atom or gram-molecule at the absolute temp. $T=0°$, or it may be the heat of the evaporation per gram-atom or gram-molecule respectively. S. Dushman and I. Langmuir also represented the relation between the rate of diffusion of metals into one another as a function of temp., so that if D denotes the diffusion constant at $T°$ K., and D_0 a constant, then $D=D_0e^{-Q/RT}$, where Q denotes the heat of diffusion per gram-atom or gram-molecule. When, say, zinc diffuses into iron, the diffusion occurs by an interchange of adjacent atoms, Q may be regarded as the energy required for a gram-atom of zinc to replace an equivalent amount of iron.

If Q denotes the latent heat of evaporation, then, according to L. Boltzmann's hypotheses—**1.** 12, 9—the amplitudes of vibration of the different atoms are not equal, but vary from zero to infinity in accord with a definite distribution law. Consequently, at any given temp., there are some atoms for which the energy of vibration is in excess of that required to separate them completely from the space-lattice, and the probability of the occurrence of atoms of such a high energy content will govern the rate of evaporation, so that if P denotes the probability that an atom will evaporate at the temp. T, then $P=P_0e^{-Q/RT}$, where $P=P_0$ when T attains its maximum value, *i.e.* when the temp. is indefinitely large. Here, P decreases as T decreases. Hence, continued S. Dushman, the probability that an atom in a grain boundary will be able to move past an adjacent atom is proportional to $e^{-Q/RT}$, where Q denotes the energy involved in this motion per gram-atom of the metal. The tensile strength is a measure of this probability, and thus the variation of tensile strength with temp. assumes the form indicated above. R. Becker studied the plastic deformation of crystals from the crystallographic point of view. He said :

> Under the action of shearing stresses there occurs a gliding of the material on definite crystallographic planes, and in some cases also the direction of gliding within the surface is determined crystallographically. The lowest shearing stress required to initiate the gliding is known as the elastic limit. . . . This limit is never measured exactly ; it is possible only to state that load which, with the measuring arrangement used, is just sufficient to produce an observable extension. . . . We assume that on the body to be deformed we apply such a load that on the crystallographic gliding plane a shearing stress, s, is effective which is less than the limiting stress, S, and we consider especially a definite gliding plane. In consequence of the irregular thermal motion, the force acting along the gliding plane will undergo irregular oscillations about the average value, s. If now the limiting value, S, is exceeded for a short time, a gliding action will suddenly be started during such an instant. . . . The plasticity of a crystal is thus affected by thermal oscillation phenomena, which leads to the consequence that at one instant gliding will occur on one plane and at another instant on another plane, the occurrence of gliding on any particular plane being governed by the law of probability.

He then calculated the rate of plastic deformation, U, and found that it can be represented by $U=U_0e^{-a(S-s)^2}/RT$, where a is a constant connected with the elastic modulus, and the quantity $a(S-s)^2$ represents an amount of energy equivalent to Q in the preceding equations. J. Frenkel assumed that gliding is similar to that of two toothed surfaces, but R. Becker objected that if so, a stress, S, would be required to produce a shearing break and not a plastic deformation. It is characteristic of plastic deformation that it must proceed with a definite velocity. W. Rosenhain stated that when mild steel undergoes plastic deformation, 10 per cent. of the work done is converted into heat, and the remainder does internal work of some kind. The subject was investigated by H. Quinney, W. S. Farren and G. I. Taylor, and C. H. M. Jenkins and M. L. V. Gayler. W. Braunbek has tried to describe the phenomena of fusion, and ionic conductivity in accord with L. Boltzmann's probability theorem.

According to P. Ludwik, the physical properties of metals, not alloys, when plotted against equal fractions of their absolute m.p., almost coincide—*e.g.* if the absolute m.p. of a metal be 1255°, the metal at half this temp. has nearly the same tensile strength as another metal at half the absolute temp. of its own m.p. M. Plaut said that the elastic properties of metals indicate that the force required to displace a particle in a solid is small for small displacements, increases linearly up to the limit of proportion, and then increases more slowly up to a maximum, after which, it falls, ultimately becoming zero when the cohesion is overcome. The area beneath the resulting curve gives the work of separation; and the work of separation is given by the heat of sublimation. The tensile strength of solids falls below the values calculated from this assumption, although the Brinell's hardness is approximately proportional to the heat of sublimation except in the case of substances with a marked cleavage—*e.g.* graphite has a large heat of sublimation but is weak in one direction. The increase in the hardness of cold-worked metals is not explained on this hypothesis.

E. Grüneisen-derived an equation of state for solids, and calculated values for the cohesive forces between atoms—$6{\cdot}25\times10^{11}$ dynes per sq. cm. for iron, and $6{\cdot}02\times10^{11}$ dynes per sq. cm. for nickel. G. Tammann found that with iron, slip-bands appeared with a stress of 2370 kgrms. per sq. cm. when the elastic limit was 5840 kgrms. per sq. cm. The corresponding numbers for nickel were 788 and 5570; and for lead, 25 and 102. R. F. Mehl studied the interatomic forces of metals; and G. Moressée, *La resistance des matériaux, résultante des forces atomiques*, and from the dynamics of the rotation of the atoms, and other assumptions, calculated a value for the elastic limit and its variation with temp. He thus calculated the elastic limit of iron, at absolute zero, to be 2300 kgrms. per sq. cm.; at 15°, 1400 kgrms. per sq. cm.; and at 1027°, 368 kgrms. per sq. cm. For steel, he calculated:

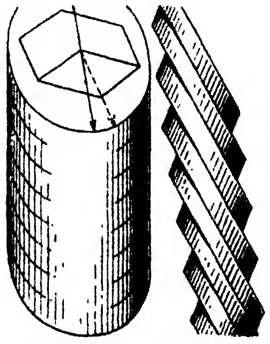
	200°	400°	600°	800°	1000°	1200°	1300°
Elastic limit .	3160	2440	1800	1240	480	200	0

M. Born calculated values for the cohesive strength of ionic lattices, and obtained values for the energy of the lattice, U per gram-molecule, of the alkali halides in agreement with observation. J. E. L. Jones and co-workers were also able to deduce values for the elastic moduli, and the surface energy. This also shows that an approach is being made to obtain a theory of cohesion based on atomic structure. M. Born, indeed, assumed that the mechanical cohesion of the space-lattice, and the chemical attraction of the ions are one and the same. F. Zwicky calculated the theoretical rupture or tensile strength from the lattice energy U. There is a marked discrepancy between the measured tensile strength, and the calculated cohesive force. This was discussed by S. Dushman. The explanations of G. Cook, E. Goens and E. Schmid, A. A. Griffiths, K. Hohenemser and W. Prager, E. Jaenichen and F. Sauerwald, T. M. Jasper, A. Joffe, H. Kotte, P. Nemenyl, M. Polanyi, W. Prager, H. Reissner, W. Schmidt, A. Schob, H. Tertsch, and J. H. C. Thompson, A. V. Stepanoff, H. Mussmann, W. Fahrenhorst and E. Schmidt, O. Manfred, and W. Widder are in agreement with that of A. Smekal, who said:

> The only logical conclusion to account for the difference between technical and theoretical rupture strength of materials is the assumption that ordinary technical materials are far from being homogeneous, as we have always assumed, but that they have many fine, microscopic and submicroscopic holes, cracks and other inhomogeneities, which decrease the technical strengths as compared with the molecular strength. The former is thus determined on the basis of a microscopic stress distribution, behind which there is hidden a quite different sort of microscopic stress distribution which depends on the inhomogeneities present in the material. . . . The old experience that coarsely crystalline material possesses a lower (technical) strength than finely crystalline, thus receives a very obvious explanation. If this view is correct, the strength of any material should be considerably increased if care is taken to reduce to a minimum the occurrence of cracks and other inhomogeneities by choice of correspondingly small dimensions and careful thermal treatment of the body under test. In fact it has been known for a long time, for example, that very thin wires are much stronger than thicker wires ; in the ideal limiting case of a single chain of molecules, the rupture strength would become of the same magnitude as the molecular strength. . . . From the above remarks we must conclude that the technical strength does not represent, in general, a physical constant characteristic of a given material, whereby the practical significance (of such a value) is naturally not taken into consideration. The physicist requires for his purpose a modification of the material which is as free from flaws as possible and reproducible in every respect, and that is the *single crystal*. As a matter of fact, it is found that not only the rupture strength but also, as has been shown by G. von Hevesy, the electrolytic as well as thermal conductivities are quite different in the polycrystalline state from those of single crystals.

and with that of F. Zwicky, who said :

> A. Smekal thinks that actual crystals are never of an ideal geometrical structure, but are made up of a great many microscopic blocks leaving cracks and other imperfections between them. We might call such a structure a mosaic crystal, according to a term used by P. P. Ewald. A. Smekal correlated this conception with a great many facts such as electric conductivity, electric strength, photo-electric absorption, etc. He succeeded in determining the size of the elementary blocks in a half empirical way, and he found that they contain in the case of rock-salt and in many other cases about 10,000 atoms each. As A. Smekal's considerations enable us to understand a great number of facts, it has to be concluded that the formation of cracks and blocks cannot be of a purely accidental nature. Otherwise, the surface cracks should occur in all kinds of different sizes on different samples. But then, it is impossible to understand why the technical breaking strength is a relatively well-defined quantity, as the different samples of a crystal would break on application of widely varied specific stresses.



Basal plane before slip *Lateral view after slip*

Fig. 209.—Mechanism of Slip with Crystals of Zinc.

According to A. Smekal, the rupture strength of a single crystal must increase with a decrease in the dimensions of the crystal until it approaches molecular strength, and that for any given material there is an upper limit for these dimensions. Z. Jeffries found the tensile strength of a tungsten ingot of diameter 200×25 mils. to be 18,000 lbs. per sq. in., of a swaged rod 26 mils. diam., 215,000 lbs. per sq. in., and of a drawn wire 1·14 mils. diam., 590,000 lbs. per sq. in.—by extrapolation, in the limiting case as the diameter approaches atomic dimensions, the tensile strength will approximate 800,000 lbs. per sq. in. A. A. Griffiths, M. Polanyi, and A. Smekal showed that the rupture strength, S, is related with the surface energy, σ, by an expression analogous with $Sl > 2\sigma$, where l denotes the elongation, or grain diameter. The calculated value of l, about 5×10^{-6} cm., is about 500 times greater than the distance at which the attractive forces between the atoms should vanish. To evade the difficulty it was assumed that the rupture strength increases when the elongation required for rupture is less than 5×10^{-6} cm. This means that the rupture of a single crystal is not a definite magnitude corresponding with the cohesive forces. With single crystals of zinc, the round wire during elongation becomes a flat ribbon, the width of the ribbon being slightly greater than that of the original wire. G. Masing and M. Polanyi represented the mechanism of the slip of single crystals of zinc by Fig. 209. The diagram on the left represents the basal plane; the large arrow indicates the direction of maximum shear, and the small arrow lying in a direction parallel to one of the prism sides gives the direction of slip. The elongation is accompanied by a continued strengthening of the crystal, due, according to M. Polanyi, to the bending of the slip planes so that the resistance to slip is increased. M. Polanyi suggested that this result is due to changes in the crystal units themselves; whilst W. Geiss and J. A. M. van Liempt attribute the phenomenon to the deformation of the atoms. The subject was discussed by W. Rosenhain and J. McMinn. D. A. G. Bruggeman discussed the elastic anisotropy of iron.

Observations show that there is an increase in the rupture strength with increasing fineness of grain, and there is a further increase by cold-working. M. Polanyi, and E. Schmid showed that the rolling or drawing of a metal does not destroy the crystal unit, but there is merely a re-orientation of certain planes so that they lie in the direction of the axis of the wire or the plane of rolling--*vide supra*, the crystals of iron. The crevices in the lattice structure of the crystals are independent of temp., and the relation between surface tension and rupture strength, indicated above, means that the effect of a variation of temp. in the one case will be attended by a similar effect in the other case. Surface energy decreases almost linearly with temp., and the tensile strength should therefore follow a similar relation. Surface tension increases with a decrease in grain-size, and this is also the case with the tensile strength. If there be no great variation with temp. in the cohesional forces between atoms, the latent heat of evaporation will be a measure of the lattice energy, but the latent heat of evaporation decreases almost linearly with temp., so that the cohesive strength should similarly decrease with temp.

There is an increase of the free energy of a metal when it is hardened by deformation. Z. Jeffries and R. S. Archer found that cold-work increased the tensile strength, the yield-point and the hardness, while the elongation and reduction of area are decreased by it. The cold-worked metal, however, immediately after working has a lowered elastic limit, but there is a recovery to the original value by ageing or by low temp. annealing. The actual treatment necessary for elastic recovery is dependent on the composition of the metal, and the extent of the deformation during the cold-working. G. von Hevesy, W. Geiss and J. A. M. van Liempt, and S. Dushman showed that the diffusion of one element into another is very much less with single crystals than it is with the rolled metal. Diffusion can occur only through an interchange of places among individual atoms owing to thermal agitation and a consequent disturbance of the lattice. In agreement with the failure of diffusion with single crystals, it is difficult to understand how such phenomena could occur in an undisturbed lattice. Diffusion is more rapid with fine crystalline wire than it is with coarse crystalline wire, indicating that the diffusion occurs along the boundaries of the crystal grains. According to R. Becker, lattice disturbances are the necessary condition for the subsequent interchange of position amongst the atoms. At a given temp., these interchanges occur the more frequently the more the structure is unlike that of a single crystal. In recrystallization, the disturbed lattice is restored to the undisturbed state and the mechanism again involves an interchange of position amongst the atoms. The probability, P, of such an interchange is given by $P=P_0e^{-Q/RT}$, where Q denotes the difference in the potential energy of the atoms in the deformed lattice as compared with that in the undeformed lattice. This is in accord with the fact that the temp. of recrystallization is decreased by cold-working, and R. Becker also showed that grain-growth must similarly increase with temp.

The observations of Z. Jeffries, and W. H. Bassett and C. H. Davis show that the rate of grain-growth varies with temp. as indicated by the equation $G=G_0e^{-Q/RT}$, where G represents the average area of the grain. J. Czochralsky, and G. Masing found that the grain-size increases rapidly with temp. at rates which indicate large values of Q. According to S. Dushman, the cold-working of metals also decreases the rate of grain-growth. This corresponds with an increase of Q with working just as was observed for the case of tensile strength tests. This means that the resistance to the motions of the atoms in forming grains is increased by the mechanical working, or, expressing the same idea in other words, the probability that atoms in adjacent grains will readjust themselves to form a continuous lattice is decreased because these grains have been deformed by working.

According to P. Ludwik, cold-working distorts the space-lattice owing to a movement along the gliding planes; an increase of strength is caused by the breaking action of the gliding planes which increases with the magnitude of the deformation until the crystal ultimately becomes homotropic. The detrimental action of alternating stresses is attributed to a reversal of the movement along the gliding planes—*vide supra*, the crystallization of iron. O. W. Ellis discussed the degree of deformation required to produce a decrease of tensile strength in the cold-working of metals. A. H. Leblond found that when steel bars nicked across opposite surfaces are tested in the tensile machine, the fracture occurs along two planes inclined at angles of 45° with the planes of the nicked surfaces, and meeting at an angle of 90°.

The work performed when a test-piece is broken by the tensile test was discussed by M. Born and O. Stern, P. Ehrenfest, M. Ensslin, W. S. Farren and G. I. Taylor, K. Honda, H. Hort, K. Ljungberg, G. Wulff, and M. Yamada. R. Plank discussed the thermodynamics of the heating of metals which attend elastic and permanent deformation. A. Robertson and G. Cook studied the transition from the elastic to the plastic state. According to O. Faust and G. Tammann, the elasticity of a metal can be increased by alternately slowly increasing the pressure beyond the first limit of elasticity, and then releasing it, until finally an upper limit of elasticity, corresponding with the limiting pressure which produces flow in the metal, is reached. The metal has, therefore, been hardened by slowly increasing the pressure. The hardening of metals is ascribed, not to formation of a harder crystalline form, or to a change to the amorphous condition, but to a diminution in the size of the crystallites of which the metal is composed, owing to the formation of systems of sliding surfaces. The hardening is, therefore, a preparation for flowing, the latter occurring when the systems of sliding surfaces have sufficiently increased. The subject was discussed by H. P. Hollnagel, W. Kuntze and co-workers, A. F. Torres, J. Vietorisz, J. G. Docherty and F. W. Thorne, G. Cook, A. Lundgren, H. O'Neil and H. Greenwood, C. Benedicks—see plastic flow; and R. Plank studied the elongation, and the reduction of area in tensile tests; L. Hartmann, the permanent deformation; and R. H. Greaves, and E. L. Hancock, the overstrain—*vide supra*.

J. Russner discussed the relations between the tensile properties, the sp. ht., and the electrical conductivity; J. Divis, the relation between tensile strength and electrical resistance; O. Leyde, F. Wüst and P. Goerens, A. Campion and H. W. Watts, and W. C. Unwin, the relations between structure and composition, and the mechanical properties; and F. C. A. H. Lantsberry, C. W. Yearsley, and M. Kralupper, the mol. changes in steel under tension. H. Sieglerschmidt found that if E denotes the elastic modulus; D, the density; A, the at. wt.; and a, the coeff. of thermal expansion, $E=CD(Aa)-n$, where C and n denote constants.

S. H. Rees observed that there is a slight increase in the maximum load, yield-point, and elastic limit of a strained, 0·85 per cent. carbon steel as a result of annealing at 200°, and a complete recovery on tempering at about 600°. J. R. Freeman and R. D. France found that cold-rolled electrolytic iron had the greatest tensile stress perpendicular to the direction of rolling, and that ductility was highest in the direction of rolling. J. A. van den Broek summarized his results as follows: (i) When mild steel is cold-worked and properly aged or tempered and subsequently tested in the same direction as that of the cold-working, its elastic limit may be raised more than 100 per cent., and from 10 to 20 per cent. beyond the stress at which cold-working was discontinued. (ii) When mild steel is cold-worked in one direction and properly aged or tempered, but tested in either one of two senses of a different direction, then its elastic limit may be raised some 50 per cent. (iii) When mild steel is cold-worked in one direction and properly aged or tempered but tested in the opposite direction, then the elastic limit remains at the value of the original elastic limit, but the yield-point is raised. (iv) When mild steel is cold-worked in any direction and tested in any direction, without any ageing or tempering, then the elastic limit falls below the value of the original elastic limit, often down to zero. (v) Tempering cold-worked steel at temp. from 100° to 300° C., or ageing cold-worked steel, has a tendency to perfect its elastic properties. Tempering merely accelerates the effects of time. The subject was investigated by A. Pomp and co-workers, A. Portevin and E. Pretet, H. Poellein, and E. Mayer.

The orientation of the crystals by cold-work has been discussed in connection with the structure of the crystal lattice of iron. From the observations of M. Masima and G. Sachs, R. G. Karnop and G. Sachs, P. W. Bridgman, and E. Grüneisen and E. Goen, T. Kawai said that in a metal with crystals belonging to the cubic system, it may be assumed that Young's modulus is smallest in the (100)-direction, largest in the (111)-direction, and greater than the mean of these two in the (110)-direction. A polycrystalline metal in which the microcrystals are oriented at random, is isotropic with respect to Young's modulus; but if the metal be stretched or drawn, it becomes aelotropic, for a definite axis of the microscopic crystals takes the axial direction of the bar by rotation due to cold-working. In the case of iron and steel, the (110)-axis of the crystals gradually takes the direction of the axis of the bar by increasing cold-work, and consequently the modulus is slowly increased. With copper, aluminium, and nickel, the (111)-axis of the microcrystals takes the axial direction of the bar by cold-working, and consequently the modulus is rapidly increased by cold-working.

L. Aitchison and L. W. Johnson examined the effect of testing materials in the direction of rolling or forging, and in other directions. The fibrous structure, frequently obvious in rolled steel, can be compared with the grain of wood, so that directions which are taken longitudinally and transversely to the directions of rolling can be said to be taken *along the grain* and *across the grain* respectively. A selection from the results is given in Table XXIV. All the samples except that indicated were normalized, and the tensile results are expressed in tons per sq. in. The results show that the values for the elastic limit, yield-point, and maximum stress are almost uniform, the values for the Izod or notched-bar test are different when taken longitudinally and transversely, and the value for the notched-bar test taken longitudinally increases as forging progresses. The fatigue strengths of specimens taken parallel and at right angles to the grains do not show large differences, but the difference is in favour of the longitudinal material; thus:

TABLE XXIV.—MECHANICAL PROPERTIES OF STEEL TAKEN LONGITUDINALLY AND TRANSVERSELY.

T. D. Yensen found that for electrolytic iron, melted in vacuo, the limits of proportion were 11 kgrms. per sq. mm.; the tensile strength, 25 kgrms. per sq. cm.; the elongation, 60 per cent. on a 50·8 mm. test-piece; and the reduction of area, 85 per cent. The effect of carbon has been the subject of numerous investigations. J. O. Arnold, working with steels containing 0·03 to 0·08 per cent. of silicon; 0·01 to 0·10, manganese; 0·02, phosphorus; 0·01 to 0·03, sulphur; and 0·02 to 0·04, aluminium, obtained for the tensile properties, in tons per sq. in., of rolled bars, *R*, normalized by heating to 1000° and cooling in air; and of bars annealed for 72 hrs. at 1000°, *A*, and cooled in the luted muffle for 100 hrs. with

The annealed steels with 1·20 and 1·47 per cent. of carbon included respectively 0·28 and 1·14 per cent. of graphitic carbon. C. R. Jones and C. W. Waggoner found the stress deformation shown in Fig. 210; and the mechanical tests, expressed in lbs. per sq. in., for steels with 0·14 to 0·17 per cent. of manganese; 0·15 to 0·19. silicon; 0·010 to 0·013, phosphorus; and 0·012 to 0·014, sulphur, as well as for iron with 0·058, carbon; 0·071, manganese; 0·008, silicon; and a trace of phosphorus, when they were annealed for 2 hrs. at 1000°, and cooled in the furnace, are:

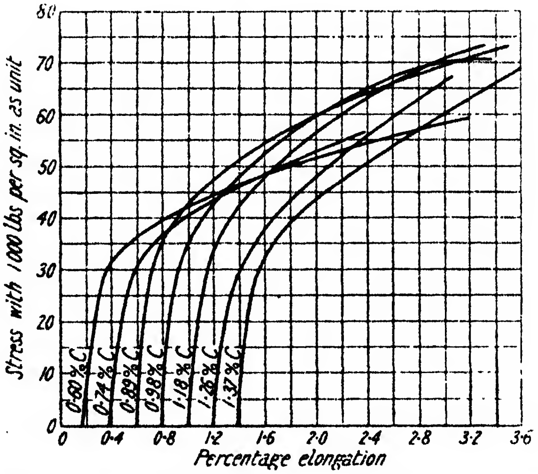

FIG. 210.—Stress-Elongation Diagram for Steels with Different Proportions of Carbon.

T . . .	12 to 15	10 to 12	8 to 10	5 to 10

According to E. J. Rang, the effect of increasing the proportion of carbon is to increase the elastic limit and ultimate tensile strength of steels; with very high carbon steels, the elastic limit is indefinite because, under load, the elastic limit is continuously being reached, and the small amount of cold-work thus done on the bar forms a new elastic limit. As a result, the stress-strain curve, though continuous, is not a straight line. The subject was discussed by E. H. W. Tafel, J. Dessent, J. O. Arnold, C. R. Jones and C. W. Waggoner, and W. A. Scoble. M. Moser said that during elongation in the tensile test, steel does not flow uniformly, but in zones. Each zone stretches at first until a certain degree of hardness is attained and then remains nearly stationary with the hardness unaltered until another zone elongates. Only when all the zones in the test-piece have been elongated does a further uniform increase in hardness set in over the whole elongated part. E. Schüz, etc., studied the relation between the tensile strength and hardness (*q.v.*), and they found that the tensile strength in general increased with the proportion of combined carbon; and M. Hamasumi, that the tensile strength increased with the rate of cooling. A. Pomp and A. Lindenberg studied the effect of nitrogenization. For the embrittling effects of occluded hydrogen, *vide infra*, corrosion. J. V. MacCrae and R. L. Dowdell studied the effect of deoxidation on the tensile strength of cast steel.

C. R. Jones and C. W. Waggoner added that all the curves for maximum strength or tenacity have the general form predicted by H. M. Howe from a consideration of the microscopic constituents. His curves show a maximum at or near the eutectoid ratio for the iron-carbon diagram. B. Stoughton has suggested that the intimate mixture of the crystalline constituents when the steel is near the eutectoid ratio has the effect of increasing the molecular attraction between the crystals, thus raising the maximum strength of the material; for below the eutectoid the pearlite is surrounded by a network of soft ferrite, while above it is surrounded by a network of cementite, both of these networks having a weakening effect upon the attraction between the molecules of the crystals. Although the experimental maximum seems to occur at a lower percentage of carbon than predicted by H. M. Howe, the curves show a strong confirmation of the theories of H. M. Howe, and B. Stoughton. The results indicate that pure iron should have a tensile strength of about 40,000 lbs. per sq. in., and that the tensile strength of the series of annealed crucible steels tested increased about 630 lbs. for each 0·01 per cent. of carbon up to 0·89 per cent., after which the strength gradually decreased. The elastic-limit-carbon curves seem to follow the same general law as the maximum strength-carbon curve, the maxima for the curves plotted occurring at the same percentages of carbon. The variation of the stresses at the elastic limit, however, is much less marked than the variation of the maximum strengths, and in other tests that the writers investigated the results were either irregular or showed more than one critical point. The curves for total elongation or ductility, and reduction of area are similar; and indicate that there is a critical point in each corresponding to the percentage of carbon which gives maximum strength. This critical point may represent a minimum value or a marked change in the direction of the curve. E. L. Dupuy's results for the percentage reduction of area with the temp. and percentage of carbon as variables, are summarized in Fig. 211. E. Greulich represented the relation between the reduction of area, ϕ, Brinell's hardness, elongation, or tensile strength, y, by $y=a+b \log \phi$, where a and b are constants.

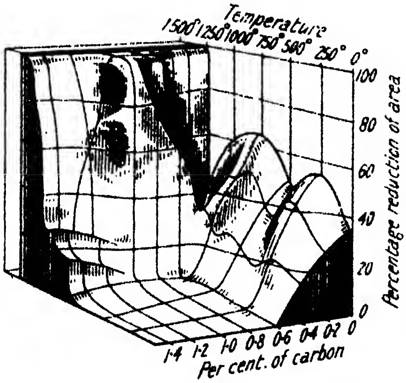

FIG. 211.—The Percentage of Area at Different Temperatures and with Different Proportions of Carbon.

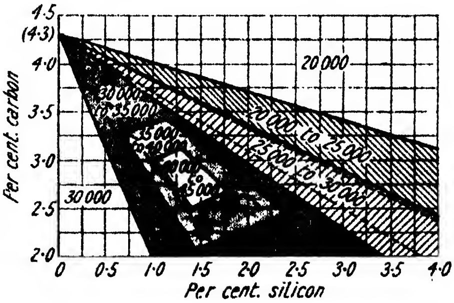

FIG. 212.—Constitution and Tensile Strength of Cast Iron.

According to P. Bardenheuer, and G. Neumann, the form and degree of fineness of the separated graphite are the dominant factors in determining the tensile strength, bending strength, and resistance to shock of grey cast iron as cast, as annealed at 850°, as quenched in oil, and as quenched and then annealed at 600° to 650°. The nature of the ground mass influences the hardness, but the highest tensile strength is obtained with the minimum amount of graphite provided it is evenly distributed throughout the metal in fine flakes. F. B. Coyle studied the tensile strength of cast iron, and found that the results can be represented by diagram, Fig. 212, where the dotted lines refer to E. Maurer's diagram of the constitution of cast iron—*vide supra*, Fig. 58. The numbers in the diagram are intended to represent the tensile strengths of cast irons, expressed in lbs. per sq. in., and whose compositions fall in the regions concerned. Analogous diagrams were prepared for cast irons with 2 per cent. of nickel, and with 0·50 to 0·75 per cent. of chromium, and with combinations up to 0·25 to 1·25 per cent. of nickel and 0·25 to 0·75 per cent. of chromium.

W. R. Webster examined a great number of steels in the attempt to find a relation between the strength of steel and its chemical composition; and the subject was also taken up by H. H. Campbell, who gave the following formulæ: Let C denote 0·01 per cent. of carbon; P, 0·01 per cent. of phosphorus; Mn, 0·01 per cent. of manganese; and *R*, a variable to denote the heat-treatment, then, the ultimate stress in lbs. per sq. in., for acid steel where the carbon is determined by combustion, is $40,000+1000C+1000P+x\text{Mn}+R$; and when the carbon is determined by colour, $39,800+1140C+1000P+x\text{Mn}+R$. While for basic steel, where the carbon is determined by combustion, the ultimate stress is $41,500+770C+1000P+y\text{Mn}+R$, and where the carbon is determined by colour, $42,000+820C+1000P+y\text{Mn}+R$. Table XXV gives the coeff. x for acid steels with over 0·4 per cent. Mn, and Table XXVI, the coeff. y for basic steels with over 0·3 per cent. Mn. Any formula expressing the relation between the strength of steel and its chemical composition can have only a limited application because of the influence of other variable conditioning factors; it is therefore assumed that the conditions of manufacture are similar to those which were employed for the standards from which the formulæ were deduced. Observations on the subject were made by J. Bauschinger, A. C. Cunningham, E. Demange, V. Deshayes, H. M. Howe, J. E. Hurst, J. B. John-

son, H. von Jüptner, A. Kroitzch, H. K. Landis, F. C. Lea, A. Ledebur, W. N. Lipin, M. Merriman, W. Minty, H. O'Neil, B. Osann, F. Osmond, E. Rasch, P. G. Salom, J. K. Smith, R. H. Thurston, H. Wedding, and J. Weyrauch. C. D. Mathews found the tensile strength of grey cast iron with 1·5, 2·0, and 2·5 per cent. of silicon to be respectively 25,600, 24,370, and 24,660 lbs. per sq. in. J. E. Hurst discussed the attempts made to show the relation between the composition and properties of cast iron by formulæ and diagrams.

R. A. Fessenden, G. Wertheim, W. Sutherland, and H. Tomlinson observed a relation between the tensile properties of the metals and their at. vol., and W. C. Roberts-Austen showed that except in cases where chemical combination occurs, the introduction of atoms of elements with a small at. vol. raises the tensile strength of a metal. R. A. Fessenden's relation is Tensile strength$=0{\cdot}5280T_mv^{-4/3}$, where T_m denotes the m.p. of the metal on the absolute scale, and v the at. vol.—*vide* **1.** 13, 17.

J. O. Arnold and A. McWilliam represented the effect of the constitution of steel, on the tensile properties, by diagrams analogous to those of Fig. 213. The *first stage*, I, Fig. 213, contains sorbitic pearlite associated with emulsified cementite, and it is very dark on etching; the maximum tensile strength is about 70 tons per sq. in., and the elongation on 2 ins. is about 10 per cent. The *second stage*, II, Fig. 213, contains pearlite with semi-segregated cementite, and it is dark on etching; the maximum tensile strength is about 55 tons per sq. in., and the elongation on 2 ins. is about 15 per cent. The *third stage* contains laminated pearlite with completely segregated cementite, and it exhibits a gorgeous play of colours when lightly etched; the maximum tensile strength is about 35 tons per sq. in., and the elongation on 2 ins. is about 5 per cent. The *fourth stage* has laminated pearlite passing into massive cementite and ferrite; the maximum tensile strength is about 30 tons per sq. in. The different stages may sometimes be observed in juxtaposition on one piece. R. Hugues, H. Meyer and W. Wesseling, and S. S. Steinberg discussed the effect of heat-treatment on the mechanical properties.

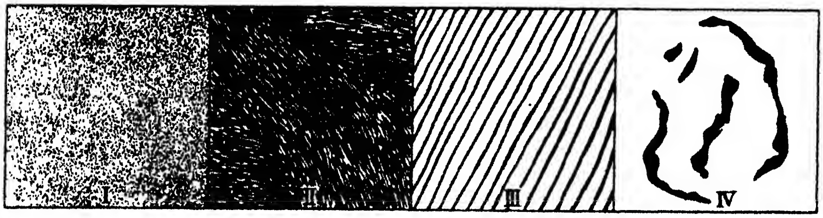

FIG. 213.—Stages in the Formation and Disruption of Pearlite.

O. Bauer and W. Schneider said that the breaking stress of electrolytic iron is not affected by quenching from 650° to 1258° in iced water. H. Hanemann measured the tensile strength, in kgrms. per sq. mm., of some hypereutectoidal steels quenched from different temp., and obtained the results indicated in Table XXVII. The

TABLE XXVII.—THE EFFECT OF QUENCHING TEMPERATURE ON THE TENSILE STRENGTH OF HYPEREUTECTOIDAL STEELS.

results show that for each steel there is a quenching temp. which gives the strongest metal; this temperature rises with the carbon-content, but when it is exceeded, the strength of the metal is impaired. The greatest strength was obtained by quenching in a lead-zinc bath at 300°. Tempering at 350° yielded a steel with a maximum tensile strength, and this agrees with E. Heyn and O. Bauer's observation that a steel heated to 900° and quenched at 14° to 18°, gives a maximum solubility when tempered at 900°. It is therefore suggested that the osmondite structure gives the maximum tensile strength. A. Jung concluded from his observations on the influence of heat-treatment on the tenacity and microstructure of hypereutectoidal steels : (i) The temp. to be employed in hardening hypereutectoid steels are restricted to a definite range, which is lower and narrower the smaller the carbon content. (ii) The ultimate strength increases to a maximum for a given carbon content as the temp. of quenching falls. (iii) For equal quenching temp., the ultimate strength increases with the carbon content. (iv) The same quenching temp. should be used for different media. (v) The greatest strength is attained by quenching in water and then tempering at 350°. (vi) By quenching in water and tempering, a comparatively brittle material, with high tenacity, is obtained; while by quenching in a medium at the same temp. as that employed for tempering, a lower tenacity and greater toughness is obtained. (vii) Different forms of heat-treatment cannot be made to produce identical results ; identity of results can be obtained only for any one property of steel. (viii) The mechanical properties depend on the state of the carbon and also on the structure of the metal. (ix) A martensitic structure gives the greatest hardness, a troosto-sorbitic structure gives the greatest tenacity, while a pearlitic structure gives the great elongation. (x) It was not possible to detect any consistent influence of the carbon content on the mechanical properties of the specimens under the conditions employed. The subject was discussed by L. Faure, M. Kuroda, and A. Pomp and A. Lindenberg.

H. Hanemann and R. Kühnel studied the hypoeutectoidal steels, hardened by quenching at 950°, and then tempered 2 hrs. in water at 100°; 1 hr. in rape oil at 200° ; 40 mins. in a bath of sodium and potassium nitrates at 300°, 400°, and 500°. The results are summarized in Table XXVIII. The tensile strength is expressed in kgrms. per sq. mm. For the 0·34 per cent. carbon steel annealed at 500° after quenching in water, the numbers were respectively 79·9, 15·0, and 51·0, and after quenching in water, 80·1, 15·0, and 51·0; for the 0·65 per cent. carbon steel quenched in oil, 84·7, 10·0, and 51·0; and quenched in oil, 84·7, 9·5, and 51·0. G. Welter found that the mechanical properties vary 10 per cent. by cooling under different conditions.

TABLE XXVIII.—THE EFFECT OF QUENCHING AND SUBSEQUENT TEMPERING ON HYPOEUTECTOIDAL STEELS.

The highest, lowest, and average tensile strength of cast iron given were respectively 9·08, 5·09, 7·19 tons per sq. in.; by E. Hodgkinson and W. Fairbairn, 10·5, 4·9, and 6·83 tons per sq. in.; by W. Wade, 20·5, 4·2, and 9·1 tons per sq. in.; by T. Turner, 15·7, 4·75, and 10·22 tons per sq. in.; by W. C. Unwin, 17·3, 14·9, and 15·7 tons per sq. in.; and by E. Adamson, 13·74, 15·62, and 14·8 tons per sq. in. E. Adamson's results show that with total carbon 3·56 to 3·57; graphitic carbon, 2·98 to 3·04; combined carbon, 0·54 to 0·59; silicon, 1·46 to 2·00; sulphur, 0·072 to 0·11; phosphorus 0·59 to 1·20; and manganese 0·65 to 0·90, considerable variations in the phosphorus, silicon, and manganese makes very little difference to the results. The elastic limit varies with the proportion of combined carbon; if all the carbon is in the combined state, the range of proportionality extends up to the point of fracture even when a pearlitic matrix is present. If the iron contains a small matrix of ferrite when the carbon is wholly graphitic, there is so low an elastic limit that some—*e.g.* I. N. Hollis—say that the material has no well-defined modulus of elasticity, or elastic limit. The yield-point of commercial cast iron also coincides with rupture, so that the elongation and reduction of area are negligibly small. G. A. Akerlind gave 40,000 to 50,000 lbs. per sq. in. for the tensile strength of malleable cast iron and 1 to 6 per cent. for the elongation, and 0·75 to 3·0 per cent. for the reduction of area. Hence, cast iron is about half as strong as the malleable. Observations on the elastic properties of cast iron were made by F. B. Coyle, J. T. Mackenzie, A. Thum and H. Ude, W. R. Needham, J. B. Kommers, E. J. Lowry, J. E. Hurst, K. Emmel, B. Osann, and O. Smalley. C. Frémont said that the elastic limit of cast irons is from one-fifth to three-fifths of that of steel; and the elastic limit occurred with 0·45 to 0·80 per cent. of the ultimate load. According to A. Thum and H. Ude some of the modern cast irons have a tensile strength of 30 kgrms. per sq. mm. where 18 to 20 kgrms. per sq. mm. was formerly thought to be very good. H. A. Schwartz discussed the tensile strength of malleable cast iron. W. C. Unwin gave 19·8 tons per sq. in. for the highest and 12·8 tons per sq. in. for the lowest tensile strength of malleable cast iron. W. H. Hatfield gave for the maximum stress of European or Réaumur's malleable cast iron 19·78 to 27·07 tons per sq. in., 3·5 to 6·0 per cent. elongation in 2 ins.; and 3·5 to 6·0 per cent. reduction in area; and for the American, or blackheart, malleable cast iron, 19·41 to 22·85 tons per sq. in. for the maximum stress, 10·0 to 14·0 per cent. elongation in 3 ins., and 7·7 to 17·5 per cent. reduction in area. H. Hanemann found that with graphite present as coarse grains, the tensile strength of cast iron was 10 to 14 kgrms. per sq. mm., and with the graphite in fine grains, 20 to 24 kgrms. per sq. mm. Many observations have been made on the influence of the separation of graphite on the mechanical properties of cast iron—*e.g.* by A. G. Ashcroft, P. Bardenheuer and K. L. Zeyen, O. Bauer, J. W. Bolton, K. Emmel, C. Gilles, C. Henning, E. Jüngst, P. Kleiber, T. Klingenstein, A. E. Macrae, E. Maurer, A. E. Outerbridge, E. Piwowarsky, H. Rolle, P. A. Russell, J. Seigle, K. Sipp, A. E. M. Smith, R. Stotz, A. Thum and H. Ude, O. Wedemeyer, T. D. West, F. Wüst and co-workers, and A. Zenges—*vide supra*, graphitization. A. Thum and H. Ude suggested that structurally cast iron can be regarded as a "notched steel" because the carbon flakes produce minute notches and so lower the mechanical properties of the metal.

P. Goerens observed the effect of tempering and annealing on cold-worked iron with 0·080 per cent. of carbon; 0·39, Mn; 0·008, Si; 0·056, S; and 0·059, P. The results are summarized in Fig. 214. Tempering at 100° gives a perceptible result, and near 520° there is an abrupt change from about 45 kgrms. per sq. mm. to 40 kgrms. per sq. mm. at 600°, which is about the normal value. The elongation and reduction of area behave in a corresponding way. Observations were made by P. F. Lee and co-workers, H. E. Publow and co-workers, and F. G. Sefing and M. Surls. The effect of the duration of the annealing is summarized in Fig. 215. J. Orland studied the influence of pearlization below the Ar_1-arrest on the mechanical properties. P. Ludwik found for cast iron annealed at 900°, and cast steel annealed at 700°, and tested at the following temp.—the ultimate strength is expressed in kgrms. per sq. mm.:

		20°	225°	335°	407°	617°	807°	835°
Iron	Strength	42·5	45·0	45·0	34·0	13·8	3·8	3·6
	Elongation	21	4	18	21	45	39	—
	Reduction	68	57	61	68	95	89	88 per cent.

		20°	250°	330°	412°	485°	617°	722°
Steel	Strength	53·5	60·2	57·6	55·0	34·7	22·0	10·7
	Elongation	16	5	9	19	20	32	35
	Reduction	63	43	54	55	62	80	63 per cent.

F. C. Lea and O. H. Crowther observed a maximum in the tensile strength, and yield-point of iron at 300°; and F. C. Lea observed a maximum in the tensile strength of armco iron at about 230°, a minimum in the elongation at about 100°, and a maximum at 350°. The elastic limit in tension had a minimum at 230°. H. J. Tapsell and W. J. Clenshaw obtained similar results. E. L. Dupuy found a maximum in the tensile strength and a minimum in the reduction of area at 250° in a 0·15 per cent. carbon steel rising to 330° in a 0·91 and 12·5 per cent. carbon steel, in which two the minimum in the reduction area was not perceptible. F. A. Epps and E. O. Jones observed a minimum in the elongation of wrought iron between 100° and 150°; and A. Sauveur and D. C. Lee, a minimum in the strength of steel. A. Goffey and F. C. Thompson observed changes at 70°, 120°, 170°, 230°, 290°, 310°, and 350°, and with steels, in addition, and at 90°, 190°. The meaning of the singularities is unknown—*vide supra*.

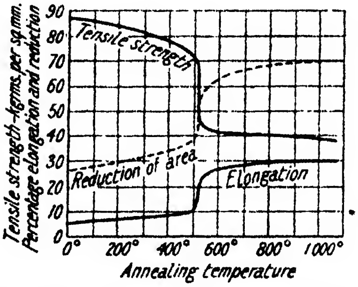

FIG. 214.—Effect of Temperature of Annealing on the Tensile Properties of Cold-drawn Wire.

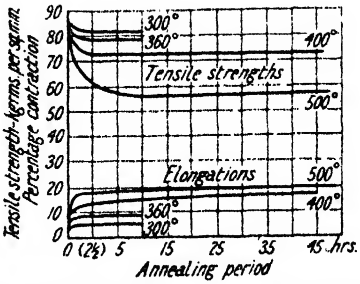

FIG. 215.—Effect of Temperature and Time of Annealing on the Tensile Properties of Cold-drawn Wire.

W. Eilender found that the changes produced by the ageing of quenched steel, containing 0·032 per cent. of nitrogen, are very remarkable. Thus, the tensile strengths after quenching from 680°, and after ageing for 14 days at 20°, were, respectively, 39·1 and 44·8 kgrms. per sq. mm., whilst the corresponding elongations were 33·0 and 2·7 per cent., and the reductions of area 61·0 and 2·5 per cent.

In 1863, K. Styffe found that the strength of iron and steel is not diminished by cooling to −40°; and C. Pardun and E. Vierhaus observed no loss in the mechanical properties of cast iron occurred by cooling it to low temp., but a change occurred when the temp. dropped to −80°. The cause of the alleged brittleness of cast iron in winter is due to shrinkage stresses, or, in the case of pipe systems, to the action of the frozen earth in which they are embedded. In 1886, T. Andrews investigated the effect of cooling down to −45°, on the strength of railway axles, and found the metal was more brittle at these low temp. F. Steiner also observed what he called "crystalline brittleness" at −50°. M. Rudeloff found that the cooling of weld iron to −20° did not markedly affect its toughness, but ingot metal became brittle; cooling to −80° caused both these metals to become brittle. Crucible steel became very brittle at −80°, but at −20° was not much affected. Basic bessemer steel was more affected by cooling than open-hearth steel. The bending capacity was reduced from 100 to 85 in the latter case, and from 100 to 81 in the former case. J. Dewar showed that at −280°, iron has double the tensile strength it possessed at 15°. A soft steel wire of 0·098 in. diameter at 15° broke with a stress of 420 lbs., and at −182°, with 700 lbs.; while an iron wire broke at 15° with 320 lbs., and at −182°, with 670 lbs. Observations were also made by C. Schäfer, F. Sauerwald and K. A. Pohle, W. H. Johnson, T. Matsuda, and J. R. Benton. R. A. Hadfield found that low temp. in the vicinity of −182° increased the tenacity or breaking load of iron and iron alloys; the ductility as measured by the elongation is reduced from 30 to 40 per cent. with mild steel, to practically *nil*. The same changes occur with the softest wrought iron, as with steels with 0·10 to 1·50 per cent. of carbon, so that the presence or absence of carbon has very little influence. Pieces of mild steel immediately after immersion, break instantly when struck with a hammer, and there is an entire absence of ductility. Thus, a sample of steel with 0·045 per cent. carbon; 0·07, silicon; 0·005, sulphur: 0·004, phosphorus; a trace of manganese; and 99·82, iron, gave:

	18°	−80°	−100°	−193°	−273°
Tenacity . .	20	27	30	44	(70) tons per sq. in.

A similar sample with 21 tons per sq. in. tenacity and 25 per cent. elongation gave at −182° a tenacity of 54 tons per sq. in., and elongation *nil*. The presence of nickel was found to counteract the tendency of iron to become brittle at these low temp. R. A. Hadfield also observed that with Swedish iron having 0·045 per cent. of carbon, the tensile strength in tons per sq. in. and the percentage reduction of area were for the annealed metal respectively 44·0 and 0·0 at −185°, and 18·5 and 75·0 at 18°; whilst for the quenched metal, these values were respectively 54·0 and 0·0 at −185°, and 20·5 and 72·0 at 18°. O. Reinhold gave for the tensile strength in kgrms. per sq. mm., and for the percentage reduction of area, of soft iron with 0·04 per cent. of carbon:

	−70°	20°	320°	400°	460°	520°	590°	620°
Tensile strength .	48·0	42·6	58·7	42·6	33·2	26·3	16·2	13·7
Reduction area .	70·0	73·0	65·0	74·6	80·3	86·5	93·0	95·8 per cent.

The question has been raised whether iron which has been exposed to a low temp. is afterwards more brittle than before the exposure. A. von Frank said that there is no evidence of any change in metal which has been exposed to the temp. of a European winter in mountainous districts, −22° to −25°; or to an Arctic winter. E. Bernardon found that the test-pieces exposed to great cold showed no marked difference when tested at ordinary temp. F. Steiner, and H. Gollner observed no apparent alteration in the bending tests of wrought iron, annealed cast iron and steel which had been cooled to −50°, and then returned to the original temp. of the room; and G. Mehrtens, no permanent deterioration in the metal of a prolonged exposure at about −88°.

The term **shortness** is often used synonymously with **brittleness**—*e.g.* in the ceramic industries a short clay is one with a low plasticity and in consequence with a tendency to rupture; and in the metallurgical industries the term is applied to a metal with a tendency to rupture under shock or stress, particularly when the stress is suddenly applied, and when the metal breaks without much elongation or reduction of area. Shortness is the opposite to toughness (not hardness). If the metal is brittle when hot, it is said to exhibit **red-shortness or hot-shortness**; when cold, **cold-shortness**; and when at a blue temper heat, about 300°, **blue-shortness.** The evolution of these apparently simple terms is curious. In an early translation of Pliny's *Historia naturalis*, by P. Holland, in 1610, the term *colsar* is used for cold-shortness; in 1637, P. Vernatt and T. Whitmore spoke of *colshire* or *coleshire* iron; in 1665, D. Dudley called it *coldshare* iron; in 1677, A. Yarranton used the term *coldshore;* and "red-short" and "cold-short" occur in a tract, *Beware of Bubbles*, by J. Moxon, dealing with W. Wood's patent for the manufacture of iron, and published about 1828. For red-hardness, *vide infra*, tungsten-steels. L. Aitchison discussed the difficulties which attend the formulation of a definition of brittleness.

F. Sauerwald and co-workers said that the brittleness of α-iron at the temp. of liquid air, −155°, is a consequence of the tendency of the crystal to split along the crystal planes. With a system of two crystalline phases, the limit for brittleness can be raised from −155° to −98° to −90°. The brittleness—cold-shortness—which develops in some alloy steels was attributed by H. Hüttenhain to the separation of graphite consequent on the metastable iron: iron carbide system being resolved into the stable iron : carbon system—*vide* the action of sulphur on iron. H. H. Lester investigated the brittle range of some chromium-nickel steels.

A peculiar brittleness is exhibited by iron between 200° and 400°, so that deformation, such as bending, within this range of temp. causes the metal to become more brittle after cooling to room temp. than would occur with a similar amount of deformation at room temp. The temper colour of iron in this range of temp. is bluish, so that the range of temp. is called *blue-heat*, and the brittleness, *blue-brittleness* or *blue-shortness*. Early reports on the ultimate strength of iron when heated showed that a maximum strength was obtained at about 260°, and from there up to over 500° the strength gradually decreased. In 1828, J. L. Fremery and P. St. Brice observed that a specimen of wrought iron, with a tensile strength of 43·4 kgrms. per sq. mm., at ordinary temp. had a strength of only 7·8 kgrms. per sq. mm. at a red-heat. K. Styffe found no change occurs in the tenacity of steel when heated up to 200°, but with soft iron there is an increase in strength between 100° and 205°. J. Kollmann observed that wrought iron maintains its strength up to 93° and then gradually weakens, the weakening goes on rapidly after 400° ; while Bessemer steel behaves in the same way except that the temp. at which the changes occur are higher—there is a constant strength up to 205° and a gradual decrease then begins, and it becomes greater above 500°. J. E. Howard found that the strength of steel decreases to a point between 93° and 150° when it increases until 260° ; after that the metal gradually weakens. The maximum strength with a harder steel occurs at a lower temp. The results with cast iron were almost constant up to about 480° when, at about 820°, the value is about half that of steels. The reduction of area decreased with temp. up to the point of maximum strength after which it increased ; the elongation was greatest at ordinary temp. M. Rudeloff observed that heating the metal to 250° has the same deleterious effect on the subsequent mechanical treatment of weld iron as it has on ingot iron ; as the temp. exceeds 300°, both weld iron and ingot iron steadily decrease in strength ; with weld iron, the elongation on fracture increased proportionally, but with open-hearth steel it reached a maximum at 350°. Hence, 300° is the limit below which the temp. must not fall when weld iron is subject to mechanical treatment, and for open-hearth steel, the temp. differs from this only slightly. Up to 250°, both open-hearth steel and weld iron steadily increased in strength, while the elongation diminished rapidly. The safety of the metal in use is not endangered up to 250°. The modulus of elasticity of open-hearth steel increased as the temp. was raised up to 250°. W. Fairbairn, G. Pisati and G. Saporito-Ricca, H. C. H. Carpenter, M. Leblant, M. Rudeloff, C. Bach, and G. Charpy all place the maximum resistance to tensile fracture at about 250° ; and R. H. Thurston, W. Fairbairn, W. G. Kirkaldy, and E. Adamson, between 250° and 300°. J. H. Andrew and H. A. Dickie, and K. Honda and R. Yamada attributed temper-brittleness to the separation of carbides along the grain boundaries during slow cooling. According to M. A. Grossman, the brittle range in steels with a low percentage of alloying element is due to a small proportion of retained austenite when the steel is quenched. The retained austenite is broken up more or less completely at a certain temp. and the resulting brittle, submicroscopic particles of α-iron, interspersed throughout the mass, make the specimen brittle.

The effect of temp. on the mechanical properties was also measured by R. G. Batson, G. R. Bolsover, G. R. Brophy, G. Charpy, H. le Chatelier, C. L. Clark and A. E. White, E. W. Fell, I. Fetchenko-Tchopivsky, F. Fettweis, J. R. Freeman and G. W. Quick, C. de Fréminville, H. J. French, R. H. Greaves and J. A. Jones, L. Grenet, L. Guillet and M. Balley, T. Inokuty, P. L. Irwin, Z. Jeffries, Z. Jeffries and R. S. Archer, J. J. Kanter and L. W. Spring, F. Körber and co-workers, F. Körber and A. Dreyer, F. Körber and A. Pomp, A. Kühle, A. Kurzwernhart, P. Ludwik, H. Lüpfert, L. H. Marshall, E. Maurer and R. Mailänder, F. Pester, A. Portevin, E. Preuss, G. C. Priester and O. E. Harder, F. Sauerwald and co-workers, P. Schönmaker, H. Schottky, K. Schichtel and R. Stolle, H. Scott and H. G. Movius, L. W. Spring, G. Wazau, and L. R. van Wert, R. Willows and F. C. Thompson, etc.

R. H. Thurston, W. Fairbairn, W. G. Kirkaldy, and E. Adamson observed a decrease in the elongation and an increase in brittleness between 250° and 300°; H. C. H. Carpenter, a minimum elongation at about 130°; and A. Martens, and M. Rudeloff a minimum resistance to tensile stress at 50°. The elongation and reduction of area rise from 300° or 400° upwards; and the minimum elongation occurs at about 150°, a temp. rather lower than the resistance to stress. The decreased elongation and the increased resistance to fracture as the temp. rises, explains the brittleness at a blue-heat, studied in 1877 by F. Valton. C. Bach, and M. Rudeloff found that with 0·16 to 0·20 per cent. carbon steels, the elongation previous to fracture reaches a minimum at 200°, but no definite relation was observed between composition and the variation in the resistance to fracture at different temp. The metals which behaved best when heated had the greatest tenacity and elongation before fracture. M. Leblant found that the maximum at 250°, and the minimum between 80° and 150° appear to occur at higher temp. as the proportion of carbon increases. According to P. Ludwik, the changes in the elastic limit during ageing, and at a blue-heat as well as blue brittleness, are due to changes in the solubilities of the minor constituents in the steel. A similar hypothesis was employed by W. J. Brooke and F. F. Hunting to explain the brittle zone with armco iron between approximately 900° and 800°.

L. Aitchison, L. H. Appleby, A. H. d'Arcambal, C. Bach and R. Baumann, H. W. Baker and A. H. Gibson, J. H. Baker, T. Baker, E. Bernardon, G. W. Barr and co-workers, J. Bartel, R. G. Batson and J. H. Hyde, A. Baykoff, N. I. Belaiew and N. T. Goudtsow, H. Bonte, H. Bouasse, J. M. Bregowsky and L. W. Spring, W. Brockbank, A. Brovot, J. D. Brunton, H. Buchholtz and E. H. Schulz, A. Campion, R. C. Carpenter, H. Carrington, W. Cassie, G. Charpy and A. Cornu-Thénard, P. Chevenard, P. Chevenard and A. M. Portevin, J. Christie, A. S. Clark, E. F. Cone, G. Cook, J. L. Cox, H. C. Cross, N. Czako, K. Daeves, W. E. Dalby, N. Davidenkoff and G. Sajzeff, V. A. Davidenkoff, W. B. Dawson, R. R. Devries, J. H. S. Dickenson, H. A. Dickie, T. G. Digges, J. W. Donaldson, P. Drosne, H. K. Dyson, H. Barnes, M. Mahoux, R. Mailänder, M. Malaval, V. T. Malcolm, A. Martens, W. Mason, T. Matsumura and G. Hamabe, M. Matweieff, K. Memmler and A. Schob, A. N. Mitinsky, R. G. Morse, K. H. Müller and E. Piwowarsky, J. Muir, F. Nakanishi, W. R. Needham, J. T. Nichols and co-workers, J. Nodder, P. Oberhoffer, W. Oertel, G. A. Orrok and W. S. Morrison, M. Orthey, N. S. Otey, J. G. Pearce, E. N. Percy, H. Perrine and C. B. Spencer, L. Persoz, W. Pinegin, A. J. S. Pippard, E. Pohl, A. Pomp, A. Pomp and A. Dahmen, G. W. Quick, E. J. Rang, W. del Regno, O. Reinhold, F. Rittershausen, F. Robin, M. Ros and A. Eichinger, W. Rosenhain and D. Hanson, O. Ruff, G. Sachs, F. Sauerwald and co-workers, A. Sauveur, E. Scharffenberg, E. Schiebold and G. Richter, C. C. Schneider, W. Schneider and E. Houdremont, A. Schob, H. Schottky and co-workers, E. Schüz, W. A. Scoble, J. Seigle, J. Seigle and F. Cretin, P. Siebe, E. Siebel, E. Siebel and A. Pomp, C. A. Smith, J. H. Smith, M. B. Smith, R. H. Smith, B. F. Spalding, A. P. Spooner, L. W. Spring, L. W. Spring and H. J. French, L. W. Spring and J. Kanter, H. Stäger, P. Stephan, R. Stribeck, H. W. Swift, W. P. Sykes, R. L. Templin, J. L. Terneden and M. von Rath,

A. F. Torres, E. Touceda, L. B. Turner, H. Ude, C. Upthegrove and A. P. White, G. Urbanczyk, M. Vitmos, E. C. Wadlow, O. Wawrziniok, F. W. Webb, W. R. Webster, P. A. Welikoff and co-workers, G. Welter, T. D. West, A. E. White, A. E. White and C. L. Clark, H. E. Wimperis, H. Wright, and H. J. Young, made observations on the tensile and elastic properties of iron and steel.

H. Perrine and C. B. Spencer gave the results indicated in Table XXIX for the ultimate strength in lbs. per sq. in., and the percentage elongation and reduction of area of Bessemer steel with 0·196 per cent. of carbon; and cast iron with 2·69 per cent. According to P. Ludwik, iron annealed at 900°, gave for the tensile strength in kgrms. per sq. mm., and the percentage expansions and reduction of area:

TABLE XXIX.—THE EFFECT OF TEMPERATURE ON THE TENSILE PROPERTIES OF IRON AND STEEL.

		25°	93·5°	204·5	260°	315·5	426·5°	537·5°
0·39 per cent. C	Elongation . . .	34·33	31·30	25·33	26·00	31·55	47·77	52·66

and for steel annealed at 700°:

	20°	250°	330°	412°	485°	617°	722°
Tensile strength .	45·0	57·2	52·6	44·5	27·8	15·0	7·0
Elongation . .	16	5	9	19	20	32	35
Reduction . .	63	43	54	55	62	80	63

H. J. French's tensile tests of iron at elevated temp., show that in the blue-heat range the tensile strength is higher than at room temp. although the reduction of area and elongation are lower. Z. Jeffries obtained similar results; and F. Robin observed that Brinell's hardness is greater at a blue-heat than at room temp. Z. Jeffries and R. S. Archer's experiments illustrate the greater hardening of iron for a given deformation-drawing from 0·042 to 0·025 in. at a blue-heat, 275°, than at room temp., for the tensile strengths lbs. per sq. in., and the percentage elongations, and reductions of area were:

	Tensile strength	Elongation	Reduction of area
Room temp.	85,720	2·60	70·0
275°	111,000	1·58	67·0

Hence the wire drawn at a blue-heat is stronger, but less plastic, than that drawn at room temp. Observations on the effect of temp. on the elastic limit are not concordant. J. E. Howard found that the elastic limit decreases with rise of temp.; W. Mauksch, that the stress with wrought iron at 200° is about half its value at ordinary temp., but rises to its original value at 300°; A. K. Huntington's curve shows no maximum in the blue-heat; C. Bach, and A. Martens observed a maximum at about 200°; and H. J. French found a maximum at 200° where the value is about 14 per cent. greater at 200° than it is at room temp. Observations were made by R. Hay and R. Higgins, R. L. Keynon, F. A. Epps and E. O. Jones, A. Kühle, H. Hubert, A. Pomp, R. C. Carpenter, K. Honda, and G. Delbart. According to E. Houdremont and co-workers, if T_0 denotes the tensile strength of unworked steel, and T is the tensile strength after being drawn from a cross-sectional area F_0 to one of F, then $T=T_0+a \log (F_0/F)$, where a denotes a constant.

A. le Chatelier found that all metals may be broken by a constant tensile stress applied above a certain temp., and that the elongation depends on the load. With a constant temp., the deformation under a given load has a decreasing value tending towards equilibrium; the deformation increases more rapidly than the loads, while the stress increases and the strains diminish with the speed of loading. Deformation under shock is inversely proportional to the shock; and with an increase in temp., the deformation increases and the resistance decreases. Cast iron at 15° can support the following loads without breaking in the periods of time stated:

Time . . .	0·5	1·0	5	15	60 mins.
Load . . .	25·21	24·63	23·87	23·49	22·86 tons per sq. in.

A. le Chatelier postulated that at temp. in the vicinity of 90°, any permanent deformation of iron gives rise to an irreversible transformation which tends to raise the tensile strength and decrease the ductility. The transformation requires a certain amount of time for its completion, but takes place more rapidly the higher the temp. Above 300°, however, the transformation is less effective in producing strength and hardness because of incipient annealing. F. Fettweis identified A. le Chatelier's transformation with the elastic recovery after overstrain. G. C. Priester and O. E. Harder observed a minimum in the tensile strength of 0·29 per cent. carbon steel between 100° and 200°, and a maximum at 300°. K. Yuasa observed that in tension, torsion, and crazing tests between ordinary temp. and 349°, armco iron in tension at 250° showed 320 breaks or sudden yieldings as it began to fail, but no breaks at 20° and 295°. Steels with 0·19, 0·5, 0·68, and 0·80 per cent. of carbon gave a diminishing number of breaks as the proportion of carbon increased until, with eutectoidal steel having 0·85 per cent. of carbon, no breaks were observed. Steels with 0·9, and 1·1 per cent. of carbon showed an increasing number of breaks as the proportion of carbon increased. Distinct sounds were heard as the breaks appeared in the stress-strain diagrams. According to A. Michel and M. Matte, several kinds of elongations are produced when a wire is maintained for a long time under a constant load, and at a raised temp. (i) an instantaneous elastic elongation, (ii) a slow elongation which proceeds with decreasing rapidity, and can be resolved into an elastic elongation with retarded elasticity or reactivity, and a permanent elongation, (iii) if the load is sufficient, the foregoing elongation is followed by another which proceeds with constant rapidity and corresponds to a so-called "viscous" deformation, (iv) after a certain time the rapidity of elongation increases very rapidly up to the breaking-point of the test-piece; this period corresponds to the striction.

A. Sauveur and D. C. Lee observed that in the case of electrolytic iron a maximum tensile strength is obtained at 250°, whilst steels containing respectively 0·10, 0·30, and 0·50 per cent. of carbon reach their maximum strength at a temp. slightly in excess of 300°. With 0·75 per cent. carbon, the maximum strength occurs at 400°. Consequently, the blue-heat phenomenon does not occur at the same temp. with all grades of iron and steel, and it is probable that, as the carbon increases, the temp. imparting maximum strength likewise increases. Electrolytic iron at room temp. has a tensile strength of 40,000 lbs. per sq. in., while at 250° its strength is 56,000 lbs. per sq. in., an increase of 40 per cent. Steel containing 0·10 per cent. carbon increases in strength from 68,000 lbs. to 86,000 lbs., or 26 per cent.; steel with 0·30 per cent. carbon, from 80,000 to 88,000, or 10 per cent.; steel with 0·50 per cent. carbon, from 110,000 to 126,000, or 15 per cent.; and steel with 0·75 per cent. carbon, from 140,000 to 145,000, or 4·3 per cent. Iron and very soft steel increase in strength by tempering at a blue-heat very much more than higher-carbon steel. It should also be noted that the increase of strength is preceded by a decrease of that property.

W. Rosenhain and J. C. W. Humfrey studied the tenacity deformation, and fracture of soft steel—0·106 per cent. C; 0·075, S; 0·050, P; 0·395, Mn; and a trace of silicon—at high temp. Some results with annealed wire are summarized in Fig. 216. The results show that with a fast rate of straining, a maximum stress of 42,400 lbs. per sq. in. was attained, while with a slower rate of straining the maximum stress was 40,250 lbs. per sq. in. The curves are fractionally identical in shape, but the curves with the slower tests lie below those with the faster rates of applying the stress, and the curves are practically parallel to one another. The two upper curves also indicate the influence of the mean size of the crystal grains. Near the Ar_1-arrest the two curves coincide. The effect of the average grain-size of the crystals is indicated in Fig. 204. The effect of temperature on the tensile properties of iron was investigated by R. G. Batson and H. J. Tapsell, C. E. Corson, H. L. Dodge, P. Fischer and V. Ehmcke, J. R. Freeman and G. W. Quick, L. Guillet and co-workers, W. H. Hatfield, H. M. Howe, L. M. Jordan, F. Körber and co-workers, J. H. G. Monypenny, E. Popl and co-workers, O. Reinhold, A. Sauveur, R. Waddell and L. Johnson, and A. E. White and C. L. Clarke. R. S. MacPherran observed that the maximum tenacity at elevated temp. is lowered by nickel, but is not much affected by chromium. R. B. Wilhelm's results for a medium carbon steel—with 0·37 to 0·40 per cent. C; 0·63 to 0·69, Mn; 0·11 to 0·14, Si; and approximately 0·012, P; and 0·037, S—are shown in Fig. 217. F. Körber and H. Hoff, and A. Pomp and co-workers, and P. Bardenheuer and K. L. Zeyen, examined the effect on the mechanical strength of over-heating cast iron.

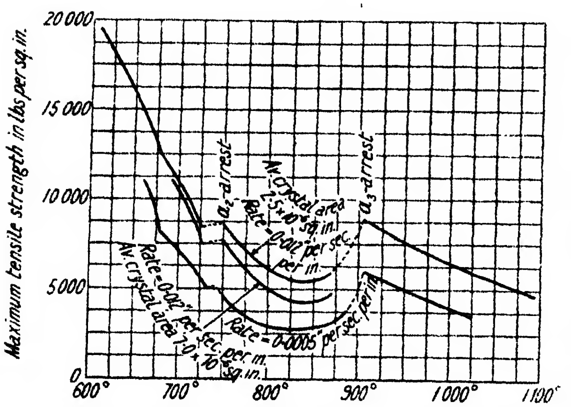

Fig. 216.—The Effect of Temperature on the Tensile Strength of Soft Steel.

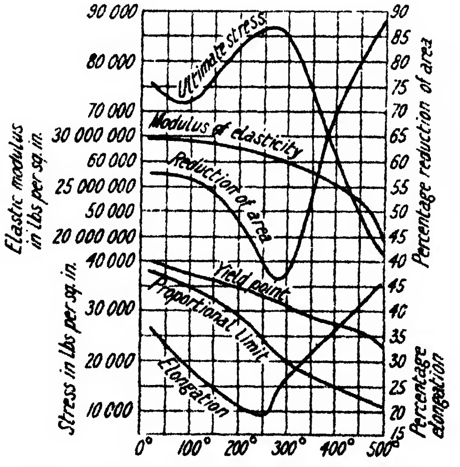

Fig. 217.—The Effect of Temperature on the Tensile Properties of Steels.

The decrease in Young's modulus due to stretching in the cold state and its subsequent recovery by ageing at room temp., or in boiling water, was studied by J. Bauschinger, J. Muir, L. B. Pfeil, C. W. Yearsley, and M. Rudeloff; C. A. Seyrich observed that with a cold-drawn, steel wire, the modulus had not recovered six months after drawing; and in another sample, P. Goerens observed no appreciable effect had occurred in three months. K. Honda and R. Yamada found that a decrease in the modulus produced by stretching had not occurred after being heated for 30 mins. at 100° to 200°, and with a sample of mild steel, severely cold-worked, no recovery of the modulus had occurred in six months, an annealing at above 600°

was required for the recovery. Measurements of the tensile strength of armco iron, mild steel, and nickel steel by T. Kawai are summarized in Figs. 218 and 219 - the hardness of these metals is indicated in Fig. 196. The recovery of Young's modulus by annealing mild steel is shown by the dotted line whose ordinates and abscissæ are on top and on the right of the diagram. E. Heyn, and G. Sachs attributed the decrease of the modulus by cold-working to the internal stresses set up by cold-working; and K. Honda and R. Yamada interpreted this explanation in terms of the atomic force. E. Murata, and T. Kawai showed that there is a release of an internal stress during annealing. T. Kawai observed that the increase in the internal stress during cold-working makes Young's modulus decrease; but the phenomenon may be more or less obscured by an increase in Young's modulus which is due to a change in the orientation of the crystals during cold-working whereby the orientation of the crystals is made to coincide with the direction of the axis of the bar or wire. O. A. Knight found that heating a wire while subjected to a load increased its resistance to deformation.

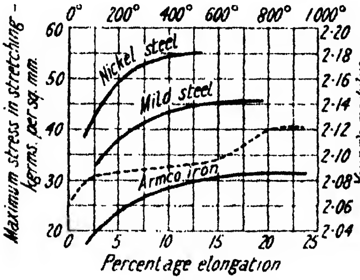

FIG. 218.—Maximum Stress in Stretching.

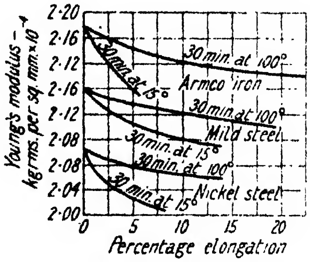

FIG. 219.—Young's Modulus of Stretched Iron.

According to C. Codron, if S denotes the sectional area of the tensile test-piece, and S', the sectional area on breaking, the coeff. of **ductility** or of malleability can be defined as $1-S'/S$, and it is a function of the reduction of area. The results by C. Codron are summarized in Fig. 219. The critical periods of ductility in steels containing different elements were found to be very variable. M. Leblant found a minimum reduction in area near 200° with extra hard steel, and at 300°, with hard steel; the corresponding elongation is a minimum between 200° and 300°. E. Preuss observed that with a pearlitic nickel steel with 0·15 per cent. of carbon, and 3 per cent. of nickel, a minimum elongation occurred at 300°, and a slight decrease in the reduction of area at the same temp. The brittleness, therefore, appears to be a minimum at these temp. F. Robin discussed the application of these results to the forging of metals; P. Junkers, the decrease in the resistance to deformation with increase of forging temp.; O. W. Ellis, the effect of temp. on the malleability of iron and steel; A. F. Shore, the measurement of toughness; and R. Stumper, the effect of the final rolling temp. on the mechanical properties. The ductility was discussed by P. Ludwik, and J. Vietorisz.

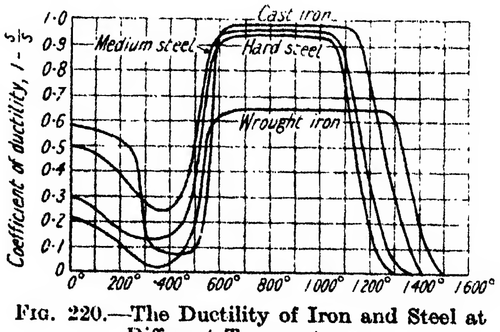

FIG. 220.—The Ductility of Iron and Steel at Different Temperatures.

Following H. J. Gough's study[0] on the **fatigue** of metals—*vide infra*—if a specimen be loaded up to a point B, Fig. 221, and the load removed, then, if no permanent elongation occurs, the materials are said to be perfectly elastic; the loading and unloading curves, *AB*, and *BA*, are the same, and the phenomena are reversible. Actually, however, when the load is *p*, while the sample is being loaded, the elongation is *OC*, and with the same load *p*, while the sample is being unloaded, the elongation is *OD*. The difference, *CD*, thus represents a lag or hysteresis in the strain when the stress is *p*. *Elastic hysteresis* is applied to the case where no permanent sets occur on removing the load, but a strain exists in other parts of the cycle. Again, if no strain disappears when the stress on a solid is removed, the material is perfectly plastic, but with all metals some strain is recovered when the stress is removed. If *AB*, Fig. 221, represents the stress-strain curve, and *b* the total strain, then when the stress is removed, a permanent elongation, *AC*, may be recorded, and this is called the *permanent set* or *plastic strain*; and *Cb* represents the *elastic strain* released by unloading. In a third case, Fig. 221, when the load is maintained at *B*, plastic strain sets in, producing the plastic strain *BF*. This strain increases at a decreasing rate, being very rapid at first, and thereafter slower and slower so that the whole process occupies days or weeks. When the stress is relieved by unloading, some elastic strain is recovered, but there remains a permanent set *AG*. In some cases the permanent set diminishes until some lower value, *AH*, is attained. The subject was discussed by J. V. Howard and S. L. Smith, W. E. Dalby, W. Kerr, M. F. Sayre, and A. Pomp and A. Dahmen. The plastic strain, *BF*, under load is often called the **creep**; and the decrease in the permanent set, *GH*, with no load can be called **elastic after-effect**—that is, *die elastische Nachwirkung*—elastic afterworking—or **elastic hysteresis or lag.** Both phenomena are cases of creep, and, according to H. J. Gough, are the same phenomenon due to the same cause. The permanence of the dimensions of steel under stress at an elevated temp. was discussed by W. H. Hatfield, and L. Jannin.

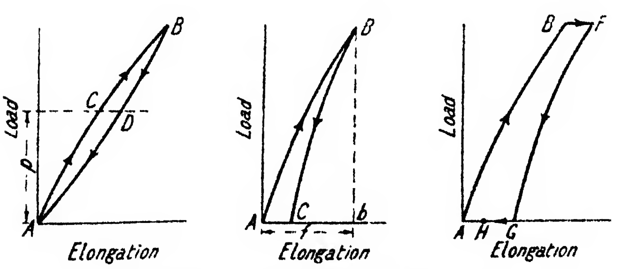

FIG. 221.—Elastic Hysteresis Loop.

In the stress-strain or load-elongation diagram, the elastic limit is taken as the load at which a deviation from Hooke's linear relation—**1.** 13, 17—is first apparent, this point is also called the *limit of proportion, P*; from a second point of view, the elastic limit may be the first permanent set which is observed on removing the load; this point is the so-called *limit of restitution, R*; and from yet a third way of considering the problem the elastic limit corresponds with a point of inflection on the stress-temperature curve; this point is called the *thermal limit* of proportionality.

As a result of the observations of J. P. Joule, and Lord Kelvin (W. Thompson), it was found that if thermal losses due to radiation, conduction, etc., are allowed for, cold is produced when a metal is strained by opposing an elastic force, and heat is developed when a metal is yielding to an elastic force; and with cyclic stresses, there is an average temp. of the metal which does not vary since heat is neither absorbed nor evolved. If a stress, p, is applied at the absolute temp., T; and ϵ denotes geometrical deformation produced by a temp. of 1° when the body is kept under a constant stress; c, the sp. ht.; D, the density; and $J+$, the mechanical equivalent of heat, then, assuming perfect elasticity, Lord Kelvin showed that the elevation of temp. produced by the sudden application of stress is $T\epsilon p/JcD$.

According to H. J. Gough, it has been observed that metals like copper, cast iron, and untempered steel undergo plastic strain when small stresses are applied, and they show no definite *P*, *R*, or *T* limits; while iron, mild steels, and many other metals show definite *P* and *R* limits which are generally in good agreement. J. A. Ewing observed that definite hysteresis loops were always obtained by direct tension with wires of iron, steel, brass, and copper; J. J. Guest and F. C. Lea, that definite hysteresis loops occurred with mild steel under all ranges of torsional stresses, though with up to a certain stress no creeping under load was observed. B. Hopkinson and G. T. Williams, with direct stresses, and F. E. Rowett, with torsional stresses, also found elastic hysteresis with low stresses. C. A. P. Turner found that the thermal limit of proportionality is generally lower than the *P*-limit; E. G. Coker observed that the fall of temp. was linear up to a stress corresponding with *P*, after which, proportionality ceased, and a sharp reversal occurred when the yield stress was reached; E. Rasch, and J. R. Lawson and J. A. Capp observed a general agreement between the *P*- and *T*-points, but elasticity was imperfect. Fatigue and **overstrain** were studied by R. Cazaud, H. F. Moore, R. H. Greaves, Z. Jeffries and R. S. Archer, J. W. Landon, J. K. Wood, H. P. Troendly and G. V. Pickwell, R. W. Bailey, H. J. French and co-workers, J. S. Brown, F. C. Lea and co-workers, D. Hanson, P. Henry, E. Honegger, and R. Liljeblad.

The elastic limit or yield-point represents the maximum distortion which a body can suffer and yet return to its original form. If the strain is not much greater than the elastic limit, the restoration of the original form will take place very slowly. The metal exhibits **elastic recovery.** Thus, we are told that some steel bridges may sag during a heavy week's traffic, but recover during a week-end's rest. It is possible to apply a much greater stress than the elastic limit provided the stress be very quickly applied. Thus, B. Hopkinson has shown that a wire with an elastic limit of 17·8 tons per sq. in. withstood a stress of 35·5 tons per sq. in. applied for less than the thousandth part of a second. Z. Jeffries and R. S. Archer thus describe the phenomenon of fatigue: When hot-rolled or mild steel is tested in tension, the first part of the stress-strain diagram is a straight line representing the elastic deformation up to about half the tensile strength. When a bar of this material is loaded to a stress well beyond the yield-point, on removing the load, it will have lost its elasticity; and the second application of the load furnishes a new stress-strain diagram which curves away from the straight line representing the proportional deformation, and the proportional or elastic limit is reduced almost to zero. If, however, the bar is allowed to rest for a few weeks after the first loading beyond the yield-point (over-straining), before the second tensile stress is applied, it will have recovered its elasticity, and may have a new proportional limit higher than the original limit. This **recovery** of elasticity takes place slowly at ordinary temp., and more rapidly as the temp. is raised; thus, J. Muir found that the recovery of elasticity is as complete after a few minutes at 100°, as it is in 2 weeks at room temp.; and at 250°, the time required for the recovery is measured in seconds or fractions of a second.

R. H. Greaves concluded from his observations on the recovery of elastic properties after simple overstrain in tension: The rate of recovery of elasticity varies greatly with different steels, the harder steels in general recovering more slowly. The greater the degree of overstrain, the longer the time required to bring about recovery at a given temp., or the higher the temp. required to bring about recovery in a given time. All steels show some progress towards recovery at atm. temp., but in the case of the harder steels, it is very slow. The effect of 30 years' rest at atm. temp on an overstrained crucible steel having 1·22 per cent. carbon, was about the same as the effect of holding the metal for 1 hr. at 100°, and considerably less than the effect of holding it for an hour at 125°. E. G. Coker, and E. J. McCaustland also found that there is a certain amount of recovery with overstrained mild steel and wrought iron at 0°, after which the recovery proceeds no further. According to Z. Jeffries and R. S. Archer, the recovery of elasticity on ageing at ordinary temp., or on heating at temp. up to about 300°, is attended by an increase in hardness, and tensile strength, and by a loss of plasticity. Elongation is usually reduced to a marked degree although the reduction of area is less affected. Hence, the change that occurs is, in general, a hardening and stiffening.

Z. Jeffries and R. S. Archer added that while the proportional limit in tension can be greatly increased—nearly doubled—by overstrain in tension followed by ageing, or heating at low temp., the limit in compression is not similarly increased. In fact, it has been reported that the gain in the tensile proportional limit is almost exactly compensated by the loss in the compressive proportional limit, so that the total elastic range is not greatly changed. J. A. van den Broek, however, found that by stretching and reheating, the tensile proportional limit of mild steel can be almost doubled while still retaining the original compressive proportional limit. H. M. Howe discussed cases where (i) the overstrain strengthens the metal against a later stress in the same direction, but weakens it against a stress in the opposite direction; and (ii) one in which it strengthens the metal in all directions though to a degree which varies with the direction of the later stress, being greater for stresses which are in the same direction as the overstrain itself.

Z. Jeffries and R. S. Archer hold that the blue-heat phenomenon and that of elastic recovery are both due to a spontaneous increase in resistance to motion of the slip-planes formed during deformation.

It is supposed that immediately after motion begins on a slip-plane the resistance is less than the shearing strength of the unbroken crystals. Deformation tends to progress by continued motion on this plane, until brought to a halt by end-resistance—that is, by the interference of adjacent grains. If the deforming load is removed immediately after slip has started and time is allowed for elastic recovery, then the resistance to motion on the plane of slip spontaneously increases to a value equal to or greater than the resistance to the formation of a new slip-plane. Further deformation must then take place on new planes. The time required for this increase in resistance is less as the temp. rises, so that at about 250° to 300° the change is practically instantaneous and occurs during the progress of any ordinary deformation, such as a tensile test. The result is that at a blue-heat a given *external* deformation produces more internal deformation, or cold-working, and hence more *hardening*, than the same amount of external deformation effected at room temp. This statement applies to deformations effected within a short period of time, such as during an ordinary tensile test. If the deformation which takes place during the tensile test at room temp. could be effected very slowly so that there was time for elastic recovery during the test, we should expect the tensile strength to be increased to an extent comparable with the increase obtained at a blue-heat. According to the theory here described, the blue-heat properties of iron are due to certain peculiarities of the process of deformation, and are not specific properties of crystalline iron. The yield-point, tensile strength, Brinell hardness, elongation and reduction of area are all properties whose measurement necessarily involves plastic deformation. The true elastic limit, on the other hand, being the stress at which plastic deformation begins, cannot be affected by the mechanism described, nor can the modulus of elasticity. Unless there is an allotropic change (change in atomic arrangement), it is to be expected that both elastic limit and elastic modulus will decrease continuously as the temp. rises. There is a lack of sustaining evidence of any allotropic change in these temp. regions, and recently E. C. Bain has found by X-ray analysis that iron at 300° has the same body-centred cubic lattice as at room temp.

In the so-called **bending test** for ductility, a bar of iron is bent by steady pressure or by hammering, until an angle of 180° is attained, or until the iron ruptures. In the latter case, the angle at which the fracture occurs on the outside of the bend is noted. The test is usually carried out at ordinary temp., but in order to detect red-shortness, or a high sulphur-content, the test may be carried out at about 900° or 1000°. In the nicked bending test the test-piece is nicked all round, before bending, so that the fracture shows the texture—fibrous or crystalline. These tests are generally used as guides in the workshop.

The subject was discussed by L. Aitchison and L. W. Johnson,[10] L. H. Appleby, C. Bach, P. Bardenheuer, J. Bartel, G. S. Bell and C. H. Adamson, B. Blount and co-workers, E. Brinckmann, G. Charpy, G. Cook, J. G. Docherty, B. A. Firth, J. E. Fletcher, H. Herbst, E. Houdremont and H. Kallen, E. Houdremont and R. Mailänder, S. Ikeda, L. Jannin, W. E. Johnston, T. von Kármán, W. J. Keep, G. H. Keulegan, R. L. Keynon, A. B. Kinzel, G. Klein and W. Aichholzer, R. Kühnel, W. Kuntez, M. Lautz, P. Ludwik, H. Lüpfert, A. Lundgren, A. Martens, G. Mehrtens, E. Meyer, H. Meyer, R. Mitsche, R. Moldenke, J. Muir and D. Binnie, E. Nusbaumer, J. G. Pearce, S. N. Petrenko, L. Piedbœuf and M. Remy, A. Pinegin, H. Pommerenke, F. Roll, W. Rosenhain and A. J. Murphy, M. Rudeloff, H. R. Sankey, H. Schottky, A. Schuchart, E. Schüz, W. A. Scoble, H. Scott, J. Seigle, E. Siebel, C. A. M. Smith, E. K. Smith and L. Lichtenfeld, R. Stribeck, O. Thallner, A. Thum and H. Ude, and H. E. Wimperis. The effect of nitrogenization was studied by A. Pomp and A. Lindenberg.

R. Schöttler, and C. Bach discussed the fact that the tensile strength of cast iron calculated from the bending tests is greater than the value obtained by applying a direct tensile stress. P. Goerens and G. Hartel measured the angle through which bars of 0·085 per cent. carbon steel could be bent at different temp. The curve for the **bending angles** required for fracture shows a sharp minimum between 400° and 500°; and the bending angle becomes rapidly less as the temp. falls from, say, 0° to —75°. O. Reinhold measured the bending angles of steels at different temp., and obtained similar results. M. Koepke and E. Hartig, and G. Mehrtens showed that wrought iron, whether cooled down to —100° or not, is somewhat more rigid than steel when tested by shock or bending. The bending number becomes less, but whereas steel behaves well, wrought iron cracks on its convex surface after a few blows. F. Steiner, and H. Gollner found that a wrought iron test-piece could be bent 180° at —50° without fracture, but a nicked test-piece could not be bent to so great an angle at this temp. as was possible at the normal temp. The fracture at the reduced temp. was of a crystalline nature, and that at ordinary temp. was of a fibrous nature. Annealed cast iron and steel which in their normal condition could be bent double without difficulty, withstood a slight bending at —50°, and, on the third light blow, it snapped like glass; E. Kuczera and E. Reinisch, and M. Koepke and E. Hartig also made observations on this subject. Steel bars which had been cooled showed a greater resistance to impact than uncooled bars—for the effect of cooling steel on the structure, etc., *vide supra*, austenite and martensite. G. Meyersberg studied the effect of work, and of the dimensions of the test-piece on the bending test.

P. Goerens measured the **flexibility** of iron in terms of the number of times it can be bent backwards and forwards to certain angles before it breaks off. The course of the flexibility curve corresponds with the tensile strength curve; up to 520°, the flexibility is influenced to a slight degree rising from 11 to 16; there is an abrupt jump to 27 at this temp.; and a subsequent rise in the annealing temp. is accompanied by a small rise of the bending number to 32. If the annealing coarsens the grain, there is a fall in the bending number. According to W. Herold, by slowly raising the load on the bending-test machine, the strength can be augmented in some cases 30 per cent. above the result of the short-time test. A change of structure is produced in the long-time test. In the case of annealed and quenched pearlitic and martensitic steels, there is a separation of the two solid phases so that the harder phase is driven to the grain boundaries which slow up more clearly giving the impression that the structure has been coarsened. In the case of pearlitic steels, the cementite migrates to the grain boundaries, and, in the neighbourhood of the fracture, it consists of ferrite with granular pearlite at the grain boundaries. J. W. Cuthbertson studied the subject. J. Muir and D. Binnie discussed the overstraining of iron by bending.

The **transverse strength** of iron is measured by the so-called transverse or cross-breaking test in which a bar of iron of standard size is supported as a beam and loaded centrally under standard conditions. The strength is measured by the central load the beam will carry without rupture; the deflection of the beam before rupture gives a rough measure of the toughness. The test is favoured for cast iron. Observations were made by E. Hodgkinson[11] in 1824. The standardization of the test has been discussed by a committee of the American Society of Mechanical Engineers, by W. J. Keep, J. E. Stead, J. A. Mathews, R. R. Devries, G. W. Dress, H. C. Dews, G. R. Johnson, C. Jovignot, R. Kröhn and F. Kintzle, E. C. de Segundo and L. S. Robinson, G. S. Bell and C. H. Adamson, J. B. Kommers, J. G. Pearce, W. R. Needham, J. Navarro, W. C. Unwin, G. Hailstone, and W. J. Millar. Working with samples of cast iron having a span of 36 ins., breadth 1 in., and depth 2 ins., averages of 1344 tests gave: ultimate strength, 3740 lbs., ultimate deflection, 0·400 in., and modulus of rupture, 50,490 lbs. per sq. in. J. A. Mathews obtained the results indicated in Table XXX, with cast iron having 3·56 to 3·78 per cent. of total carbon; 2·68 to 3·08, graphitic carbon; 0·70 to 1·04, combined carbon; about

0·45, manganese; 0·8, phosphorus; 0·1, sulphur; and silicon. E. Adamson found for cast iron with 3·56 to 3·58 total carbon; 2·98 to 3·05, graphitic carbon; 0·54 to 0·59, combined carbon; 1·30 to 2·00, silicon; 0·072 to 0·11 sulphur; 0·59 to 1·20, phosphorus; and 0·65 to 0·90, manganese, the transverse strength in 3 ft. was 27·5 to 38·5 cwts.; the deflection, 0·314 to 0·386 in.; and the moment of resistance, 16·588 to 20·796. J. Bauschinger's results are indicated in Table XXX.

TABLE XXX.—TRANSVERSE STRENGTH OF CAST IRON.

Silicon (per cent.)	Span (inches)	Mean centre load (lbs.)	Modulus of rupture (lbs. per sq. in.)	Tensile strength (lbs. per sq. in.)
1·50	12	3000	47,100	25,600
	18	1935	45,600	
	24	1425	44,700	
2·00	12	2900	45,500	24,370
	18	1835	43,200	
	24	1265	39,700	
2·50	12	2880	45,200	24,660
	18	1905	44,900	
	24	1400	44,000	

H. Meyer gave for the effect of temp. on the modulus of rupture (tons per sq. in.), and the maximum deflection in inches:

	18°	85°	155°	370°	580°	810°
Modulus of rupture .	23·6	21·9	21·3	21·0	16·0	6·2
Max. deflection .	0·30	0·28	0·28	0·30	0·57	0·79

L. H. Appleby[12] measured the resistance of iron to **shearing and torsional stresses,** and found that open-hearth steel had a torsional limit of 20·09 tons and a breaking stress of 39·29 tons per sq. in., while the shearing resistance was 29·7 tons per sq. in. Some results of the breaking stress, in tons per sq. in., are indicated in Table XXXI. The numbers in brackets refer to the number of twists on a length of 30 diameters which were found after fracture. J. Bauschinger's results for the tensile and compressive strengths, the transverse strength, the shearing strength, and the torsional strength are indicated in Table XXXI; and those of L. H. Appleby, in Table XXXII. J. Platt and R. F. Hayward found that the shearing strength is always less than the tensile strength; and that the ratio shearing strength : tensile strength increases as the tenacity increases and is 85 per cent. for wrought iron, 81 per cent. for mild steel, 64 to 70 per cent. for steels with a high proportion of carbon, and for cast iron, 40 per cent.; the torsional strength is greater than that of the direct shear, and the ratio varies with the tenacity and nature of the materials. The modulus of elasticity in torsion is about 40 per cent. of the modulus in tension. E. G. Izod, and J. Goodman obtained higher results than J. Platt and R. F. Hayward for the shearing strength of cast iron. E. G. Izod

TABLE XXXI.—MECHANICAL PROPERTIES OF IRON AND STEEL.

	Tensile strength	Compressive strength	Bending test	Torsional strength		Shearing strength
				Limit	Rupture	
Cast iron . . .	12·517	—	—	—	14·417 (0·04)	12·338
Wrought iron . .	25·410	—	—	8·928	26·042 (10·56)	22·436
Cast steel . . .	29·060	23·131	39·495	20·094	39·286 (0·90)	29·700
Forged steel . .	28·415	—	51·351	11·163	30·878 (7·64)	24·436
Bessemer steel . .	34·465	-	66·267	17·857	38·231 (16·03)	18·933

gave for the ultimate tensile stress of cast iron, 9·7 to 13·7 tons per sq. in., and for the ultimate shearing stress, 13·9 to 17·4 tons per sq. in. J. Goodman gave for cast iron, 10·9 to 11·5 tons per sq. in. for the ultimate tensile strength, and 12·9 to 13·0 tons per sq. in. for the ultimate shearing stress. W. Püngel discussed the effect of cold-work on the torsion strength of steel.

Observations with iron, etc., were made by G. C. Anthony, W. Bader and A. Nadai, A. J. Becker, G. S. Bell and C. H. Adamson, B. Blount and co-workers, T. H. Burnham, E. G. Coker, G. Cook, G. K. Elliott, J. V. Emmons, O. Föppl, C. Frémont, A. Glazunoff, J. J. Guest and F. C. Lea, E. L. Hancock, P. Henry, W. Herold, A. G. Hill, L. J. Johnson and J. R. Nichols, W. Jolley, J. B. Kommers, W. Kuntze, C. E. Larard, F. C. Lea and F. Heywood, E. Lehr, W. Lode, P. Ludwik, P. Ludwik and co-workers, D. J. MacAdams, L. Perard, P. Régnauld, M. Rudeloff, A. Sauveur, H. A. Schwartz, W. A. Scoble, F. B. Seely and W. J. Putnam, J. Seigle, J. Seigle and co-workers, Y. Sekiguchi, K. Sipp, C. A. M. Smith, J. H. Smith and F. V. Warnock, R. L. Templin and R. L. Moore, V. Vieweg and A. Wetthauer, P. B. Whitney and G. K. Dohner, and F. P. Zimmerli and co-workers.

TABLE XXXII. MECHANICAL TESTS OF CARBON STEELS (kgrms. per sq. mm.).

Carbon (per cent.)	Tensile strength limits	Tensile strength	Compressive strength limits	Compressive strength	Transverse strength limits	Transverse strength	Shearing stress	Torsional strength limit
0·14	30	44	28	48	38	--	34	—
0·19	33	48	30	54	42	—	37	15
0·46	35	53	34	63	40	83	36	15
0·51	34	56	33	70	42	93	40	--
0·54	35	56	34	61	40	86	39	15
0·55	33	56	35	62	42	88	40	--
0·57	33	56	34	66	45	96	36	16
0·66	37	63	38	66	44	86	43	17
0·78	37	65	38	73	47	88	41	18

0·87	43	74	39	89	47	77	50	20
0·96	49	83	50	99	69	85	58	27

In the fracture of iron by alternating torsional stresses, fracture may occur when the total distortion is small or inappreciable. H. Gough found that with single crystals of α-iron, the direction of slip is the octahedral direction. At any point on the surface of the specimen there will exist a plane on which the value of the shear stress resolved in the contained octahedral directions is a maximum for all similar resolved shear stresses. Slip will not, in general, occur on this plane, unless the plane coincides exactly with a dodecahedral (110), icositetrahedral (112), or hexakis-octahedral (123) plane of the crystalline structure (and then only when conditions of perfect symmetry obtain). In other cases, the distortion is produced by slipping on two planes, each of which corresponds to one of the above crystal planes. These slip-planes are situated on opposite sides of the plane of maximum resolved shear stress, although not, in general, equidistant from that plane. Each slip-plane is determined by the consideration that it is subjected to a greater value of resolved shear stress than any other possible slip-plane on the same side of the plane of maximum resolved shear stress. The slip-bands will, in general, be of a duplex type, the *average* slope being that of the trace of the plane of maximum shear stress on the surface of the specimen. The limits of slope of the slip-bands will agree with the traces of the planes of slip. Under very small deformations, the slip-bands appear either as short separate traces of the slip-planes, or of a combination of these traces, and can be identified as such. Under great deformations, however, the component slopes of the slip-bands are difficult to resolve, and sometimes they cannot be resolved at all. In the latter case they present a very wavy, branched appearance bearing no appreciable relation to the crystalline structure. Observations on single crystals were made by J. Königsberger. For mild steel,

E. G. Izod, and J. Goodman respectively gave 26·9 and 23·6 tons per sq. in. for the ultimate tensile strength, and 21·0 and 18·9 tons per sq. in. for the ultimate shearing stress. The ultimate shearing stress of cast iron—free from blow-holes and springiness—is greater than the ultimate tensile strength. J. Frenkel discussed the theory of the shearing strength of crystals; D. Binnie, the overstraining of steel by torsion; G. H. Gulliver, and C. Frémont, the shearing strength of iron and steel. W. Jolley found the measurements with cast iron to be unsatisfactory. M. Majima found that when the elastic limit of mild steel is exceeded in torsion, the deformation becomes plastic, and with a constant twisting couple the angle of twist ultimately reaches an upper limit. After several hours the material recovers its elasticity, the recovery being nearly proportional to the time of rest. If, then, the twisting couple is increased, elastic deformation is produced, and up to the new elastic limit the stress-strain relationships are approximately equal to those observed within the original elastic limit. The results are satisfactorily explained by the slip-band theory. P. Chevenard measured the variation with temp. of the torsional rigidity of some carbon steels, and found that the variation with temp. of the inverse squares of the times of oscillation only represents the apparent variation of the torsion modulus up to 300°. Above 300°, the decrements showed a rapid increase. The anomaly in the elasticity of carbon steels is directly proportional to the carbon content. L. di Lazzaro found that when torsional and tensile stresses are applied simultaneously, the torsion modulus diminishes, and rises again after the tension has been released.

According to H. Tomlinson, the longitudinal and torsional elasticity of iron are not so much affected by raising the temp. as is the case with internal friction. The torsional elasticity of annealed iron is temporarily decreased 2·693 per cent. when the temp. is raised from 0° to 100°; an annealed wire tested with a certain load at 12° was temporarily elongated 0·751 mm.; when heated to 100°, 0·793 mm.; and when cooled again and tested 24 hrs. afterwards, 0·725 mm. Thus, as with torsional elasticity, there is a permanent increase of elasticity, and a temporary decrease of 2·58 per cent. Time is here an important factor, for the elasticity immediately after cooling is appreciably less than it is after a long rest. With both torsional and longitudinal elasticity, after an iron wire has been permanently extended by traction, the elasticity is permanently increased by long rest. The carrying power of a magnet, also, can be considerably increased by putting on the load in small quantities at a time, with long intervals of rest between. All this is taken to mean that if the molecular arrangement of iron be disturbed by any stress whatever, exceeding a certain small limit, the molecules will not assume at ordinary temp. those positions which will secure a maximum of elasticity, until after a rest of many hours. K. Yuasi's observations were indicated in connection with the tensile tests. H. J. Tapsell and W. J. Clenshaw studied the subject.

For the **torsion modulus,** in kgrms. per sq. mm., C. A. Coulomb gave for iron, 7,651; G. Pisati, 8,082; N. Katzenelsohn, 7,505; M. Baumeister, 7,975; A. Gray and co-workers, 8,230; C. Schäfer, 7,337; H. Tomlinson, 7,590; and F. Horton, 8,280. For the torsion modulus of steel, W. Voigt gave 8,070; H. Tomlinson, 7,731; G. Pisati, 8,262; A. Gray and co-workers, 7,965; G. F. C. Searle, 7,872; F. Horton, 8,470; and F. A. Schulze, 8,022. For **Poisson's ratio,** P. Cardani gave 0·321; J. D. Everett, 0·310; M. Baumeister, 0·304; J. R. Benton, 0·288; N. Katzenelsohn, 0·272; H. Tomlinson, 0·281; J. Morrow, 0·263; A. Mallock, 0·253; O. Littmann, 0·243; C. Schäfer, 0·247; and E. Grüneisen, 0·280 for steel with 0·1 per cent. of carbon to 0·287 for steel with 1·0 per cent. of carbon. H. Polnick calculated Poisson's ratio, w, from $w=0·5\text{-}tEk$, where E denotes Young's modulus, $21·3\times10^{-11}$ c.g.s. units, and k the coeff. of compressibility, $0·606\times10^{11}$, so that $w=0·285$, when E. Grüneisen observed 0·28. Observations were also made by W. P. Wood, C. Frémont, E. G. Izod, W. E. Lilly, W. C. Popplewell, E. L. Hancock, C. A. M. Smith, E. Siebel and A. Pomp, C. Bach, O. Bretschneider, T. Reimers, J. J. Guest, G. Moreau, E. Goens, F. W. Alexander, and J. Seigle and F. Cretin.

A. E. H. Love and others have studied the mathematical theory of elasticity and shown that for simple torsion, in static testing, and in the range where stress is proportional to strain W, the energy absorbed per unit vol. is $W=C_1S_a^2/2F$, where C_1 is a constant; S_a, the maximum stress in torsion; and F, the modulus of torsional elasticity. Likewise also for tension or compression, $W=C_2S_b^2/2E$, where C_2 is a constant; S_b, the maximum stress in tension or compression; and E, the modulus of elasticity in tension. In the case of reversed stresses, W, the amount of energy involved per unit vol. per cycle of stress at the endurance limit, is $W=(S_1^2+S_2^2)/2E$, where E is the modulus of elasticity; S_1, the maximum stress per unit area; and S_2, the minimum stress per unit area. If the cycle does not involve a reversal of stress, $W=(S_1^2-S_2^2)/2E$, when S_1 and S_2 are both values in tension or both in compression.

J. Goodman showed that as the range of repeated stress on a steel is decreased, the maximum stress that can be carried successfully an indefinitely large number of times is increased; and H. F. Moore and T. M. Jasper showed that whilst this relation holds for normalized steels over a considerable range, with heat-treated steels, when the elastic limit and yield-point approach proportionately nearer the ultimate strength, the limits of endurance do not follow J. Goodman's relation; and the upper limit of the range then rarely goes beyond the yield-point of the material. The endurance limit represents the maximum stress a metal can withstand in repeated stress for an indefinitely large number of cycles. If the repeated stress of a ferrous metal is run at a stress very little above the endurance limit, it will usually fail before it has reached 2,000,000 cycles, whereas if the metal is repeatedly stressed at or near the endurance limit, it will withstand at least 100,000,000 cycles without failure, and in some cases as much as 900,000,000 cycles.

In his study of the kinetic theory of solids, W. Sutherland showed that if F denotes the modulus of shear at any temp. T° K.; F_0, the modulus of shear at 0° K.; and T_m, the absolute temp. of the m.p., then $F/F_0=1-(T/T_m)^2$. A. E. H. Love, and A. Morley have shown that for an isotropic elastic solid, if B represents the bulk modulus, $E=9BF/(F+3B)$, and $B=FE/(9F-3E)$; and W. Sutherland deduced for the bulk modulus, $B=2hJc\delta/9a\{1/(aT)-4\}$, where J denotes the mechanical equivalent of heat; h, the sp. ht.; δ, the density; a, the coeff. of linear expansion; c, a constant which is nearly unity; and T, the absolute temp. at which the test is made. Since J and c are constant, and δ may be taken to be constant over the range 0° to 1400° F., the equation assumes the form $B=kh/a\{(1/aT)-4\}$, where k is a constant. H. Brearley investigated the energy involved in bringing a steel to the yield-point. T. M. Jasper examined these relations for steel. The results in Table XXXIII for $W=(S_1^2+S_2^2)/2E$ were calculated by T. M. Jasper—for static tests where S_2 is zero, and $W=S_1^2/2E$. The results show that the value of the energy involved per complete cycle of stress for a specific wrought ferrous metal at the endurance limit, is nearly constant; and the energy involved in bringing the stress to the static yield-point under different temp. below 510°, is a constant; above 510°, the value of the modulus changes abruptly

TABLE XXXIII.—THE ENERGY ABSORBED IN BRINGING STEEL TO THE YIELD-POINT.

Temp. (°F.)	Yield-point (tons per sq. in.)	S_1 (lbs. per sq. in.)	E (lbs. per sq. in.)	$S_1^2/2E$	Per cent. deviation from mean
65	38·8	87,000	30,000,000	126	− 3·4
212	37·0	82,800	28,000,000	123	− 5·7
392	37·0	82,800	25,300,000	135	+ 3·6
572	33·44	75,000	22,400,000	126	− 3·4
752	33·6	75,300	19,500,000	145	+11·1
842	31·32	70,300	18,200,000	135	+ 3·6
932	28·68	64,200	16,700,000	123	+ 5·7

indicating a possible critical point. G. D. Newton, and F. Schleicher discussed the energy necessary to shear steel at a high temp. H. H. Lester, and H. H. Lester and R. H. Aborn discussed the behaviour of the atoms within a crystal of iron when stressed up to and beyond the elastic limit. C. Schäfer observed a relation between the temp. coeff. of the torsion modulus, λ, and the m.p. of metals corresponding with that observed in the case of the temp. coeff. of the hardness. J. H. Poynting observed that when a loaded wire is twisted, it lengthens by an amount proportional to the square of the angle of twist; and that with a wire previously straightened by heating under tension, the lengthening is the same for all the loads which were tried. Hence, the only function of the load is to straighten the wire. He also discussed the theory of the phenomenon.

The modulus of elasticity in shear, the modulus of transverse elasticity, or the modulus of **rigidity,** of iron at 15° is, according to W. Sutherland, 750×10^{-6} gram per sq. cm. For the ratio at 100° with that at 0°, A. W. Napiersky gave 0·979; F. Kohlrausch and F. E. Loomis, 0·960; and H. Tomlinson, 0·950. Lord Kelvin (W. Thomson) gave for the absolute value between 0° and 20°, per gram per cm., 790×10^{-6}; H. Tomlinson, 751×10^{-6} to 773×10^{-6}; G. Pisati, 811×10^{-6}; F. Kohlrausch and F. E. Loomis, 694×10^{-6}; A. T. Kupffer, 713×10^{-6} to 742×10^{-6}; C. Schäfer gave $0·734\times10^{-6}$ kgrm. per sq. mm. at 20°; E. Grüneisen, $0·828\times10^{-6}$ at 18°; and B. Gutenberg and H. Schlechtweg gave for the average rigidity of iron, $7·8\times10^{11}$ dynes per sq. cm. For drawn steel having 1·0 per cent. of carbon, E. Guye and V. Freedericksz gave $0·857\times10^{-6}$ kgrm. per sq. mm. at $-196°$; $0·829\times10^{-6}$ at 0°; and $0·811\times10^{-6}$ at 100°; K. Iokibe and S. Sakai, $0·7985\times10^{-6}$ at 24°; $0·750\times10^{-6}$ at 216°; $0·706\times10^{-6}$ at 418°; $0·649\times10^{-6}$ at 595°; and $0·518\times10^{-6}$ at 650° with wire having 0·0085 per cent. of carbon, annealed at 800°; and K. R. Koch and E. Dannecker gave for annealed wire with 1·0 per cent. of carbon, in kgrms. per sq. cm.:

	20°	200°	400°	600°	800°	1000°	1200°
Torsion modulus $\times10^6$.	0·805	0·764	0·712	0·461	0·277	0·270	0·181

H. Tomlinson gave 704×10^{-6} grm. per sq. cm. for hard-drawn and also annealed iron wire, and W. P. Wood gave for the torsion modulus, in lbs. per sq. in.:

Hard-drawn	Tempered			
0·56 to 0·58 % C	0·76 to 0·83 % C	0·44 % C	0·67 % C	0·78 C
11,299,000	11,427,000	11,299,000	11,437,000	10,607,000

For steel with 0·35 and 0·90 per cent. carbon annealed at 900°, T. Kikuta gave for the coeff. of rigidity, $E\times10^6$ kgrms. per sq. cm.:

	20°	199°	443°	631°	795°	924°
0·35 per cent. C $E\times10^6$ . .	0·823	0·784	0·713	0·533	0·324	0·211
	20°	221°	446°	619°	780°	937°
0·90 per cent. C $E\times10^6$ . .	0·805	0·764	0·695	0·5295	0·321	0·262

and for steel wire with 0·55, 0·90, and 1·30 per cent. carbon, K. Iokibe and S. Sakai gave for coeff. of rigidity $E\times10^6$ kgrms. per sq. cm.:

	43°	207°	399°	600°	
0·55 per cent. C $E\times10^6$ . .	0·783	0·765	0·737	0·562	—
	56°	187°	419°	616°	
0·90 per cent. C $E\times10^6$ . .	0·782	0·762	0·683	0·600	—
	29°	221°	412°	599°	700°
1·30 per cent. C $E\times10^6$ . .	0·773	0·758	0·739	0·640	0·447

K. Honda and T. Terada gave $0·75\times10^{12}$ at 14° for the coeff. of rigidity with a load of 3113 grms. per sq. mm. G. H. Keulegan and M. R. Houseman studied the subject. A. Gray and co-workers found for the modulus of rigidity of mild steel: $7\cdot9648\times10^{11}$ dynes per sq. cm. at 17·0°, and $7\cdot7704\times10^{11}$ at 89·2°—a diminution of 0·000338 per degree; and for soft iron, $8\cdot2855\times10^{11}$ at 13·6°, and $8\cdot0125\times10^{11}$ at 93·8°—a diminution of 0·00041 per degree. T. Kawai observed that there is a decrease in the modulus of rigidity of iron and mild steel due to cold-working until a minimum is attained, after which, the amount of decrease diminishes with an increase in the degree of cold-working. K. Iokibe and S. Sakai studied the effect of temp. on the rigidity. P. W. Bridgman found that under a press. of 10,000 kgrms. per sq. cm., the rigidity of steel is increased 2·2 per cent. *Vide infra* for the effect of rigidity on magnetization. K. Honda and H. Hasimoto found that the rigidity is slightly decreased by an increase of carbon; it is decreased by quenching, and increased by annealing. The effect of annealing was studied by F. P. Zimmerli and co-workers, and T. Kawai.

A. Mallock observed that the elastic rigidities of iron and steel are identical at the same temp., and this value diminishes slowly from ordinary temp. to a red-heat. The limits of the elasticity of the two are widely different: very small for iron, and increasing with the carbon-content of the steel. Just below 800°, the rigidity and elastic limits begin to diminish rapidly. The changes in viscosity and rigidity are not coincident with the change of state, and this is particularly noticeable in steels with a high proportion of carbon. The diminution in the rate of subsidence of torsional oscillations in wires was studied by H. Streintz, O. Feussner and E. Ramb, G. S. von Heydekampf, O. Föppl, S. Higuchi, and G. Pisati. A. Gray and co-workers observed that the rate of subsidence of the amplitude is slower at the lower temp. Analogous results were obtained for soft iron. F. C. Lea observed two discontinuities in the torsional rigidity modulus of mild steel at 120° and 230°; and discontinuities were also observed in a 0·57 per cent. carbon steel. *Vide supra*, the viscosity of iron.

According to H. Tomlinson, the loss of torsional rigidity produced by twisting or stretching a wire beyond the limits of elasticity is partly diminished by rest. The loss is more sensible with large arcs of vibration than with small ones. The influence of rest is more apparent with large vibrations than with small ones. Continued vibration through large arcs has a similar effect on the rigidity to that produced on the longitudinal elasticity by heavily loading and unloading. The effect of vibrating hard steel through a large arc for several minutes makes temporarily the rigidity determined for large vibrations greater than that determined from smaller vibrations. The torsional rigidity is temporarily depressed by the passage of a powerful electric current, but is very little, if at all, altered by currents of moderate intensity. The torsional rigidity of iron is temporarily diminished to a small extent by a high magnetizing force. Both these effects are independent of changes produced by the current in the temp. of the wire.

E. L. Hancock showed that (*a*) an overstrain in either tension or torsion destroys the elasticity of the material, but that this elasticity gradually returns when the piece is allowed to rest, the elastic limit becoming, in some cases, greater than its original value, and the modulus of elasticity the same as its original value. (*b*) That the elastic properties of the overstrained material are restored by immersion for a short time in boiling-water. (*c*) That recovery is not aided by repeated impact from a light hammer. (*d*) Materials overstrained in either tension or compression lose their elasticity for stress of the opposite kind, but the elasticity is restored by rest. (*e*) The carbon-steels seem to recover more quickly than the nickel steels. This, however, has not been shown conclusively by these tests, but all evidence goes to show that it is true.

Observations on the resistance of metals to impact were made by Leonardo da Vinci,[13] E. Mariotte, P. de la Hire, M. de Cessart, W. J. Gravesande, F. J. de Camus, J. V. Poncelet, G. Juan, M. Rambourg, J. R. Perronnet, L. de Maupéon, etc. E. Hodgkinson [14] applied the impact or shock test to iron in 1833. E. D. Estrada examined the effect of a sudden application of the load on the tensile properties of wrought iron and steel. He found that some fractures were finely granular or silky; in some cases a small load suddenly applied will produce a permanent set, and, in general, the elongation increases and the elastic limit diminishes with loads suddenly applied. Elongation is a function of the time, since it increases as the time diminishes though the ultimate resistance remains the same. The tests applied to iron and steel with the object of finding their mechanical properties can be grouped as static and dynamic; and it has been found that the dynamic tests—illustrated by the so-called impact test—show characteristics of the metal which are not revealed by the static tests. The **impact or shock test** may be applied to notched or un-notched bars. It gives an idea of the toughness or brittleness or resilience of the metal. T. E. Stanton and L. Bairstow, and P. Welikhoff observed that with un-notched bars, the results of the tensile impact tests are virtually the same as those obtained with static tensile tests.

Observations were also made by T. Asano, L. Aitchison, N. Akimoff, J. H. Andrew and R. Hay, T. Andrews, J. O. Arnold, L. Auspach, H. Bancke, P. Bardenheuer, R. Baumann, M. Belanger, G. Berndt, B. Blount and co-workers, H. T. Bovey, E. Brechbühl, P. Breuil, R. C. Carpenter and H. Diederichs, G. Charpy, G. Charpy and A. Cornu-Thénard, H. le Chatelier, E. G. Coker, A. L. Colby, A. Cornu-Thénard, N. Davidenkoff, N. Davidenkoff and K. Yureff, P. Dejean, M. Delbruck, M. Denis, M. Derihon, G. Dilber and H. T. Hannover, E. H. Dix, W. A. Doble, J. G. Docherty, P. H. Dudley, F. W. Duesing, B. W. Dunn, J. Durand, C. A. Edwards and F. W. Willis, H. C. Ehrensberger, H. A. Elliott, A. Elmendorf, F. Eloy, L. E. Endsley, H. Enshaw, P. Fain, H. J. Fereday, F. Fettweis, P. Fillunger, P. Fischer, F. B. Foley and co-workers, C. de Fréminville, C. Frémont, S. R. Fuller and W. A. Johnston, A. Gagarine, A. Gossner, W. A. Gibson, W. Giesen, P. Goerens, E. P. Gooch, W. F. M. Goss, H. J. Gough and A. J. Murphy, R. H. Greaves, R. H. Greaves and H. Moore, L. Grenet, M. Guillery, L. Guillet, L. Guillet and co-workers, L. Guillet and L. Révillon, R. A. Hadfield, R. A. Hadfield and S. A. Main, J. H. Hall, H. I. Hannover, F. Harboard, W. H. Hatfield, W. K. Hatt, W. K. Hatt and E. Marburg, W. K. Hatt and W. P. Turner, P. Heymans, E. Heyn, E. Höeg, W. Honiger, A. Horzenberger, H. M. Howe, S. L. Hoyt, H. Hubert, J. C. W. Humfrey, D. H. Ingall, E. G. Izod, F. H. Jackson, L. Jannin, J. B. Johnson, R. M. Jones and R. Greaves, W. R. D. Jones, H. Jungbluth, C. Jungst, H. Kamura, T. Kawai, W. J. Keep, A. B. Kinzel and W. Crafts, H. B. Knowlton, F. Körber and co-workers, F. Körber and J. B. Simonsen, H. Kreuger, E. Kuhlmann, E. F. Lake, F. C. Langenberg, G. Lanza, F. Laszlo, E. Leber, A. Ledebur, M. Legrand, F. Leitzmann, A. Leon and P. Ludwik, J. M. Lessells, P. Longmuir, P. Ludwik, P. Ludwik and R. Scheu, A. Lundgren, T. D. Lynch, D. J. McAdam, C. McGarvey, J. S. Macgregor and B. Stoughton, D. R. MacLachlan, A. McWilliam and E. J. Barnes, W. T. Magruder, R. Mailänder, C. E. Margerum, A. Martens, A. Martens and E. Heyn, A. Martens and F. W. Hinrichsen, S. S. Martin, T. Matsushita and K. Nagasawa, H. S. Mattimore, K. Memmler, M. Merriman, J. T. Milton, M. A. Mimey, O. Miyagi, R. W. Moffatt, H. F. Moore, H. F. Moore and co-workers, R. R. Moore, G. Moreau, J. F. Morrison and A. E. Cameron, M. Moser, J. H. Nead, F. Nehl, J. A. Newlin and T. R. C. Wilson, E. Nusbaumer, W. Oertel and L. A. Richter, J. Okubo, J. Okubo and M. Hara, A. Olry and P. Bonet, T. Y. Olsen, A. Ono, A. E. Outerbridge, R. Pawliska and M. Schmidt, J. G. Pearce, A. Pérot, A. Pérot and H. M. Lévy, F. Pester, S. N. Petrenko, H. P. Philpot, J. A. Pilcher, R. Plank, H. Pommerenke, A. Pomp, E. Preuss, M. Prevez, H. S. Primrose and J. S. Glen, G. W. Quick, H. S. Rawdon and S. Epstein, P. Régnauld, C. Richardson and C. N. Forrest, N. Richardson and E. K. MacNutt, C. H. Ridsdale, F. Robin, R. Rötscher and M. Fink, F. Rogers, C. V. Roman, W. Rosenhain, M. Rudeloff, S. B. Russell, G. Sachs, H. R. Sankey, H. R. Sankey and J. K. Smith, F. Sauerwald and H. Wieland, M. Schaper, A. Schmid, M. Schmidt, E. Schneider, W. Schneider, P. Schönmaker, F. Schule and E. Brummer, E. Schulz and R. Fiedler, R. Sergeson, W. Schwinning, A. E. Seaton and A. Jude, H. Seehase, E. Seidl, E. Simonet, W. A. Slater and G. A. Smith, C. A. M. Smith, E. B. Smith, J. P. Snow, J. Snyders and P. A. M. Hackstroh, R. V. Southwell, H. J. Stagg, T. E. Stanton, T. E. Stanton and L. Bairstow, T. E. Stanton and R. G. Batson, R. Stribeck, Z. Takao, O. Thallner, J. J. Thomas, W. N. Thomas, F. C. Thompson, R. H. Thurston, H. D. Tiemann, T. Tredgold, E. U. Tschudi, W. C. Unwin, J. E. P. Wagstaff, R. G. Waltenberg, C. L. Warwick, O. Wawrziniok, W. R. Webster and L. Baclé, P. Welikhoff, G. Welter, T. D. West, H. L. Whittemore, and A. B. Wilson.

T. Kawai worked out the impact energy diagram of armco iron, mild steel, nickel steel, and nickel-chromium steel. The results are summarized in Figs. 222 and 223. In the usual form of the test, the impact energy required just to break the test-piece is determined. The impact energy is expended partly on heating the specimen, and is not stored up as potential energy, so that when the stress is reversed, the test-piece does not return to its previous length, and the elastic limit is reduced—*vide supra* for the effect of slow and rapid loading in the tensile strength test. T. Kawai found that the stress-strain relation with the impact test is not affected by the mode of applying the stress, that is, whether the stress is steadily increased, or whether it is applied and released several times in the stage of loading. The greater part of the impact energy is expended in producing an elastic and plastic strain in the test-piece. The former is at once returned to the pendulum hammer as rebound energy, and the latter is absorbed by the test-piece. T. Kawai found that the apparent absorbed energy varies linearly with the number of impacts, and a similar relation obtains between the apparent absorbed energy and the elastic strain energy of the test-piece. The relation between the bending and the net absorbed energy in the impact test is illustrated by Fig. 223 for notched bars 10×10×54 cu. mm. The results for the stress-strain energy of impact are summarized in Fig. 224. The energy absorbed in the impact test was discussed by G. Charpy and A. Cornu-Thénard, A. Cornu-Thénard, K. Honda, F. Körber and R. Sachs, M. Moser, and R. Yamada. R. W. Boyle discussed the compression waves produced in the metal by impact.

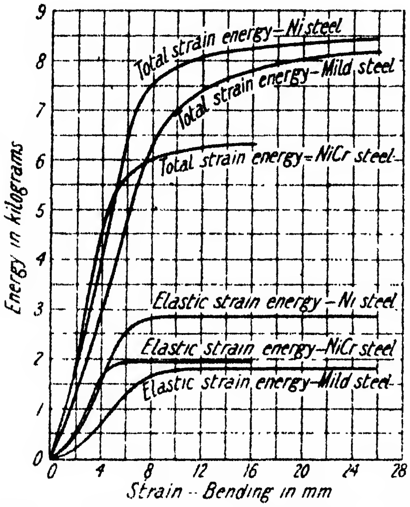

FIG. 222.—The Total Strain of Impact.

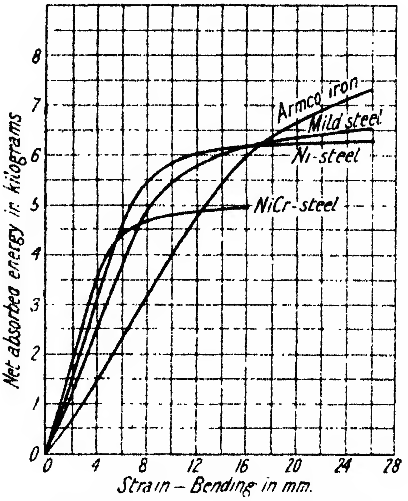

FIG. 223.—The Net Absorbed Energy of Impact.

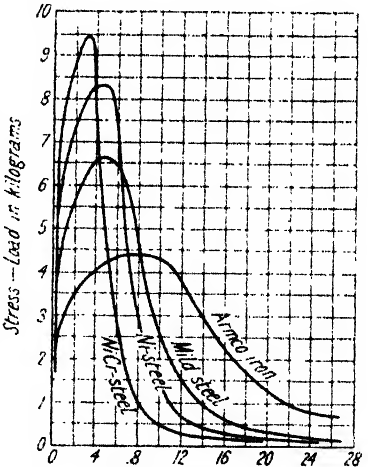

FIG. 224.—The Stress-Strain Energy of Impact.

The fundamental principles underlying the test were discussed by R. Plank, and he showed that rupture in the tensile test is totally different from rupture by the impact tensile test; in the static test there is a gradual increase in the applied stress, whereas with the dynamic test the stress suddenly increases to a maximum and then decreases. The stress-strain impact test was also examined by M. Moser, T. Inokuty, S. B. Russell, H. A. Dickie, T. Ishigaki, R. Mailänder and F. P. Fischer, W. Kuntze, F. Fettweis, K. Honda, R. H. Greaves, R. H. Greaves and J. A. Jones, A. McCance, J. Cournot, H. Sawagawa and R. de Oleveira, R. W. Moffatt, A. Gessner,

L. Jannin, E. Brechbühl, J. H. Hall, E. Preuss, O. Bauer, E. Heyn and O. Bauer, H. M. Howe, L. Klein, A. Mimey, H. Bornstein, F. N. Menefée and A. E. White, W. J. Keep, A. E. Outerbridge, A. M. Portevin, F. J. Cook, J. B. Kommers, J. G. Pearce, H. A. Schwartz, H. J. Tapsell and W. J. Clenshaw, A. N. Talbot and F. E. Richart, F. Körber and H. A. von Storp, W. Schwinning and K. Mathaes, S. Watanabe, Y. N. Morozoff, and R. Yamada. G. Delbart studied the impact toughness of cold-worked steel.

T. Sutoki observed that with 0·3 and 0·5 per cent. carbon steels, the highest temp. at which the test-pieces were abruptly broken by the impact test were 600° and 650°, respectively. A test-piece of a brittle material breaks abruptly at a maximum stress, but in the case of a tough material, the breaking occurs in several steps. The bending of the test-piece increases almost linearly with a rise of temp., but from 200° to 300° it begins to decrease, falling, at about 550°, almost to the value at ordinary temp. Above 550° it rapidly increases. K. Honda, T. Inokuty, and T. Sutoki discussed the theory that the thermal brittleness is the combined effect of work hardening and of the softening due to temp. R. W. Moffatt found that grey iron castings have a low impact resistance at room temp.; and this becomes less and less as the temp. is reduced below the f.p. The impact resistance of straight carbon steel castings decreases as the temp. falls below f.p., so that at −35° the resistance is only one-fourth of its value at room temp. The heat-treatment of these castings increases the resistance so that the value at −40° compares favourably with that at room temp. Low-carbon castings have a higher impact resistance than high-carbon castings. For the effect of hydrogen, see that element.

G. Charpy examined the impact toughness of iron by the notched-bar impact or shock test, between 80° and 600°. The work, in kilogrammetres per sq. cm., done by a hammer of weight W, falling a height H with a rebound h, when a denotes the effective sectional area of the fracture, is $W/(H-h)/a$. G. Charpy found a maximum in the vicinity of 200° and a minimum in the neighbourhood of 500°, and at higher temp. the toughness rapidly increased. A. le Chatelier, and E. Ehrensberger also measured the toughness of iron in terms of the notched-bar impact test at ordinary temp. L. Guillet and L. Révillon's observations agree with those of G. Charpy. The subject was also investigated by P. Breuil, W. H. Hatfield, R. A. Hadfield, P. Fillunger, R. Stribeck, T. Sutoki, F. Robin, and G. Goldberg,

E. W. Kaiser observed that the effect of cooling is very marked with the notched-bar impact test of wrought iron, and much more so in the case of steel. Mild steel lost 85·5 per cent. of its notched toughness when cooled from 15° to −20°; whilst under the same conditions wrought iron lost only 42·3 per cent. L. Aitchison found that most plain carbon steels give a marked drop in the notched-bar test at a low temp.—and generally between normal air temp. and −40°; between −40° and −80° the drop is small, and in some cases there is a small rise in value.

P. Goerens and G. Hartel found that, with a steel containing about 0·85 per cent. of carbon, between −75° and 1000°, the curves for the work on impact, or the resilience, in kilogrammetres per sq. cm. of effective section, are regular and show maxima at about 35° and 600°, with a minimum at 400°. Above 600° the work required for fracture falls off very rapidly, likewise also below 35°, so that at −75° the steel is very brittle. No discontinuities have been observed at the critical temp. R. H. Greaves and J. A. Jones found a maximum at 100° to 150° in the notched-bar tests; the exact position depends on the form of the test-pieces and the striking velocity. O. Reinhold's results with steels containing 0·08 C, 0·24 Si, 0·36 Mn, 0·050 P, and 0·04 Si; 0·15 C, 0·28 Si, 0·49 Mn, 0·034 P, and 0·03 S; 0·25 C, 0·12 Si, 0·39 Mn, 0·048 P, and 0·038 S; and 0·04 C, 0·23 Si, 0·51 Mn, 0·036 P,

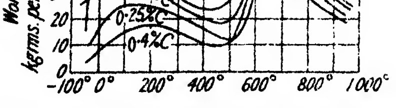

FIG. 225.—The Effect of Temperature on the Impact Work Required for Fracture.

and 0·015 S, are summarized in Fig. 225, and they illustrate the effect of carbon as well. A. Pomp used a soft iron with 0·07 per cent. carbon; he found that when heated to various temp. above 1000°, and slowly cooled, the toughness decreases, and this the more rapidly the higher is the temp., and a minimum brittleness is attained. R. M. Brown observed that cold-drawing greatly reduces the resistance to impact of mild steel, and a minimum is attained with a 30 per cent. reduction of area. A. Ono found that the cold straining of mild steel reduces its resistance to impact, but the resistance is restored on annealing. A steel containing 0·065 per cent. of carbon, after annealing at 920°, withstood 1010 blows; after annealing, followed by 8 per cent. straining, it withstood 940 blows; after annealing, straining, and again annealing:

Annealing temperature .	450°	500°	600°	700°	800°	900°	980°
Blows resisted . .	1013	1013	1013	496	553	1104	572

F. Wüst and E. Leuenberger made some observations on this subject. For L. Aitchison and L. W. Johnson's observations on the notched-bar test taken longitudinally and transversely, to the direction of forging, *vide supra*. The impact strength (notched bar) of mild steel castings was found to decrease on ageing at 250° for 1 hr. after forging to a reduction in area of 7 to 10 per cent., but not nearly to the same extent as it does after complete annealing. The values for the annealed metal at 20° to −20° were consistently below 2 mkgrms. per sq. cm., whereas those for the aged metal varied from about 6 mkgrms. per sq. cm. at 20° to about 2 to 3 mkgrms. per sq. cm. at −20°. A. B. Kinzel and W. Crafts studied the effect of inclusions on the impact test.

A. E. Seaton and A. Jude found that some nuts of connecting-rods broke down under conditions which could not be explained by the results of ordinary tensile tests, or of the alternating tensile stress tests. The repeated impact test was therefore investigated by J. O. Arnold, W. K. Hatt and E. Marburg, A. Pérot, M. Denis, T. E. Stanton and L. Bairstow, J. B. Johnson, J. B. Kommers, L. Bairstow, and J. O. Roos. According to T. E. Stanton and L. Bairstow, the angle of the notch in repeated impact tests has no influence on the number of blows which occasion fracture, for this depends solely on the relation between the diameter of the bar at the bottom of the notch, the diameter of the test-piece, and the distance between the supports. E. Nusbaumer compared the results of the simple impact test, and of the repeated impact test with Swedish iron, 0·07 to 0·46 per cent. carbon steels, nickel steels, and nickel-chromium steels subjected to different heat-treatments. It was found that the resistance always varies in the inverse ratio to the fall, and the rate of repetition of the stress—with the one exception of hardened nickel-chromium steel. The influence of the rate of the repetition of the impacts becomes less and less as the depth of fall increases, so that, provided the shock be sufficiently intense, the number of blows required to break the test-piece remains virtually the same, no matter what the rate of repetition of the test may be. H. Hanemann and R. Hinzmann found that the impact values with the notched-bar test are altered considerably by variations in the grain-size of the metal; and A. B. Kinzel and W. Crafts examined the effect of inclusions in the steel on the results.

A. E. Seaton and A. Jude found that the resistance to fracture with repeated impact-tests decreases as the proportion of carbon increases from 0·15 to 0·30 per cent.; and T. E. Stanton and L. Bairstow obtained a similar result provided the impacts are below a certain intensity. A. McWilliam and E. J. Barnes obtained the same results as A. E. Seaton and A. Jude. Steel with 0·75 to 0·80 per cent. of carbon offers a good resistance to repeated shock. According to J. O. Arnold, J. E. Stead and A. W. Richards, C. E. Stromeyer, and J. B. Kommers, phosphorus, and nitrogen in steel have an unfavourable influence on the repeated shock test; according to P. Longmuir, occluded hydrogen is deleterious; and, according to T. E. Stanton, J. H. Smith, and E. F. Lake, nickel, and titanium do not increase the resistance of steel to repeated shocks. E. Nusbaumer found that with carbon steels the resistance varies directly with the percentage of carbon as long as this percentage does not exceed 0·25 to 0·30, but with over this amount the resistance has a tendency to diminish, and this tendency is increased by hardening. In other words, the semi-hard steels always have a greater resistance than the mild steels. Hard steels resist better than mild steels (except in the hardened state), but not so well as the semi-hard steels. Swedish iron does not apparently display any greater resistance than soft steel. Generally speaking, the nickel steels have a greater resistance than soft carbon steels, but they do not appear to be superior in this respect to semi-hard steels. This is true only in cases where the depth of fall is not excessive; when the shock attains a certain intensity, the influence of the nickel disappears and the steel tends to behave like a simple carbon steel, no matter what the percentage of nickel may be. A second exception arises in the case of the steels containing from 0·30 to 2 per cent. of nickel, which in the hardened state display extraordinary resistances, far higher than those of the best carbon steel. The steel with 0·30 per cent. of nickel behaves almost as well or even better than steels containing a higher proportion of nickel (with the exception of the steel with 25 per cent. of nickel, and rolled). Finally, the nickel-chromium steels display much greater resistance than ordinary carbon steels, or even than nickel steels; but, of the nickel chromium steels, the dead-soft steel is the most resistant, and the semi-hard variety is the steel which gives the least satisfactory results. It has been said that, generally speaking, the resistance varies in inverse ratio to the depth of fall. Nickel steels, and in particular those containing both nickel and chromium, are much more sensitive than carbon steels to any variation in the depth of fall. This sensitiveness reveals itself by a considerable increase in the resistance once the depth of fall decreases.

A. E. Seaton and A. Jude found that hardening increases the resistance of steel to repeated shocks; but A. McWilliam and E. J. Barnes obtained a contrary result, and they also found that a sorbitic structure is unfavourable to the resistance of soft steels to repeated shock. According to E. Nusbaumer, hardening followed by annealing slightly increases the resistance of carbon steels. Its influence is, however, more appreciable with steels containing less than 0·30 per cent. of carbon than it is with the "hardening steels." Thus, semi-hard steels, hardened and annealed, are always higher in resistance than hard steels that have undergone similar treatment. Owing to the same phenomenon, hardening followed by annealing markedly raises the resistance of steels containing a low percentage of nickel (0·30 per cent. of nickel), but leaves steels with 2 per cent. of nickel practically unchanged. Lastly, it diminishes the resistance of nickel-chromium steels, but seems to have more influence upon soft nickel-chromium steels than on semi-hard steels. The latter, once hardened and annealed, display rather more resistance than the former when similarly treated. This is the reverse of what is found in the annealed (normalized) state. Hardening (not followed by annealing) considerably raises the resistance of Swedish iron, and, particularly, of mild steel—at least when the depth of fall is not excessive. In the opposite case (and this is a general observation applicable to all steels independently of their composition) the influence of the depth of fall becomes paramount and obliterates every other influence, *e.g.* that of the rate of repetition of the stress, of the chemical composition, and of the thermal treatment. Quenching either fails to affect or tends to diminish the resistance of semi-hard steel; it reduces to zero that of the "hardening" steels. The presence of nickel, either alone or combined with chromium, exaggerates to an extraordinary degree the effect of the quenching. The resistance of steel with 0·30 per cent. of nickel which has been quenched is, as a regular thing, equal to more than twenty-five times that of the same steel annealed, that is, for low depths of fall. That of steel containing 28 per cent. of nickel and quenched is, similarly, equal to nearly ten times that of the same steel after annealing; on the other hand, the steel with 25 per cent. of nickel subjected to the operation of quenching undergoes a sudden diminution in its resistance (nearly one-half). The nickel-chromium steels also have their resistance raised to a notable degree, but it is in the soft steels that the phenomenon is most marked, and in the semi-hard steels in which it is the least so. Lastly, in most cases overheating notably diminishes the resistance of all steels.

According to T. E. Stanton, the resistance of steel to repeated impacts agrees with its resistance to simple impact when the number of impacts determining fracture is small, but not so if the number of shocks is large. J. O. Roos obtained concordant results with endurance, rotary bending, and repeated impacts, but added that, in general, endurance under alternating tests is the reverse of the endurance under simple impact. L. Bairstow, however, believed that there is a complete lack of agreement between the results of the repeated shock test and those of alternating stresses. According to E. Nusbaumer, if the curves of resilience are comparable with those of the resistance to repeated shocks, it will appear at first sight as if there was no relationship between the two types of test. There is, however, a relation between the brittleness test and the repeated shock test. Every time the same steel in the same physical state (possessing the same essential constituents) undergoes—for any reason—a diminution of resilience, its resistance to repeated impact diminishes likewise ; and, on the other hand, whenever (under the same conditions) the resilience remains sensibly constant the resistance to repeated impact does not vary. It should be noted as a corollary to the foregoing proposition that the differences between the resistances of a normalized steel and a more or less overheated steel are greater in proportion as the depth of fall is less. Here is found once again the influence of the depth of fall which, as we know, tends to mask every other factor.

Fracture takes place by progressive fissuration. There exists at each point of fracture a dullness occasioned by the fact that the edges of the crack have become roughened or dulled by rubbing against one another, and the crack has enlarged until the moment when, the section having become too small, the test-piece has broken suddenly, yielding this time a crystalline fracture. This crystalline fracture invariably consists of a central band more or less wide and perpendicular to the line which joins the points of impact. Austenite is the particular constituent which offers the most resistance to repeated shocks, ferrite offers a far lower degree of resistance, and, finally, of all the constituents, martensite is the one whose resistance is lowest and, generally speaking, very closely in the vicinity of zero.

C. Frémont plotted the crushing curves at 15°, 800°, and 1300° for a soft steel with the tensile strength of 35 kgrms. per sq. cm. The curves were similar. F. Robin found that at a red-heat the ratio of the resistances is the same for static and dynamic crushing. The work done during static crushing was found to be less than during dynamic crushing. A. Martens gave for the static and dynamic work, in kilogrammetres per sq. mm., necessary to reduce the depth to a certain percentage of the height at a single blow :

	Soft steel				Soft steel			
Reduction depth .	95	90	80	70	95	90	80	70 per cent.
Compression (static) .	11·2	32·8	100·7	204·5	11·1	39·0	82·0	168·7
Crushing (dynamic) .	66·3	148·7	401·2	802·8	77·3	170·2	409·3	774·2

He showed that the proportion of work necessary to produce a certain reduction in depth increases with the intensity of the crushing, and to more than the anticipated proportionate number. C. Codron measured the resistance, in kilogrammetres per sq. mm., of forged metals to compression at different temp., and found :

	0°	100°	200°	300°	400°	500°	600°	700°	800°	1000°	1200°	1400°
Cast iron . .	50	50	49	48	47	44	40	36	28	18	8	0
Wrought iron . .	40	49	39	38	37	34	30	25	20	12	8	4

The values would be different with other modes of testing. With malleable metals the yield in the press. may be quadruple, triple, or double that of the hammer working at an average speed. With elastic metals, like steels at a red-heat, the coeff. of the relative yield falls, and the compression requires nearly the same amount of mechanical energy as does forging. The coeff. of the yield may here vary from 0·3 to 0·7. The work, in kilogrammetres per sq. mm., found by F. Robin for two steels at different temp., by static and dynamic compression, was as follows :

	0·07 per cent. carbon			0·9 per cent. carbon		
	15°	275°–290°	500°	15°	200°	500°
Elastic limit	35·2	17·5	19·9	108	110·7	60·7
Work Static	11·04	10·2	6·5	16·0	13·3	14·4
Work Dynamic	24·55	24·3	12·74	34·2	25·1	27·5

The curves for the static stresses up to a red-heat diverge completely from the curves of dynamic stresses. Soft metals like lead, tin (cold), and steels at a red-heat give higher values for the dynamic work for equal amounts of deformation ; and as the hardness and elasticity increase, the difference between the static and dynamic work may become less, or even reversed as in the case of the nickel, chromium, and tungsten steels, because of the work lost in the drop weight. The special austenitic steels, and often the martensitic steels, display this property. F. Robin extended this subject to the work of the drop-hammer, and the press. in forging metals. F. Sauerwald found that at moderate temp. the application of press. did not increase the size of grain of powdered iron, not previously worked in the cold, but at a higher temp. an increase in grain-size was observed.

C. de Fréminville[15] investigated **the effect of vibrations** on the tensile properties of steel. He said that in metallic rods and bars, elementary vibrations are propagated with but a very slight loss in work, and are reflected back again from the ends of these conductors. If these vibrations encounter the reflected vibrations, considerable stresses result. Excessive stresses leading to breakages may be set up by waves, or considerable vibrations being arrested in their course, at some point within the mass. C. Frémont, and C. Faroux found that, at this point, these vibrations occasion cracks, for the prevention of which any mode of strengthening the piece is absolutely useless. R. A. Henry studied the propagation of vibrational pressures within elastic bodies, and concluded that if there is complete synchronism between the vibratory movement a solid body may assume the periodic repetition of the stress, the vibratory movement becomes exceedingly exaggerated and develops elastic stresses wholly disproportionate to the intensity of the isolated stresses. He also showed that for any simple cylindrical body subjected in the direction of its axis to a simple sinusoidal pulsation applied to one extremity, the other being fixed, periodicities exist at which the body will undergo fracture, independently of what the amplitude of the pulsation may have been. A. Boudouard, and A. Guillet investigated the influence of various factors on the resistance to vibrations of cylindrical bars vibrating in diapason, and found that fracture occurred with stresses far below the ordinary elastic limit. Puddled iron resisted the vibrations better than did dead soft steel; and the number of vibrations necessary to fracture a bar of steel varies inversely as the percentage of carbon. Hardening diminishes the resistance of hard steels to vibrations. J. Resal made some observations on the subject, and E. Nusbaumer concluded from his observations that : (i) In carbon steels, the resistance, in the annealed state, varies in direct proportion to the percentage of carbon ; the rise in resistance, corresponding with a relatively slight increase of carbon, is considerable. Quenching markedly diminishes the resistance, but affects hard steels to a much greater extent than soft steels. Quenching followed by an annealing is the treatment that ensures the maximum resistance. (ii) In nickel steels, the resistance, in the annealed state, varies in direct proportion to the percentage of nickel. Quenching reduces the resistance. Quenching followed by annealing gives the most marked resistance. The 2 per cent. nickel steel, quenched and annealed, is distinctly superior to the best carbon steel. (iii) In nickel-chromium steels, the resistance varies inversely with the hardness of the steel, except in the quenched state. Hard nickel-chromium steels, quenched and annealed, display less resistance than semi-hard steels, which, in turn, again display less resistance than mild steels. In contradistinction to what occurs with carbon steels or with nickel steels, quenching considerably raises the resistance of nickel-chromium steels. It seems, moreover, to affect hard steel to a greater extent than it does mild steel. Quenching, followed by annealing, gives the minimum resistance. Any treatment that increases the tensile strength of nickel-chromium steel appears likewise to increase its resistance to vibratory stresses. (iv) An important fact is that all the steels, no matter what their nature (carbon, nickel, or nickel-chromium), ended by breaking, notwithstanding that they were being worked at less than their elastic limit. Thus, a steel may break by vibration without its effective deflection having attained that calculated from its elastic limit.

The question : What is the effect of repeated stresses on the tendency of metals to fracture ? was raised by W. A. J. Albert [16] in 1829, and later by H. James and D. Galton. In 1837, E. Hodgkinson stated that the repetition of any stress, however small, would permanently deform a metal exposed to the stress ; and in 1848, J. Thomson, however, added that the limits of proportionality might be initially very low, and in consequence small permanent sets might result from the first application of relatively small stresses, but a secondary result would be that the limits of proportionality would be greatly widened, so that subsequent applications of initial small stresses would produce no further deformation. Mysterious failures in fracture, and in the testing of wrought iron, etc., for railway bridges, appear as if (i) the ultimate strength of the metal deteriorated with time, or else (ii) failure was due to the mere repetition of the applied stresses. In 1849, a Royal Commission was appointed to inquire into this subject; it was found that the first hypothesis did not explain the phenomenon, but it was shown that a metal could fracture by the frequent repetition of a stress less than the statical ultimate stress, and that the failure was not due merely to the presence of a vibration, although vibration acted as an accelerating agent.

Metals will break under the repeated application of a stress very much less than what would be required to produce rupture if the stress were applied gradually and continuously. The strength of a piece of metal when tested in the ordinary way is not a sure guide for material which is to be subjected to a series of vibrating stresses such as might occur in the piston of an engine, in steel springs, in the axles of a railway carriage, in the supports for railway bridges, etc. F. Braithwaite attributed the breakage of some girders to a similar phenomenon. W. Metcalf found that hard steels suffer less from vibrations than do soft steels. W. Fairbairn investigated this subject for the Board of Trade, and he showed that a beam with a statical breaking load of 12 tons might withstand 3×10^6 applications of a load of 3 tons, but with a greater load, fracture occurred with a correspondingly smaller number of reversals. Hence, a safe vibrating load can be applied which can be sustained indefinitely. A. Wöhler concluded :

> Wrought iron and steel will rupture at a unit stress not only less than the ultimate static strength of the material, but even less than the elastic limit, if the stress is repeated a sufficient number of times. Within certain limits, the range of stress rather than the maximum stress determines the number of cycles before rupture. For a given maximum or a minimum unit stress, an increase of range of stress decreases the cycles necessary for rupture. For a given minimum or maximum unit stress, there appears to be limiting range of stress which may be applied indefinitely without producing rupture. As the maximum applied unit stress increases, this limiting range of stress decreases.

A. Wöhler found the safe unit stress for wrought iron under an alternating stress might be 8600 lbs. per sq. in. ; but under tension, it might vary from 3300 to

19,300 lbs. per sq. in.; and that the range of stress was constant if the ultimate stress fell below 3300 lbs. per sq. in. The alternating stress for untempered cast steel might be 12,800 lbs. per sq. in.; and in one direction only, from 11,500 to 35,000 lbs. per sq. in. For cast spring steel, the stress might vary from 96,000 to 128,0000 lbs. per sq. in. A. Wöhler's work was confirmed by L. Spangenberg, and B. Baker. The subject was followed up by J. Bauschinger, and he concluded that:

(i) A tension stress above the yield-point up to the applied stress, even if the bar is immediately re-tested: upon the release of the load and the lapse of time, the yield-point increases even above the previous maximum applied stress. This increase is noticeable even after one day, and may continue for even years. (ii) A tension stress above the yield-point reduces the elastic limit (determined by delicate measurements of deformations) often down to zero. Upon the release of the load and the lapse of time, the elastic limit increases, reaches the applied stress after several days, and may rise above this stress after sufficient lapse of time. (iii) A tension stress which lies above the elastic limit immediately, the more so the higher the initial stress. When the applied stress approaches the yield-point, the elastic limit reaches a maximum, and is lowered when the yield-point is exceeded. (iv) As a rule, a stress above the yield-point lowers the modulus of elasticity. Upon the release of the stress and the lapse of time, the modulus increases, and after several years is found to be considerably above the original value. (v) Severe jars, as by cold-hammering, lower the elastic limit which has previously been raised by over-stress and rest. If the hammering produces tension, the elastic limit decreases down to its original value, but otherwise it remains above it. (vi) Heating followed by subsequent cooling, will again reduce the elastic limit and yield-point which have been increased by overstress and rest. For low-carbon steel the effect becomes noticeable at 350° if the cooling is rapid, and at 450° if the cooling has no effect on the two limits. With wrought iron the effect is produced at about 400° both for rapid and slow cooling. (vii) Rapid cooling lowers the elastic limit and yield-point, especially the former, more effectively than slow cooling. Rapid cooling usually decreases the elastic limit to zero, or nearly zero, after heating up to 500°, and surely by heating up to cherry-red heat. This is true for wrought iron, low-carbon steel, and Bessemer steel. Slow cooling even after heating to a cherry-red heat does not produce such a great decrease. (viii) A stress in tension (or compression) beyond the elastic limit reduces considerably the elastic limit in compression (or tension) the more, the higher the applied stress is above the original elastic limit. Even relatively small transgressions of one elastic limit will produce the opposite elastic limit. A period of rest will not again increase the elastic limit, as is possible by loading in one direction above the yield-point. (ix) Gradually increasing alternating stress in tension and compression will not decrease the opposite elastic limit unless one of the original limits is exceeded. (x) An elastic limit in tension (or compression) which has been lowered by previous stress above the elastic limit in compression (or tension) can again be increased by applying a gradually increasing alternating stress, but it can be increased only up to a value which is considerably below the original elastic limit. (xi) Repeated stresses between zero and an upper limit which coincides with or is close to the elastic limit will not cause rupture. The elastic limit, however, must not previously have been raised artificially by tension or cold-working, nor must there be any flaws in the material. In the latter respect homogeneous material like low-carbon steel is especially sensitive. (xii) Repeated stress between zero and an upper limit in tension which coincides with or lies slightly above the elastic limit will increase the elastic limit, and the more so the greater is the number of repetitions, but not above a certain limiting value. (xiii) If by the previous action (as in xii) the elastic limit is increased above the applied stress, fracture will not take place; but if the applied stress is so high that the elastic limit cannot be augmented to this value, failure must take place after a limited number of repetitions. (xiv) If a material is to withstand an indefinite number of repetitions of alternating stress, then the applied stress must not exceed the natural elastic limit.

J. Bauschinger understood by the *yield-point* the unit stress at which a metal shows an increase of deformation without additional stress; and he explained his use of the term *natural elastic limit* by supposing a material with an artificially raised elastic limit would have its elastic limit reduced to a certain value by applying alternating stresses below this artificial limit, and that this new elastic limit would be the same as that obtained when an elastic limit which has been reduced is gradually increased by applying a slowly increasing alternating stress.

The effect of surface conditions on the resistance of metals to repeated stresses was studied by F. C. Lea and co-workers, D. J. McAdam, and R. H. D. Barklie and H. J. Davies.

The fact that when metals are fractured by repeated stresses, the fracture has a crystalline appearance led to the assumption that the metal gradually develops a crystalline structure under the influence of repeated stresses. There has been some discussion as to whether vibration and shock, under ordinary working conditions, can cause a metal to become crystalline and brittle. P. Argall, for instance, held that this is probably the case; whilst R. W. Raymond supported the opposite view. According to P. Kreuzpointer, the mode of breaking a metal may produce a crystalline fracture even though the metal is uniformly fibrous. Iron and those classes of steel which are supposed to be capable of crystallizing under shock and vibrations will not break until long after the primary or original elastic limit and the yield-point have been passed, and the metal has "flowed" more or less. The natural and inevitable consequence of "flow" in iron and steel is to break up and reduce the size of crystals and fibres; hence, the forces which operate to break and destroy a structural member of whatever kind are directly antagonistic to the formation of crystals out of fibres, these forces being fibre producers, as it were, from the moment they become active until the point of rupture is reached. This tendency is increased as the point of rupture is approached, since flow is most rapid in iron and steel just before the metal breaks, as is proved by the reduction or contraction of area at the point of rupture, and by the amorphous condition of "detail" fractures of iron and steel. Consequently, the theory of the crystallization of iron and steel under stresses and strains is based upon a misconception of the nature and properties of those metals, because the low heat or the heat that can possibly be produced in service, as well as stress and strain, with their effects analogous to mechanical work produced under hammer and roll, all tend to break up crystals in iron and steel, to make them smaller instead of making them larger, or permitting the formation of a new structure. R. A. Hadfield stated that all the fractures he had observed were more likely to have been the result of defective heat-treatment, than to have been produced by changes in the molecular structure of the metal. The subject was discussed by H. M. Howe, F. Rogers, C. H. Risdale, J. E. Stead, and E. B. Grub. R. W. Raymond does not consider that W. Fairbairn believed in crystallization as an explanation of the fracture, and there is no proof that a metal which has undergone much vibration has a more crystalline fracture than it originally possessed. When the bars which ruptured under fatigue showed a coarsely crystalline structure, this was not due to crystallization produced by cyclic stresses but rather to overheating, to defective chemical composition, or to faulty treatment in manufacture. J. Bauschinger proved that millions of repetitions of a stress do not alter the structure of the metal, nor reduce the ultimate static strength. A. E. Outerbridge said that brittle cast iron, after being subjected to repeated shocks, may become less brittle because a molecular annealing may occur at ordinary temp. which releases the strains in castings. The subject was discussed by A. Ledebur, and J. O. Arnold. H. Hädicke found that the repeated hammering—15,000 blows—of a piece of iron an inch square changed the fibrous to a granular structure. The blows went beyond the limit of elasticity, but if not subjected to this excessive treatment the metal does not change in this way.

According to P. Oberhoffer and W. Oertel, commercial iron shows a maximum grain-size after a 10 per cent. deformation between 700° and 800°, but with electrolytic iron this is not the case. The grains of electrolytic iron, however, do continue to grow at this temp. W. Riede showed that many alloy steels—Si-Mn, Cr, and Ni-Cr steels—as well as carbon steels, show a recrystallization of the material when subjected to rapidly alternating stresses.

Just as the *elastic limit*, or, in ductile metals, the *yield-point*, is the important criterion in the resistance of static stresses, so with alternating or repeated stresses the *endurance limit* is the important criterion, and with impact stresses the important criterion is the *modulus of resilience* or the capacity to absorb energy up to the elastic limit. Repeated stresses may vary from zero or from a positive or negative minimum to a positive maximum, so that the range of the stress is the algebraic difference between the maximum and the minimum stress. The **endurance limit** is the stress that may be applied to a given material for an indefinitely large number of cycles without producing rupture; or it may be regarded as the number of repetitions of a given stress required to cause failure. The term **fatigue** refers to the phenomenon of fracture under repeated stresses—*vide supra*. It is assumed that the metal becomes "weakened" by the repeated stresses, and then breaks more readily.

Excepting the eighth conclusion, the general results of J. Bauschinger have not been disproved. H. F. Moore and J. B. Kommers found that hot-rolled, 0·18 per cent. carbon steel wire, reduced by cold-stretching from 0·50 to 0·44 in., had originally an elastic limit of 38,200 lbs. per sq. in. and an ultimate strength of 61,500 lbs. per sq. in., and an endurance limit of ±28,000 lbs. per sq. in., and after the cold-stretching the endurance limit was ±41,000 lbs. per sq. in. after having been heated to 260°. Hence the elastic limit in compression which was reduced to zero by cold-stretching must have been restored to something like 41,000 lbs. per sq. in., and possibly a period of rest would have had a similar effect. G. Sulzer said that the stresses lead to cracking when they exceed the elastic limit, no matter how high the tensile strength of the metal may be; and C. B. Dudley, that breaking occurs when the calculated maximum stress reached half the ordinary elastic limit. T. E. Stanton and L. Bairstow found that the elastic limit after a certain number of alternating tensile and compression tests is lower than the original elastic limit; and L. Bairstow showed that the iron and steel adapt themselves to these variations so as to remain perfectly elastic and to exhibit no trace of fatigue. The variations of the elastic limit of tensile strength are slighter than those of the elastic limit of compressional strength, so that it is the latter which determines the permissible variation of stresses. Similar conclusions were obtained by J. H. Smith with alternating tension and compression; and by J. E. Howard, and L. B. Turner with rotatory bands.

The life or endurance of a metal can be referred to the number of repetitions of a stress of a given range of magnitude. The stress may be direct, bending, or torsional, or a combination of these stresses. The results of T. E. Stanton and J. R. Pannell with a reversed bending test on mild steel are summarized in Fig. 226, and the curve is sometimes called the *S/N*-curve. The endurance limits of stress on a 10 million reversals basis are ±12·75 tons per sq. in.; the limiting range of stress on a 10 million reversals is 25·5 tons per sq. in., using reversed stresses, or the limiting range of stress on a 10 million reversals basis is 12·75 tons per sq. in. The general type of curve is the same for various other modes of applying the test, and with many different materials. The curves become more and more nearly horizontal to the *N*-axis as the endurance increases. The curves have a certain formal resemblance to the so-called human endurance curves, where, owing to muscular fatigue, the speed of, say, a Marathon runner becomes less the greater the distance traversed. The question has arisen whether a material will fail at all stresses if the number of repetitions be sufficiently high, or whether there exists a limiting range of stress which would never produce failure. E. M. Eden and co-workers were unable to find a limit of stress, however slight, for which the necessary number of alternations required to produce fracture becomes infinite. C. E. Stromeyer denied the existence of any relation between resistance to alternating stresses, elastic limit, and breaking strain.

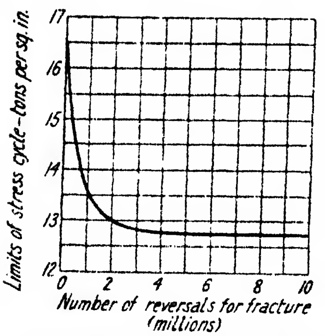

FIG. 226.—Endurance Curve of Mild Steel.

The subject has been discussed by K. Aders, C. R. Austin, F. Bacon, L. Bairstow, W. B. Bartels, O. H. Basquin, R. G. Batson and co-workers, K. Baumann, P. Billet and H. Wantz, R. M. Brown, G. R. Brophy, H. Buchholtz and E. H. Schulz, C. H. Bulleid,

R. Cazaud, C. L. Clark and A. E. White, G. Colonnetti, J. L. Cox, J. F. Cunningham and J. Gilchrist, J. Czochralsky and E. Henkel, C. H. Desch, H. Deslandres, W. Deutsch, H. C. Dews, C. B. Dudley, E. Duryea and J. Mayer, E. M. Eden, E. M. Eden and co-workers, A. Esau, W. H. Finley, O. Föppl, J. R. Freeman and co-workers, H. J. French and co-workers, Y. Fujii, T. S. Fuller, J. C. Gardner, J. Geller, H. W. Gillett, J. C. Godsell, H. J. Gough and co-workers, J. H. Grindley, L. Guillet, G. H. Gulliver, R. G. Guthrie, G. A. Hankins, G. A. Hankins and G. W. Ford, D. Hanson, O. E. Harder, V. Müller and H. Leber, W. R. Needham, F. H. Norton, J. Oehschläger, A. Ono, R. E. Peterson, E. Pohl and co-workers, W. C. Popplewell, E. Preuss, V. Prever and E. Balma, H. S. Prichard, W. Riddlesworth, F. Rittershausen and F. P. Fischer, T. L. Robinson, T. Robson, F. Rogers, W. Rohn, J. O. Roos, W. Rosenhain, F. W. Rowe, N. A. Schaposhnikoff and co-workers, W. Schneider, W. Schwinning and E. Strobel, J. Seigle and F. Cretin, R. Sergeson, C. Shiba and K. Yuasa, W. R. Shiner, A. Shimizu, J. H. Smith and co-workers, T. A. Solberg and H. E. Haven, E. P. and B. H. Stenger, R. Stribeck, C. E. Stromeyer, H. J. Tapsell and W. J. Clenshaw, H. R. Thomas and J. G. Lowther, A. Thum and co-workers, J. R. Townsend and C. H. Greenall, L. B. Tuckerman and C. S. Aitchison, C. A. P. Turner, G. B. Upton and G. W. Lewis, G. Welter, J. K. Wood, and J. G. R. Woodvine, etc.

H. J. Gough concluded that a definite limiting range of stress exists for an indefinitely large number of reversals, and it can be determined, for all practical requirements, by the endurance test on a basis of 10 million reversals. He also studied the effect of alternating torsional stresses on a single crystal of α-iron. A. Thum and W. J. Wiss found that by subjecting steel to 5,000,000 reversals of a load just below the fatigue strength and then repeating the treatment several times after increasing the load by 1 kgrm. per sq. mm. every time, the fatigue limit may be increased by as much as 20 per cent. If the load is increased after fewer reversals the material acquires a greater strength at the cost of a shorter effective life. Previous cold-work increases the fatigue strength and the capacity of the metal to withstand overload in dynamic tests. According to H. J. Gough and D. Hanson, armco iron after being exposed to repeated stresses about 40 millions in number and 0·4 ton less than the limiting fatigue range, shows, microscopically, dark slip-bands consisting of fine lines which appear to be masses of slip-bands rather than one slip-band widened by attrition. It is doubtful if continuous slipping occurs on the planes first formed. A mobile film was postulated to explain the behaviour of overstrained metal, particularly with respect to the gradual recovery of elasticity after overstrain, but it does not readily account for the fact that recovery of elasticity can be attained by subjecting overstrained material to reversals of stress at high speed. Failure under repeated stresses does not appear to differ essentially from failure under static stresses. When a sufficient stress is applied, slip occurs within certain crystals in the material, resulting in local strain-hardening, and when the stress is reversed further slip takes place, but not on the original slip-band, which has been strengthened by the previous slip. This process is repeated, and if the range of stress is not too great the metal may be sufficiently strengthened to withstand an indefinite number of reversals of that range of stress without further slip occurring. In this way the formation of a very large number of slip-bands within the fatigue range may be explained. The subject was studied by H. F. Moore and T. Ver.

According to W. Herold, the structure of pearlitic steel at the point of fracture by fatigue under repeated stress shows that the cementite has been forced towards the grain boundaries, whilst lamellar pearlite has been crushed and converted into granular pearlite, giving the metal a very coarse-grained structure. In martensitic steels the hard η-phase becomes crushed into small particles which are forced through the softer ϵ-phase towards the grain boundaries. In some austenitic steels after fracture by fatigue, cementite may be observed at the grain boundaries, although the presence of this constituent is not visible in the original structure; in other cases, the fatigued metal has a nodular structure which cannot further be resolved. In general, steels which have been hardened and tempered lose their capacity for damping, *i.e.* for converting energy into heat by internal friction after being subjected to repeated stresses sufficient to produce failure by fatigue. G. S. von Heydekampf studied the effect of cold-work on the fatigue or endurance limit of steel and found that the fatigue limit is raised by cold-work, and similarly with the safe working range of repeated reversals of stress.

Attempts have been made to find a relation between the safe range of the stress, and the mean stress of the cycle, by W. Gerber, H. Lippold. W. Launhardt, O. H. Basquin, F. Schäffer, J. Gilchrist, J. Weyrauch, J. Goodman, F. Rogers, B. P. Haigh, A. Wöhler, J. B. Johnson, J. H. Smith, H. J. Gough, H. F. Moore and T. M. Jasper, T. M. Jasper, H. F. Moore and F. B. Seely, C. E. Stromeyer. F. C. Lea, etc. Attempts have also been made to find a relation between the endurance, and other physical properties—*e.g.* hardness, tensile strength, and impact tests—by H. J. Gough, R. R. Moore, P. D. Merica and co-workers, W. M. Corse and G. F. Comstock, R. L. Templin, T. E. Stanton and R. G. Batson, T. E. Stanton and L. Bairstow, H. R. Sankey, etc. C. Mimey, N. Davidenkoff, P. Breuil, A. Portevin, H. Seehase, R. Stribeck, and H. le Chatelier discussed the transformations of impact energy into thermal energy during the impact testing of steel. The effect of the shape of the specimen, and of sudden changes in the section of the specimen tested—by flaws, holes, etc.—has been discussed by A. Wöhler, J. O. Roos, B. P. Haigh, W. N. Thomas, J. S. Wilson and B. P. Haigh, E. M. Eden and co-workers, C. E. Inglis, K. Suyehiro, E. G. Coker, G. I. Taylor and A. A. Griffith, L. Bairstow, H. W. Gillett and E. L. Mach, F. C. Lea, T. E. Stanton, H. F. Moore and co-workers, etc.; the effect of the surface finish, by E. M. Eden, G. A. Hankins and M. L. Becker, H. F. Moore and J. B. Kommers, J. Sondericker, W. N. Thomas, A. A. Griffith, etc.; the effect of internal stresses, by H. F. Moore and co-workers, L. Aitchison, H. W. Gillett and E. L. Mach, S. Whyte, etc.; the effect of surface decarburization, by C. R. Austin; and the effect of corrosion, by D. J. McAdam, B. P. Haigh, and R. R. Moore—*vide infra*.

The possibility of applying the elastic formulæ of W. J. M. Rankine, A. J. C. B. de St. Venant, and C. A. Coulomb, which has been developed on the assumption that the metals are homogeneous and isotropic, turns on the fact that although the metal is really an aggregate or a colony of minute crystalline grains, and that the formulæ are consequently not true for individual grains, or for small groups of grains, yet with large aggregates the formulæ are statistically true in the same sense that mortality statistics enable the death rate of a *community* to be predicted, but are not applicable to *individuals*. The subject has been discussed by J. J. Guest, W. A. Scoble, R. G. Batson, B. P. Haigh, E. L. Hancock, L. B. Turner, C. E. Stromeyer, D. J. McAdam, H. F. Moore and J. B. Kommers, H. F. Moore and T. M. Jasper, and T. E. Stanton and R. G. Batson. The effect of the speed of repetition upon the fatigue range was discussed by O. Reynolds and J. H. Smith, J. B. Kommers, H. J. Gough, H. F. Moore and T. M. Jasper, T. E. Stanton and J. R. Pannell, G. A. Hankins, W. Mason, B. P. Haigh, etc. O. Reynolds and J. H. Smith with alternating bends, L. Bairstow with alternating tension and compression, and J. O. Arnold with repeated impacts observed that the resistance of the metal varies inversely as the rapidity of the reversal of the stresses, but B. Hopkinson with periodic tensile tests, and J. O. Roos with rotary bending tests came to the opposite conclusion; while T. E. Stanton, and E. M. Eden and co-workers concluded from alternating bending tests that there is no relation between the endurance and rates not exceeding 2,000 alternations per minute. T. E. Stanton and L. Bairstow, T. E. Stanton, J. B. Kommers, and E. M. Eden and co-workers, showed that in the alternating bending tests, deep grooves and even tool marks on the test-pieces spoil the results; and C. de Fréminville, and C. Frémont attribute this to the fact that deep grooves and tool-marks stop vibrations—*vide supra*, the action of vibrations. L. Aitchison and L. W. Johnson discussed longitudinal and transverse tests—*vide supra*. The effect of understressing was examined by J. H. Smith, H. F. Moore and T. M. Jasper, E. G. Coker, etc.; and the effect of overstressing, by J. H. Smith, H. F. Moore and co-workers, etc.

Railway engineers have noticed that with axles and rails, hard metals resist alternating bending stresses far better than soft metals, and this is in agreement with the observations of T. E. Stanton and L. Bairstow, and J. E. Howard. The last-named reported that steels with 0·75 to 0·80 per cent. of carbon resist very well rotary bending stresses, while with higher or lower percentages of carbon the resistance is not so good—*vide infra*, repeated impact tests. Impurities like slag, manganese sulphide, etc., were found by M. Longridge, M. Ziegler, and C. B. Dudley to act injuriously on alternating bending or rotary stresses, and repeated impacts. In the solidification of these impurities, owing to their contraction, they leave minute fissures and flaws within the steel, and these enlarge under the influence of repeated stresses. According to C. E. Stromeyer, J. O. Arnold, J. E. Stead, and J. B. Kommers, phosphorus and nitrogen favour resistance to alternating bending stresses, but not to repeated shocks; according to T. E. Stanton, J. H. Smith, and E. F. Lake, nickel and titanium favour resistance to alternating bending stresses, but not to repeated shocks; and, according to P. Longmuir, occluded hydrogen makes the steel more susceptible to fracture by repeated shocks. E. Biard said that the relative breakage of railway axles owing to the development of cracks, is as follows: Open-hearth steel, 1; Bessemer steel, 0·625; crucible steel, 0·333; puddled steel, 0·256; crystalline iron, 0·213; and fibrous iron, 0·092. A. Boudouard also found that puddled iron resists vibrations better than soft steel.

F. Rogers, T. E. Stanton, B. Blount and co-workers, and E. M. Eden and co-workers found that the hardening of steel raises its resistance to alternating bending stresses, and annealing has the converse effect; J. C. Gardner obtained similar results with rotary bending stresses; J. H. Smith, with alternating tensile and compressive stresses; and A. E. Seaton and A. Jude, with repeated shocks. A. McWilliam and E. J. Barnes said that hardening diminishes the resistance of steel to repeated shocks; and A. Boudouard, to vibrations. F. Rogers, and A. W. Richards and J. E. Stead found that overheated steel has a poor resistance to alternating bending stresses, but the metal can be restored by a suitable heat-treatment. A. Boudouard, and A. W. Richards and J. E. Stead found that a sorbitic structure, obtained by hardening and annealing, favours the resistance of steel to vibrations and alternating bending stresses; but, according to A. McWilliam and E. J. Barnes, not so with repeated impact tests on soft steels. E. M. Eden and co-workers found that no heat treatment improves resistance to alternating bending stresses, tension, or compression by raising the permissible load; the sole advantage of heat-treatment is to increase the number of alternations before fracture under a given load. L. Bairstow found that a fatigued steel—*i.e.* a steel whose elastic limit has been displaced by repeated stresses—regains its ordinary limit after testing for several months, or on treatment with boiling water—*vide infra*, recovery. According to E. P. and B. H. Stenger, there is one certain quenching temp. for steel to yield a maximum fatigue strength, and with high-carbon steel this corresponds with the A_{cm}-point.

L. Aitchison and L. W. Johnson found that the fatigue strength is higher with specimens cut parallel to the direction of forging than it is with specimens cut at right angles to that direction. H. F. Moore observed that the failure by fatigue of the metals he examined was due to the growth of minute flaws and cracks; and it is generally agreed that fracture takes place gradually by the development of a flaw, which, to begin with, may be microscopic. For K. Yuasa's observations, *vide supra*, tensile tests. According to J. A. Ewing and J. C. W. Humfrey, A. E. Seaton and A. Jude, W. Schwinning and E. Strobel, and T. E. Stanton and L. Bairstow, the development takes place either by slip-bands or twinnings. A. E. Seaton and A. Jude, F. Rogers, T. E. Stanton and L. Bairstow, and W. Giesen consider that the flaw develops by preference within the ferrite.

The observations of J. A. Ewing and co-workers on the development of slip-bands and cracks when a metal is subjected to alternating stresses, have been previously discussed. T. E. Stanton and L. Bairstow obtained confirmatory results. One of the characteristic features of fractures due to stress reversals is the fact that they occur abruptly without the local drawing out and necking associated with ordinary tensile tests with ductile materials. This phenomenon fits very well into the slip-band hypothesis. In agreement with some observations of H. F. Moore and J. B. Kommers, H. J. Gough and D. Hanson found that with armco iron the endurance limit may be greater than the static yield-point. Analogous cases where the endurance limits are higher than the proportional elastic limits have been reported by H. F. Moore and T. M. Jasper, R. R. Moore, D. J. McAdam, and J. M. Lessells. H. J. Gough and D. Hanson observed that with static stresses, below the limit of proportionality, there is no indication of strain, but for stresses above the proportional limit, definite markings developed like the slip-bands produced by elastic strain; with alternating stresses, just below the limit of proportionality, after 11,750,000 cycles, surface markings developed on only a few crystals, the other crystals showed no evidence of stress, and with stresses a little above the proportional elastic limit, the markings were the same as before, but more crystals were affected. With stresses greater than the static yield-point, but less than the endurance limit, dark areas appeared on some of the crystals. These areas contained numerous slip-bands, proving that the slip-bands develop at stresses below the endurance limit, and that the production of these bands is not a criterion of ultimate failure by fatigue. D. J. McAdam, and A. M. Binnie studied the corrosion fatigue of iron—*vide infra*, corrosion.

L. Bairstow found that a specimen of axle steel with a yield-point of 55,700 lbs. per sq. in. and an ultimate strength of 85,500 lbs. per sq. in., when subjected to

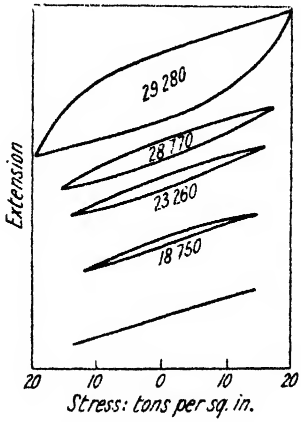

Fig. 227.—Elastic Hysteresis under Repeated Stresses.

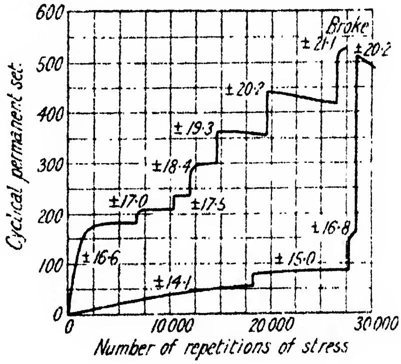

Fig. 228.—Effect of Reversals on the Permanent Set.

equal and opposite stresses of 31,600 lbs. per sq. in., gave a straight line as the cycle of extensions, but as the number of cycles increased to 18,750, the width of the hysteresis loop was about 11 per cent. of the original elastic extension. As the stress on the specimen was increased to 33,600 lbs. per sq. in., the width of the loop increased, so that with a stress of 45,200 lbs. per sq. in., and 29,280 cycles, the loop became very wide. At lower stresses the width of the loop tended to a constant value as the number of cycles increased, and at higher stresses the width of the loop decreased with an increase of cycles. When the stresses were not completely reversed, a "permanent extension" was developed, due to the repeated stresses, and he called it the *cyclical permanent set.* Observations on the hysteresis loops were made by J. A. Ewing, B. Hopkinson and G. T. Williams, F. E. Rowett, J. J. Guest and F. C. Lea, J. Arnott, H. F. Moore and J. B. Kommers, H. J. Gough and D. Hanson, J. H. Smith, J. H. Smith and G. A. Wedgwood, etc.

L. Bairstow studied the development of the cyclical permanent set with reversals (Fig. 228). At each stress range the cyclical permanent set appears to be approaching a constant value, which was in some cases temporarily preceded by a higher value. The constant values attained with the two specimens shown increased with the intensity of the applied range. L. Bairstow plotted these constant values of the cyclical permanent set against the applied stresses, and obtained an approximate straight line intersecting the stress axis at a positive value. He concluded that a range of stress was indicated under which the material would possess or attain a state of perfect elasticity under indefinite repetitions of the stress range. This means that the fatigue range is an elastic range. In the case of reversed stresses no permanent extension occurred during the test.

The phenomenon of **creep** (Fig. 228) was studied by R. W. Bailey, L. Bairstow, R. G. Batson, R. G. Batson and H. J. Tapsell, H. J. Tapsell and co-workers, H. J. Gough and D. Hanson, W. Herold, W. Kerr, F. Körber and A. Pomp, F. C. Lea, W. Mason, K. Memmler and K. Laute, L. S. Moisseiff, E. Pohl and co-workers, A. Pomp and co-workers, A. Pomp and W. Enders, W. Rohn, W. Rosenhain, L. W. Spring, H. Stäger, etc.—*vide supra,* plastic flow. H. F. Moore and J. B. Kommers stated that when a metal is stressed above a certain value, plastic yielding and creep occur with certain unfavourably placed crystals. This, they said, causes a local redistribution of internal stresses, which may cause an increase or decrease of stress in the immediate vicinity. A local increase of stress acting on a suitably placed cleavage plane may cause further slip, which induces a further redistribution of the stresses. With some ductile metals, creep may produce a sudden yielding at a particular load, and in others it may continue until it reaches a maximum. This creep increases as the stress increases, until finally a stress is reached at which the creep continues indefinitely and the metal fails. If the creep under a certain stress has ceased, the portions of the metal which have not suffered plastic deformation will be under a higher stress than those which have slipped. When the stress is reduced, slip may occur in those parts previously free from slip. When the stress reaches zero the redistribution of stress continues in the form of the so-called elastic after-effect. Hence, creep and elastic after-effect are two aspects of the same process, the one positive creep and the other negative. H. F. Moore and J. B. Kommers continued:

> The well-known fact that metal which is stressed below its endurance limit is strengthened is in itself sufficient to show that even at these lower stresses there must be an action in the material which is not elastic. It is difficult to conceive how elastic action could strengthen the material, but it is easily understood how inelastic action could do this. The evidence of slip-bands and hysteresis loops at stresses less than the endurance limit of the material is further evidence that a material has the power of adjusting itself to cycles of stress if these cycles of stress are within certain limits. That a process of strain-hardening is going on under repeated stresses below the endurance limit is evidently quite as possible as it is under the action of static stresses above the yield-point.

The creep at an elevated temp. was studied by F. C. Lea and co-workers, who found that, at a given temperature, there is a limiting creep stress above which the material is viscous; at ordinary temp., and with stress above the static yield-point, specimens may show a fairly steady creep for hours, but the creep eventually ceases if the stress is below the ultimate strength. This shows that at a given temp. there is a stress below which creep ceases, and above which it is continuous. H. F. Moore and J. B. Kommers added that "the limiting range of stress appears to be that range below which molecular slips can take place in the material, but after which new bonds may be established. This new bonding is materially helped by raising the temp., and also by permitting slip to take place in very small increments during the application of cycles of stress. If the applied stress exceeds a certain value the relative movement of the molecules is too great to permit re-bonding, and molecular separation occurs, which results in the formation of a fatigue crack and final failure."

L. Bairstow compared the yield in static and fatigue tests. In Fig. 229 the curve *FABC* represents the ordinary load-elongation static test for axle steel; while the curve *FEJHBC* represents the total elongation produced by repeated stresses, when the upper limit of the safe range coincides with the ordinates of this curve. Thus the repeated application of a safe range of stress with a superior limit, *OG*, produces a total permanent set equal to *GH*; *FE* represents half the safe range of stress and it produces no permanent elongation. Between this stress and the static yield-point, the permanent set is greater with a repeated stress than with a static stress. The two curves are the same at the static yield stress, and remain so for higher stresses, so that the curve *FEJHBC* is continuous. Hence, for stresses below the yield-point, iron and steel can maintain an unstable condition for a considerable time under cyclic stress. The first application may not show a measurable extension, but the extension may be greatly augmented under a constant cycle of repeated stress. The region *EABJE* can be explored by repeated stresses, but not by a single application of stress as in a static test. According to H. F. Moore and J. B. Kommers, this indicates that the elastic limits and yield-points of static tests cannot be correlated with endurance limits. C. L. Clark and A. E. White studied the effect of temp., and found that if y denotes the stress in lbs. per sq. in., and x the duration of the stress in hours, $y = ax^b$, where a and b are constants for a particular metal. They found for steels:

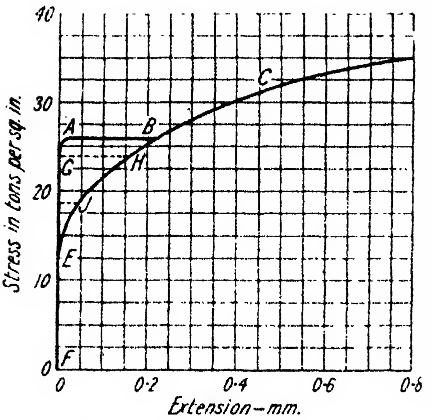

FIG. 229.—Permanent Set of Static and Repeated Loading.

	0·13 per cent. C		0·38 per cent. C		
	593°	538°	677°	593°	538°
a	9566	24,125	7670	16,300	27,275
b	−0·1477	−0·1333	−0·1600	−0·1384	−0·1375

While the term *fatigue* is an effect which will finally lead to fracture, the term **recovery** is applied to the opposite effect. J. A. Ewing found that overstrained iron or steel gradually approaches its original unstrained state with time, and J. Muir added that the recovery may occupy 17 days, but the recovery may be accelerated by raising the temp. to 100°. The observations of J. H. Smith, and of H. F. Moore and T. M. Jasper, show that for any degree of overstressing there is a limiting number of reversals below which the fatigue range is not affected, and that this limiting number decreases as the magnitude of overstraining increases. Overstressing has a greater effect on hard than it has on soft steels. Where the effects of overstressing are negligible, it is assumed that recovery has taken place. H. J. Gough defines recovery as that process by which a metal attains, or tends to attain, a state of elasticity from a non-elastic state. (i) *Recovery by the application of repeated stresses.* Some metals, under safe ranges of stress, have a large primary hysteresis loop; and under the application of repeated stresses the loop diminishes in width so that a state of elasticity is attained and maintained indefinitely. Hence, repetitions of a safe range of stress constitute an effective agent of recovery. In some cases a similar phenomenon occurs with unsafe ranges of alternating stresses. (ii) *Recovery by rest.* There is nothing to show that a state of elastic hysteresis is affected by rest, but with ranges of stress exceeding the limiting range, J. H. Smith and G. A. Wedgwood, W. E. Dalby, and H. J. Gough showed that rest has a marked effect in diminishing the area of the hysteresis loop. Recovery by rest occurs whether the specimen is under stress or free from stress. (iii) *Recovery by mild heat-treatment.* J. Muir, and R. H. Greaves have shown that a mild heat-treatment—*vide supra*—accelerates the recovery produced by resting. (iv) *Recovery by annealing.* If an annealed specimen with a definite primitive limit of proportionality and yield-point be subjected to repetitions of a range of stress, the primitive limits are rapidly readjusted; and if, after a few repetitions, the specimen be annealed, the primitive properties of the material reappear. E. G. Coker, and E. J. McCaustland discussed the effect of low temp. on the recovery of steel from overstrain.

Several hypotheses have been suggested to explain fatigue. The crystallization hypothesis has been discussed. J. Goodman assumed that a range of alternating stress should be regarded as a live load superposed on a statical load, so that the live load has the destructive effect of a suddenly applied load. This does not agree with the general form of the S/N-curve. J. Bauschinger's range of natural elastic limits did not imply any mechanism by which the elasticity was attained. J. A. Ewing and J. C. W. Humfrey applied their theory of deformation by slip, or slip-bands. G. T. Beilby, and W. Rosenhain developed the theory of the production of an amorphous phase by deformation through mechanical strain. B. P. Haigh assumed that the change from the crystalline to the amorphous phase precedes the gliding action, so that the glide is a result of the change of phase and not the cause, as assumed by G. T. Beilby. The actual slip is a protective agency against fatigue, and not a contributory cause. Once a cyclic state has been established, the inelastic work done per cycle is a function of the range of applied stress, whether that range is safe or unsafe. Hypotheses on the subject have been developed by A. A. Griffith, S. L. Smith and J. V. Howard, C. F. Jenkin, and W. E. Millington and F. C. Thompson. H. J. Gough thus summarizes B. P. Haigh's theory of the hysteresis:

> In a metallic test-piece subjected to repeated stresses, certain molecules are in unstable positions, some being ready to be projected from the crystalline lattice into the vitreous state. Under repeated stresses, a dual process of crystallization and decrystallization is in action. This is equally true whether the range is safe or unsafe; also, as the change of state is associated with gliding motion resisted by friction, the process will not be thermo-dynamically reversible, and work will be done on the specimen by the external forces producing a hysteresis loop. B. P. Haigh has likened this dual action, with the ensuing heat loss, as equivalent to the action of a reversed heat engine with a considerable thermal leakage. Under safe ranges of stress, the dual actions of ravage and repair will either balance each other, resulting in a steady rate of evolution of heat, or the repair forces may slightly preponderate and the heat evolution will gradually diminish. When the applied range is increased, the dual action occurs at a greater number of zones, and more actively at each of the original zones. The mechanism is still the same, molecules being cyclically projected from and into the crystalline lattice by an orderly arrangement of replacement. So long as this continues, the limiting range of stress has not been exceeded. At some stage, however, the simultaneous movement of such a large number of neighbouring molecules renders impossible the previous orderly replacement, and cavities form which subsequently develop into cracks. The fatigue range has been exceeded, and the process is now mechanically, as well as thermo-dynamically, irreversible. Thus, the limiting condition is that the dual processes of crystallization and decrystallization shall no longer balance each other, but produce cumulative effects.

H. E. Tresca[17] showed that homogeneous and isotropic solid substances under deformation obey the laws of the flow of liquids, and that, from this point of view, solids can be regarded as liquids possessing a greater or less degree of viscosity; and F. Robin found that the law is applicable to wire-drawing and to the rolling or forging of carbon steels. The crushing of a body depends on its physical condition and geometrical form, and it is usual to keep the shape of the test-piece constant—a straight cylinder with circular bases. The bases undergo friction from the crushing surfaces so that the flow of the metal is different at the extremity bases and at the middle. The cylinder generally bulges out so that the equatorial or medium diameter is greater than the diameters at the ends. H. E. Tresca also observed that under the influence of shock, delivered at the same rate, the resulting deformations are larger, the greater the intensity of the shock; and on similar test-pieces the deformations are similar and proportional to the shock. The specific work performed by shocks of equal intensity, in kilogrammetres per c.c., on similar shaped solids of similar materials, results in equal amounts of crushing deformation. J. V. Poncelet showed that the greater the amount of deformation on the surface receiving the shock, the less the lag on the bases; the difference in the deformation at the two bases increases with the intensity of the shock; and the form of the cylinder under compression is symmetrical only in the case of static compression. The median bulge is greater the more slowly the test is conducted, and the less smooth the bases of support—*vide supra*, plastic flow.

A. Martens, C. Codron, and F. Robin discussed the work done during the deformation, as well as the resistance to crushing as affected by the dimensions of the test cylinders, the number of blows delivered, and the rate of succession of shocks by impact. According to F. Robin, in the neighbourhood of atm. temp., the resistance to crushing (Fig. 230) of pearlitic carbon steels varies but little. If the metal be cooled the resistance increases, and there is a sudden rise at about −80°, and a high value is attained at −185°. The resistance to crushing at −185° is a little more than one and a half times its value at 15°, that of steels containing free cementite is very high at these low temp. A rise in the temp. from 0° to 300° diminishes the resistance of carbon steels to crushing. The curve is not uniform throughout this interval, but assumes a wavy direction, which more often than not is distinguished by a marked fall in the resistance at about 100°. At about 300° all the curves of the carbon steels attain a minimum. The resistance to crushing is at this temp. lower than it is at any other except when a red-heat is reached. Above 300° the curves rise, and the resistance to crushing increases up to about 500°, where it reaches a maximum which occurs probably a little below the exact temp. of 500°. Above 500° the resistance of the metal decreases rapidly up to 1000°, carbon steels being ranged at that temp. in the same order as at the ordinary temp. Above 1000° with highly carburized steels, or above 900° with mild and dead-soft steels, the diminution of the resistance to crushing in terms of the temp. takes place very slowly. Steels containing free cementite are somewhat resistant at about 1300°, and commence to split beneath the shock and to lose their cohesion. Dead-soft steels, on the contrary, are still forgeable at 1480°, where their resistance to crushing reaches about 1·5 kilogrammetres per c.c. At higher temp. the metal burns or fuses, and is no longer forgeable. The curvature appears to be very nearly uniform at a red-heat; at a nascent red-heat, only in the case of steels with a high percentage of carbon; soft steels and dead-soft steels appear to present two successive bends towards 500° and 600°. The difference between the maximum and the minimum resistance to crushing does not vary greatly in its absolute value. This difference does not depend on the percentage of carbon, but seems rather to bear a ratio to the amount of foreign elements present, and, in particular, to elements dissolved in the iron.

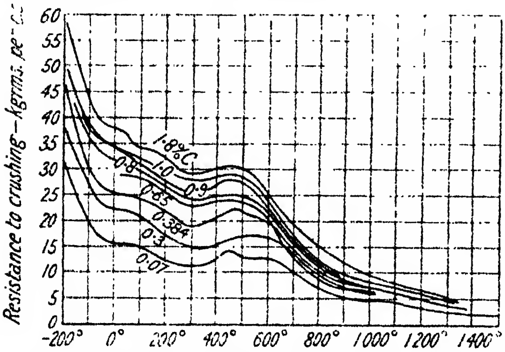

Fig. 230.—The Resistance of Carbon Steels to Crushing at Different Temperatures.

The presence of phosphorus greatly increases the resistance of steels to crushing. Thus the resistance of a steel containing 0·06 per cent. of carbon and 1 per cent. of phosphorus is equal to that of a rail steel containing 0·4 per cent. of carbon. The influence of phosphorus is to produce a rapid decrease in the resistance to crushing at a red-heat; its intensity may fall below that of other steels so long as the percentage of phosphorus is fairly considerable. The presence of sulphur appears to harden the steel somewhat at about 700° and at a higher temp. Burnt steel (steel contaminated with oxide) revealed no anomalies in the curve of resistance to crushing. The presence of silicon or of manganese in small percentages in carbon steels does not appear to exert much influence on the appearance of the curves.

Cast iron cannot be regarded as forgeable, and the investigations relating to this part of the subject have been but few in number. Generally speaking, it was not possible to obtain a reduction of one-fifth in the depth of normal cylinders, so that the crush numbers had to be ascertained by interpolation from the results obtained with lesser degrees of crushing. The presence of phosphorus greatly increases the resistance of cast iron, and the appearance of the resistance curves differs from that of the steels. The fall in the resistance to crushing is very nearly uniform from 300° up to the temp. of fusion. Neither a maximum nor a minimum can be seen. Cast iron generally, and phosphoric pig iron in particular, crack on forging before the temp. of fusion, and have no cohesion. When the fusion point of the eutectic is reached, the elements separate in a granular form, and crushing "yields nothing but a shower of sparks." A. Pomp gave for the crushing strength of steel with 0·5 per cent. of carbon, 14·5 tons for rods 10 mm. diameter; and with 0·06 per cent. carbon steel, 12·7 tons.

In general, *pearlitic steels* undergo the same variations as carbon steels; variations in the resistance to crushing may be greatly reduced or even obliterated by the presence of a sufficient amount of an element in soln., such, for example, as chromium. *Martensitic steels* yield a decreasing curve which possesses neither maximum nor minimum; the greatest fall in resistance commences at 500°. *Austenitic steels* vary little in their resistance to crushing up to about 550° or 600°. The resistance to crushing increases considerably at liquid air temp. Starting from 0° the curve is in general practically rectilinear up to about 600°, where the most important fall in the resistance occurs. Special steels containing the free carbide and the high-speed steels behave similarly. Their resistance at ordinary temp., and particularly at about —190°, is, generally speaking, high. Some steels preserve a high degree of resistance to crushing at high temp., a resistance much greater than that of carbon steels. The presence of nickel favours this resistance at high temp.—*vide* the special elements.

P. Galy-Aché showed that for copper and iron the elastic limits under tensile stress and compression are the same. M. Koepke and E. Hartig, and R. Thurston, found that brittle metals showed a constant relation between the resistance to fracture under tensile stress, and under compression. F. Robin added that the resistances to fracture by tensile and compressive stresses are not comparable, but the elastic limits under tensile stress and compressive static stresses can be compared, and for pearlitic carbon steels, they are generally the same; but M. Rudeloff found that for nickel and manganese steels they are quite different. J. O. Arnold gave 40 to 60 tons per sq. in. for the crushing strength of cast iron. Observations were also reported by A. P. Carman and M. L. Carr, H. I. Coe, M. Denis, G. H. Gulliver, H. I. Hannover, S. H. Ingberg and P. D. Sale, R. L. Keynon, E. Kieft, F. Körber and H. Müller, M. Lorenz, P. Ludwik and E. Schen, W. Mason, H. Monden, S. Nadasan, F. B. Seely and W. J. Putnam, E. Siebel and A. Pomp, C. A. M. Smith, A. H. Strang and L. R. Strickenberg, W. C. Unwin, and A. Victorin; and H. A. Schwartz measured the effect with malleable cast iron.

Only in the case of metals like copper, silver, and aluminium does a variation of temp. cause the physical properties to vary in a continuous manner; with iron, the alloy steels, and many other alloys, the variations in the properties display sudden changes. These metals are known to undergo transformations, and there may be some relation between these transformations and the variations in the physical properties. M. Leblant and others have noticed that starting from 100°, the elongation may take place intermittently, and it may be accompanied by jerks and noises. Steels show characteristic properties at about 15° and 400°, and this is in agreement with F. Robin's results except for the hardness developed by mechanical deformation, and the notched-bar brittleness after cold-working, which indicate that steel is harder and more brittle after mechanical working at 400° than it is at 15°. M. Leblant also found that the resistance, and the proportional limit elongation are a minimum at about 100°, while from 200° to 400° there is a maximum resistance, and a minimum contraction and elongation. This explains the greater likelihood of breaking a test-piece while deforming it within the latter range of temp., than there is in testing it between 20° and 100°. The results with dynamic tests are different. The resistance to crushing under shock is a minimum at 300°, and the ductility shown by the median bulge is a maximum at this temp., whereas the tendency to fissure, and the crushing brittleness are here lower than at neighbouring temp. As F. Robin shows, it is difficult to draw any conclusions as to the constitution of iron from these results. Between 0° and 100°, the hardness, the elastic limit, the resistance to breaking, and the resistance to crushing decrease, and hence it might appear as if the elongation would be augmented, but it diminishes. Again, from 100° to 200° the elastic limit is low and there is but little elongation, while the resistance to stress, and hardness increase; the resistance to crushing is low, and the interstrain hardness due to deformation, and the median bulge increase. Hence, each physical property exhibits discontinuity at very different points, and the part played by the different states of iron has not been determined for each case.

According to F. Robin, from a visible red-heat upwards, it appears that all the properties resulting from static or dynamic effects agree, not perhaps numerically, but in their mode of variation. The rate of speed of the stresses applied act, therefore, uniformly on steel and on other hard metals, such as lead in the cold, in proportion as they lose their elasticity. It would appear that from this temp. onwards metals become pasty during their transition to the liquid state; the results of various tests collated resemble each other in a general way. A variation in the allotropic state, such as that of iron, appears, therefore, but little marked. Towards 700° the curves of steel have a bend which might be referred to the allotropic transformation point; but copper and nickel give similar results at neighbouring temp. The transformation of α-iron into β-iron may, however, betray itself in the curves representing the variation of the mechanical effects in terms of the temp. without the possibility of definitely affirming that it does so. The hardness curves and curves of the resistance to crushing show that the steels give curves which become very nearly horizontal at about 800°. Unlike the case of metals which do not possess transformation points, such as copper, the resistance of the metal decreases rapidly and uniformly at a cherry-red heat, there is with steel a break in the curve. M. Leblant found a similar break during the tensile testing of steels containing 0·2 to 0·4 per cent. of carbon. He even found a slight increase in the resistance to breakage for a dead-soft steel at about 800°. These remarks are not based upon decisive results, but they agree with the recent observation made by W. Rosenhain and J. C. W. Humfrey. They remarked that, when making tensile tests *in vacuo* on thin, polished, and heated discs of several metals, at about 800°, the temp. in the neighbourhood of the transformation of γ- to β-iron in a soft steel, the appearance of the deformed metal under tensile stress altered in a characteristic manner; the point of least resistance of the metal when heated unequally is found at the limit of α-iron shown by the deformation and by a more resistant zone; although at a temp. slightly higher and probably corresponding to the sphere of influence of β-iron. The diametrical bulge, which diminishes from 900° to 1000° upwards, indicates the commencement of the disintegration of the metal and the diminution of the cohesion of the grains. It does not indicate the return of the metal to its anterior condition, for the other properties belie this hypothesis.

J. E. Howard studied the cubic **compressibility,** the cold flow, and the crushing strength of iron and steel. The test cylinders were 2·5 diameters long; the compressions are expressed in lbs. per sq. in. The results are summarized in Table XXXIV. The specimens began to bulge laterally under the influence of free compressive stresses when the elastic limit was passed, and thereafter the stress per sq. in. increased for a time, whilst the shortening in length and increase in diameter continued. Whilst the gross load was gradually increased to the end of the test, a period was reached where the stresses per sq. in. on the sectional area, as it existed, ceased to increase, and for an interval the flow was continuous, with practically no increase of stress. This period marked the ultimate compressive resistance of the metal. No marked difference in tensile strength resulted from the cubic compression; neither was the ductility of the metal, as indicated by elongation and reduction of area, materially changed by the compression. Under ordinary free tests by tension or compression, certain stresses—below the elastic limit—do not cause any change in the physical properties; but stresses exceeding the elastic limit usually bring about a series of phenomena which culminate in rupture or disintegration. Under cubic compression, no press. were reached which gave evidence of such a tendency in the ultimate result as that caused when the flow of metal occurred. This means that whilst it is probable that there is a restricted molecular orbit represented by the elastic limits of tension and compression, and that these orbits may be disturbed and thrown into new positions by loads exceeding the elastic limit, in the case of cubic compression, sufficiently high press. to disturb them were not employed in the experiments—nor is it certain whether such a limit can be attained by the means employed. J. Bauschinger's results are indicated in Table XXXIV. Observations were made by J. G. Dagron, W. K. Hatt, A. Portevin and F. le Chatelier, and S. H. Ingberg and P. D. Sale.

TABLE XXXIV.—THE CUBIC COMPRESSION OF IRON AND STEEL.

Metal	Reduced length (inches)	Concurrent compressive resistance	Ultimate compressive resistance	Percentage maximum elongation of surface	Tensile stress of ruptured section
0·09 C steel	1·24–0·83	84,030–85,470	85,580	72·8	106,434

Wrought iron ann.	1·555–1·18	91,600–93,610	93,610	51·4	—

J. O. Arnold holds that compression tests furnish by far the best mechanical means of measuring the molecular rigidity of metals, because the interfering effects of variations in intercrystalline cohesion are reduced to a minimum. The flow curve for normal steels falls off until the iron contains 0·89 per cent. of carbon when it is practically stationary to 1·5 per cent. of carbon, for the dotted line in the curve is taken to represent the true result—the downward flow of the observed curve being due to the undesired separation of some graphite and the consequent production of a little soft iron. The annealing curve up to 0·89 per cent. of carbon measures graphically the effect on the flow from diffused to crystallized cementite; when more than 0·89 per cent. of carbon is present, the curve passes downwards, until, at 1·47 per cent. of carbon (most of which exists as graphite), the flow is actually greater than that of iron alone. This is attributed to the loosely deposited graphite crystals being themselves capable of some compression. The curve for hardened steel shows that molecular flow ceases with 0·89 per cent. of carbon, whilst the curve is very steep in passing from 0·2 to 0·6 per cent. of carbon.

T. W. Richards[18] gave $\beta=0\cdot0_641$ for the coeff. of compressibility of α-iron at 20° with press. of 100 to 500 atm.; this datum was afterwards corrected to $0\cdot0_660$. E. Goens and E. Schmid gave $5\cdot8\times10^{-13}$ dyne per sq. cm., and P. W. Bridgman, $5\cdot9\times10^{-13}$ dyne per sq. cm.; E. Grüneisen gave $0\cdot0_662$ at —190° for press. of 10 to 150 atm.; $0\cdot0_665$ at 18°; $0\cdot0_668$ at 128°; and $0\cdot0_669$ at 165°; E. Madelung and R. Fuchs, $0\cdot0_661$ megabar per sq. cm.; and A. Mallock gave $0\cdot0_664$ at 20°. L. H. Adams gave $\beta=0\cdot0_660$; and for $d\beta/dp$, $-0\cdot0_{11}4$. R. F. Mehl and B. J. Mair calculated from the compressibility of invar-steel, with iron in the γ-form, that the compressibility of γ-iron is $0\cdot0_685$, a value which would make γ-iron to be more compressible than α-iron.

Observations on steel were made by H. V. Regnault. E. Amagat gave $0\cdot0_668$; and P. W. Bridgman, $0\cdot0_655$ at 6500° atm. and 20°; and at 10,000 atm. press., $0\cdot0_660$ at 10°, and $0\cdot0_662$ at 50°. E. Madelung and R. Fuchs gave for steel $0\cdot0_661$ megabar per sq. cm., L. H. Adams and co-workers gave $0\cdot0_6575$ for a 2 per cent. carbon Bessemer steel, and a 0·8 per cent. carbon tool-steel. R. F. Mehl gave for the internal press., 587 kilomegabars, and for the maximum disruption press., 1884 kgrms. per sq. mm. R. F. Mehl and B. J. Mair observed that a quenched, eutectoid steel, with 0·89 per cent. carbon, and highly martensitic, had a compressibility of $0\cdot0_661$, and the same result was obtained after the steel had been annealed. A quenched, hypereutectoid steel, with 1·36 per cent. carbon, had a compressibility of $0\cdot0_683$, and after annealing, $0\cdot0_685$. The normal sp. gr. of the hypereutectoid steel showed that the high compressibility is not due to pore-spaces in the metal. Though the compressibilities of iron and of eutectoid steel are the same, the Brinell's hardness are, respectively, 75 and 241. The results show that the hardness of steel produced by quenching is not caused by any change in the normal cohesive forces. The fact that a glass-hard steel suffers the same vol. decrease with an increase of press. as does an annealed steel, is explained by the slip interference theory of hardness on the assumption that no increase in the binding forces between the atoms occurs on hardening, for the hardness is supposed to be caused by the mechanical arrangement of the structural units. L. H. Adams and E. D. Williamson gave for wrought iron; $\beta\times10^6=0\cdot60$ to $0\cdot68$; and for cast iron, 0·89 to 1·45. Cast iron, at a press. p megabars, suffers the vol. change, $(3dv/v)\times10^6=2\cdot04(p-69)-6\cdot1(p-69)^210^{-4}-10$, and has $\beta\times10^6=2\cdot010-0\cdot152(p-2000)10^{-4}+0\cdot006e^{-0\cdot003(p-2000)}$. The compressibility of cast iron between 0 and 12,000 megabars is indicated in Fig. 231. P. W. Bridgman's experiments on the compressibility of rolled metals show that neither variations in grain-size, nor mechanical strain make any appreciable difference to the compressibility, so that an increase in hardness caused by either or both these effects can have no marked influence on the compressibility. If lattice distortion be a cause of hardness in steel, it will be produced by an alteration of the interatomic forces, and this should make an appreciable difference in the compressibility

§ 19. Thermal Properties of Iron and Iron-Carbon Alloys.

The **thermal expansion** of iron has to be taken into consideration in the construction of iron bridges, in fixing buckstays of furnaces, etc. Under the influence of the sun's rays, the Eiffel Tower twists from east to west, its point forming an arc with a diameter of about 4 inches. After sunset, the tower slowly untwists. The twisting is greater in summer than it is in winter. There are many records of measurements of the coeff. of thermal expansion of iron and steel, made usually upon commercial samples, where the composition is not usually stated. This, of course, makes the results of less general importance. A. L. Lavoisier and P. S. Laplace[1] gave $0{\cdot}0_4122045$ for wrought iron, and $0{\cdot}0_4123504$ for soft iron drawn into wire; and E. Troughton, $0{\cdot}0_4144010$ for iron wire. J. Smeaton gave $0{\cdot}0_4125833$ for soft iron; M. G. von Paucker, $0{\cdot}0_411612$; H. Kopp, $0{\cdot}0_4125$; H. Rudolph, $0{\cdot}0_41197$; J. F. Daniell, $0{\cdot}0_411808$; A. Gray and co-workers, $0{\cdot}0_4124$ for soft iron; and H. Fizeau, $0{\cdot}0_41210$ for electromagnet iron at 40°, and $0{\cdot}0_41228$ at 50°. P. L. Dulong and A. T. Petit gave $0{\cdot}0_41182$ for iron between 0° and 100°, and $0{\cdot}0_41469$ between 0° and 300°; P. Glatzel, $0{\cdot}0_41387$ between 16° and 100°; and for wrought iron between −45° and 100°, T. Andrews gave $0{\cdot}0_586$; between −18° and 100°, $0{\cdot}0_4114$; and between 100° and 300°, $0{\cdot}0_4133$. I. von Zakrzewsky gave $0{\cdot}0_41092$ between −103° and 25°; $0{\cdot}0_41110$ between −78° and 25°; $0{\cdot}0_41252$ between 25° and 100°. E. Grüneisen gave $\alpha=0{\cdot}0_5907$ between −190° and 17°;

and $0{\cdot}0_4 1189$ between 17° and 100°. H. G. Dorsey gave $0{\cdot}0_5 930$ between -180° and 20° for purified iron, and $0{\cdot}0_5 840$ for iron with 1·4 per cent. of carbon. For iron with 0·057 per cent. of carbon, 0·13 manganese, and 0·05 silicon, H. le Chatelier gave $0{\cdot}0_4 11$ between 0° and 100°; $0{\cdot}0_4 16$ between 500° and 600°; $0{\cdot}0_4 165$ between 600° and 700°; and $0{\cdot}0_4 15$ between 700° and 800°. F. Henning gave for wrought iron with 0·1 per cent. of carbon, $0{\cdot}0_5 919$ between —191° and 16°. Observations were also reported by F. C. Calvert and co-workers, R. Roberts, R. S. Woodward and co-workers, W. Broniewsky, A. Börsch, C. Markham, J. Seigle, etc. K. Honda observed 0·000013 for iron at 100°; 0·0000149 at 300°; 0·0000158 at 500°; and 0·0000154 at 600°; whilst S. Sato obtained 0·0000212 between 906° and 1400°; and 0·0000125 between 1400° and 1535°. S. Sato gave 0·000016, but O. C. Ralston showed that 0·0000125 agrees better with the observed data. The best representative data are plotted in Fig. 232. The curve shows clearly how the coeff. of expansion of γ-iron exceeds that of α-iron; and that it is probable that the curve for δ-iron is a continuation of that for α-iron. O. C. Ralston calculated from these and the sp. gr. data, the average changes in vol. as purified iron is heated from 0° to 1670°:

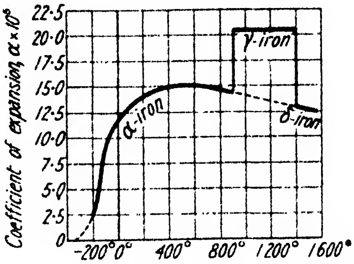

FIG. 232.—The Coefficients of Thermal Expansion of Purified Iron.

Form of iron	Temperature range	Change in volume per unit volume, or dv/v
α-iron	0° to 906°	0·000014 per degree
$\alpha \rightarrow \gamma$-iron	906°	$dv/v = -00846$
γ-iron	906° to 1400°	0·000021 per degree
$\gamma \rightarrow \delta$-iron	1400°	$dv/v = +0{\cdot}002553$
α-iron	1400° to 1535°	0·0000125 per degree
Melting-point	1535°	$dv/v = +0{\cdot}036$
Molten iron	1535° to 1670°	0·000483 per degree

R. Bach was not satisfied that his thermal expansion, and X-radiograms agreed with the assumption that the α-state of iron is distinguished uniquely from the β-state by magnetic differences. H. Quinney found that the change from single crystals to polycrystals reduces the contraction at the Ac_3-arrest where α-Fe passes to γ-Fe.

A. L. Lavoisier and P. S. Laplace gave $0{\cdot}0_4 107880$ for unhardened steel, $0{\cdot}0_4 107960$ for hardened steel, and $0{\cdot}0_4 123956$ for hardened steel tempered at 65°. W. Roy gave $0{\cdot}0_4 111000$ for unhardened steel; E. Troughton, $0{\cdot}0_4 118990$; J. Eliccot, $0{\cdot}0_4 10750$; M. Vandervyver, $0{\cdot}0_4 1101$; W. Struve, $0{\cdot}0_4 11301$; and J. K. Hörner, $0{\cdot}0_4 1150$ for Styrian, $0{\cdot}0_4 11120$ for Schaffhausen steel, and $0{\cdot}0_4 1070$ for Huntsman's steel. J. Smeaton gave $0{\cdot}0_4 115000$ for unhardened steel, and $0{\cdot}0_4 122500$ for hardened steel; F. Berthoud, $0{\cdot}0_4 10040$ for unhardened steel, and $0{\cdot}0_4 13715$ for hardened steel. W. Dittenberger gave for $\alpha \times 10^8$ for iron with 0·16 per cent. of carbon, for wrought iron with 0·14 per cent. of carbon, steel with 0·55 per cent. of carbon, and cast iron with 3·22 per cent. of carbon:

	0°–250°	0°–375°	0°–500°	0°–625°	0°–750°
Wrought iron .	1286	1354	1406	1461	1488
Iron . . .	1272	1358	1405	1454	1470
Steel . . .	1248	1317	1379	1437	1329
Cast iron . .	1118	1198	1258	1393	--

or $\alpha \times 10^9 = 16777\theta + 4{\cdot}64\theta^2$ for wrought iron; $11392\theta + 5{\cdot}42\theta^2$ for iron; $11181\theta + 5{\cdot}26\theta^2$ for steel; and $9794\theta + 5{\cdot}66\theta^2$ for cast iron. J. A. N. Friend and R. H. Vallance gave $0{\cdot}0_4 123$ for the coeff. of expansion of armco iron, and for wrought iron between 10° and 100°—the former metal had 0·025 per cent. of carbon, and the latter metal 0·06 per cent. H. Fizeau gave for Huntsman's steel, $0{\cdot}0_4 1018$

at 20°, $0{\cdot}0_41038$ at 30°, and $0{\cdot}0_41077$ at 50°; T. Andrews gave for hardened Bessemer steel, $0{\cdot}0_585$ between −45° and 100°; $0{\cdot}0_4101$ between −18° and 100°; and $0{\cdot}0_4133$ between 100° and 300°; and for annealed Bessemer steel, $0{\cdot}0_593$ between −45° and 100°; $0{\cdot}0_4117$ between −18° and 100°; and $0{\cdot}0_4159$ between 100° and 300°. He also gave:

			Coefficients of thermal expansion		
			−45° to 100°	−18° to 100°	100° to 300°
Rolled bars	Wrought iron		0·0000086	0·0000114	0·0000133
	Bessemer steel	Soft	0·0000093	0·0000117	0·0000159

	Siemens-Martin steel	Soft	0·0000088	0·0000116	0·0000144
		Hard	0·0000079	0·0000100	0·0000139
	Cast steel	Soft	0·0000086	0·0000112	0·0000150
		Hard	0·0000084	0·0000101	0·0000130
Hammered forgings	Wrought iron		0·0000096	0·0000117	0·0000131
	Bessemer steel		0·0000099	0·0000107	0·0000137
	Siemens-Martin steel		0·0000093	0·0000113	0·0000142

J. E. Howard found for the coeff. of expansion of weld iron, 0·00001211; for steel with 0·09 to 0·51 per cent. of carbon and 0·11 to 0·58 per cent. of manganese, 0·00001194; for steel with 0·57 to 0·97 per cent. of carbon and 0·93 to 0·80 per cent. of manganese, 0·00001133; and for cast iron, 0·00001067. H. le Chatelier gave for hard steel at 1000°, $0{\cdot}0_4140$. H. Fizeau found for annealed cast steel $0{\cdot}0_41101$ at 40°, and $0{\cdot}0_41113$ at 50°; and when hardened, $0{\cdot}0_41322$ at 40°, and $0{\cdot}0_41363$ at 50°; and for grey cast iron, $0{\cdot}0_41061$ at 40°, and $0{\cdot}0_41075$ at 50°; while H. le Chatelier gave $0{\cdot}0_41175$ at 100°; and for steel with 14 per cent. of manganese, $0{\cdot}0_4245$ at 1000°. For cast iron with 3·5 per cent. of carbon, F. Henning gave $0{\cdot}0_5886$ between −191° and 16°; for steel with 0·1 per cent. of carbon, $0{\cdot}0_5915$; and with 0·5 per cent. of carbon, $0{\cdot}0_5896$. G. Charpy and L. Grenet gave for hardened steel with 1·5 per cent. of carbon, $0{\cdot}0_41000$ between 0° and 100°, and when annealed $0{\cdot}0_41115$. W. Souder and P. Hidnert gave for electrolytic iron which had been melted in vacuo, $\alpha=0{\cdot}0_412$ between 25° and 100°; the average for steels was $0{\cdot}0_4112$ between 25° and 100°; and $0{\cdot}0_4142$ between 25° and 600°; and for ordinary steels above the critical range, $0{\cdot}0_423$. R. von Dallwitz-Wegner gave $0{\cdot}0_4351$ for the cubic coeff. at 0°, and $0{\cdot}0_4383$ at 100°. Observations were also reported by O. Bauer and H. Sieglerschmidt, E. Bernardon, F. C. Calvert and co-workers, E. G. Coker, H. J. French, A. W. Gray, H. C. Knerr, C. Markham, R. Roberts, A. Schulze, E. Straube, R. S. Woodward and co-workers, etc.

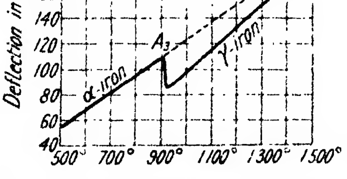

FIG. 233.—The Effect of Temperature on the Expansion of Purified Iron.

G. Gore, R. Norris, and W. F. Barrett made observations on the changes which occur during the recalescence of cooling iron. C. Benedicks measured the coeff. for iron of a high degree of purity—99·967 per cent. Fe. The corresponding curve by S. Sato is shown in Fig. 233. A. Mallock found no discontinuity in the coeff. of thermal expansion between 1400° and 1500°. As also observed by G. Charpy and L. Grenet, and J. Driesen, there is a discontinuity at the A_3-arrest, and the change is reversible, but there is some hysteresis. According to E. Maurer, the maximum observed by J. Driesen at 755°, is not connected with the A_2-arrest; but C. Benedick's curve, and also that of P. Chevenard, showed that it is connected with the appearance of the magnetic properties of iron. Observations were made by H. Esser, H. S. Rawdon and co-workers, H. E. Publow and co-workers, and H. Ebert. F. C. Powell estimated that the mean increase in length, l, of iron on passing from the non-magnetic to the magnetic state is $dl/l=1{\cdot}2\times10^{-4}$. With nickel there is an anomalous contraction in the magnetized state. The calculation is based on W. Heisenberg's theory of ferromagnetism which assumes that magnetization is accompanied by a change in the strength of the bond between the atoms. W. P. Davey discussed the expansion of crystals from the point of view of the space-lattice theory as the temp. passed from the absolute zero to the m.p. F. L. Uffelmann observed that the curve for the coeff. of thermal expansion of steel is a little different if taken on heating and cooling curves.

A. Gray and co-workers gave $0{\cdot}0_4136$ for the coeff. of thermal expansion of mild steel. H. G. Dorsey observed that the effect of carbon on the coeff. of thermal expansion is approximately linear. H. le Chatelier found the values of $a \times 10^7$ for temp. between the limits indicated, starting from 0° for steel with 0·13 to 0·24 per cent. manganese, and 0·05 to 0·14 per cent. of silicon, and

Carbon		0·057	0·205	0·49	0·75	0·80	0·84	1·21 per cent.
$a \times 10^7$	100°	110	110	110	110	110	110	105
	200°	120	110	110	110	110	110	110
	300°	130	120	118	118	118	118	118
	400°	140	125	101	101	101	101	125
	500°	150	130	130	130	130	130	130
	600°	160	135	135	135	139	135	133
	700°	165	139	139	139	135	139	137
	800°	130	—	—	—	—	—	—

Consequently, all sorts of iron and steel at ordinary temp. have a coeff. of linear thermal expansion of 0·000011; and at 758°, approximately 0·000017; or the mean value, between 0° and 758°, is 0·000014; or the true coeff. of expansion at temp., θ°, between 0° and 758°, is $da/d\theta = 0{\cdot}000011 + 0{\cdot}0_8 8\theta$. Above the critical zone, 758°, the coeff. increases with the proportion of carbon so that

Carbon	0·05	0·2	0·8	1·2 per cent.
$da/d\theta$	$0{\cdot}0_4 15$	$0{\cdot}0_4 17$	$0{\cdot}0_4 22$	$0{\cdot}0_4 29$

Consequently, there is a kind of shrinkage with increasing proportions of carbon, and this attains a minimum with about 0·8 per cent. of carbon:

Carbon	0·05	0·2	0·5	0·8	1·2 per cent.
Transformation temp.	840°	768°	728°	730°	725°
Shrinkage	0·26	0·23	0·21	0·08	0·10 per cent.

H. le Chatelier showed that steel with about 0·8 per cent. of carbon expands regularly up to about 700°, and above that temp. it suddenly decreases in vol. about 0·1 per cent. Thus follows a gradual, or at 50° higher temp., an abrupt expansion, so that the vol. is nearly the same as before the contraction occurred. Beyond this temp., the expansion is regular. These changes are reversed on cooling. When the sudden contraction occurs, the metal consists of pearlite, and when the sudden expansion occurs, of martensite, and in between, of troostite. At the critical point A_1, there is not only a simple volume change corresponding with the melting or dissolution of a substance, but there are also two opposing volume changes which are approximately compensated with steel containing 0·9 per cent. of carbon. Thus, the expansions, δl mm. per 100 mm., were:

	315°	500°	600°	760°	800°	830°	860°	900°	950°
δl	0·35	0·63	0·82	0·05	1·00	1·12	1·20	1·25	1·34

The maximum is here twice as much as the value obtained by G. E. Svedelius, who heated his samples very rapidly, while H. le Chatelier heated them very slowly. No sudden vol. change, above 0·01 mm. per 100 mm., was observed at the A_2-arrest. There are some anomalies at the A_3-arrest, which seem to be connected with the presence of hydrogen or sulphur, because, working with iron with 0·05 per cent. carbon, the results varied with the nature of the atm. Thus:

Atmosphere	Transformation temperature	Change in length
Hydrogen	840° to 860°	0·26 mm.
Hydrogen	900° to 1000°	0·25 ,,
Air	950° to 1025°	0·20 ,,
Hydrogen	925° to 975°	0·14 ,,

F. Sauerwald and co-workers found for pig-iron an expansion which increased from a sp. vol. of 0·1460 to a maximum 0·1484 at 840°, and then decreased steadily as the m.p. was approached—*vide supra*, sp. gr. H. Sieglerschmidt observed a marked increase in the thermal expansion of high- and low-carbon steels as they passed through the transition temp.—approximately 700°. J. Seigle studied the subject. K. Honda and co-workers found for the coeff. of linear expansion, α, of cementite steels:

Carbon . . .	1·5	1·8	2·0	2·5	2·9 per cent.
α	$0\cdot0_4208$	$0\cdot0_4202$	$0\cdot0_4194$	$0\cdot0_4186$	$0\cdot0_4179$

and for cementite between 0° and 1130°, 0·0000315. K. Honda's results with Swedish iron, and carbon steels are summarized in Fig. 234. The A_1- and A_3-transformations can be easily detected by the abnormal change in length in the ranges of these transformations. The coefficients of expansion of these steels, below the A_1-arrest, increase rapidly with temp., the coeff. of expansion-temp. curve being slightly concave towards the temp. axis. The contrary is the case with low-tungsten steels. According to G. Sirovich, at 370°, the A_0-arrest, where $\alpha_1\text{-Fe} \rightleftharpoons \alpha_2\text{-Fe}$, the coeff. of thermal expansion of the two forms of α-iron are different. W. Broniewsky found three critical points in the expansion curves of purified iron, one for α-iron stable below 730°, another for β-iron stable at 950°, and a third with γ-iron at 1020°. The observations of J. H. Andrew and co-workers are summarized in Table XXXV. J. H. Andrew and co-workers found that with the slow cooling of steel, at the $Ar_{3,2}$-arrest there is an increase in vol. which is continuous with the Ar_1-arrest. At the Ar_1-arrest there is a sudden expansion depending on the carbon-content, and initial temp. At 150° to 60° there is a large expansion independent of the carbon-content. On tempering, at 100°, there is a contraction when the carbon-content is greater than 0·6 per cent. when quenched above the Ac_3-, $_2$-, $_1$-arrest; between 150° to 300°, there is no change; between 300° and 330°, the contraction is neutralized by the γ-iron present; and at 500°, there is no change. The changes in volume and expansion which occur when austenite is transformed into martensite were discussed by E. Scheil, G. Tammann and E. Scheil, J. H. Whitehead, S. Sato, F. Stäblein, A. Schulze, B. D. Enlund, F. Wever and P. Rütten, L. E. Daweke, F. A. Fahrenwald, Z. Jeffries, W. Fränkel and E. Heymann, H. Hanemann and L. Träger, S. Konno, T. Kase, F. Ribbeck, and A. M. Portevin and P. Chevenard—*vide supra*, tempering. F. Roll studied the thermal expansion of cast iron. M. A. Grossmann studied the changes in length from 606° to room temp. when a high-speed steel—0·72, C; 18·0, W; 4·0 Cr; 1·0, V—is being cooled from its hardening temp., and found that when the quenching temp. is low, 938°, the transformation to such martensite as is formed is sudden and complete, but the amount of martensite formed is comparatively small. As the quenching temp. is raised, there are two effects:—(i) the austenite cools further before transforming to martensite, the austenite being more stable because it has dissolved more alloy and carbon; and (ii) the transformation to martensite takes place over a wider range of temp. At the highest quenching temp., the expansion, once begun, proceeds during the whole cooling period to room temp., and, indeed, the expansion continues at room temp.—with the 1321° curve, at room temp. an expansion of 0·00003 in. occurred during the next 12 hrs. The results show how difficult it is to locate transformation points by

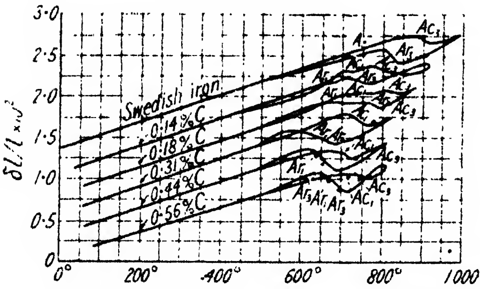

FIG. 234.—Thermal Expansion of Iron and Steel.

cooling curves, and also that martensite continues to form over a long period of time down to room temp. Some measurements were also made by E. C. Bain and W. S. N. Waring, H. Scott, and S. L. Hoyt. A. Werner found that with hardened soft steels, the coeff. of thermal expansion was 7 to 21 per cent. greater than the same alloy in the soft state; the actual values were $10{\cdot}4\times10^{-6}$ to $12{\cdot}6\times10^{-6}$ for soft steels, and $11{\cdot}1\times10^{-6}$ to $14{\cdot}7\times10^{-6}$ for hardened steel at 20°. At the temp. of liquid air, say −160°, the minimum values fell to $6{\cdot}3\times10^{-6}$ and $7{\cdot}1\times10^{-6}$ respectively, and at 150°, they varied between $12{\cdot}1\times10^{-6}$ and $14{\cdot}6\times10^{-6}$ respectively. The introduction of manganese raised the coeff. of thermal expansion. The effect of cold-work was studied by W. Jubitz, who observed that the rolling or hammering of cast iron produced no change greater than 1 per cent. in the coeff. of thermal expansion.

TABLE XXXV.—THE EFFECT OF INITIAL TEMPERATURE ON THE PHYSICAL PROPERTIES OF STEEL.

Critical point	Thermal capacity	Thermal expansion	Resistivity	Magnetic properties
		1. *Slow Cooling*		
$Ar_{3,2}$	Evolution of heat	Increase in vol. continuous with Ar_1	Fall in resistivity continuous with Ar_1	Slight change.
Ar_1	Evolution of heat	Sudden expansion depending on carbon-content and initial temp.	Sudden decrease in resistance	Sudden increase in permeability.
400° - point in Ni-Cr steels	,,	,,	,,	,,
Low point at 150° to 60°	Small evolution of heat	Large expansion independent of carbon-content	Decrease in resistance	Increase in permeability.
		2. *Tempering*		
Point at 100°	No change noted	Contraction with carbon greater than 0·6 per cent. when quenched above $Ac_{3,2,1}$	Decrease in resistance	Slight increase in permeability.
150°–300°	Evolution of heat	No change	Above change continues	Above change continues.
300°–250°	Evolution of heat if gamma iron be present	Contraction neutralized by γ-iron present	Sudden decrease in resistance if γ-iron present	Sudden increase in permeability if γ-iron present.
500°	None	None	None	Increase in permeability.

O. Weigel gave for the true linear coeff. of expansion of steel:

	0°	100°	200°	300°	400°
Linear coeff. $\times10^6$ . .	9·193	10·388	11·563	12·748	13·933

and he represented the length at θ° by $l_0(1+0{\cdot}0_59193\theta+0{\cdot}0_85925\theta^2)$. For the two coeff. α and β, L. Holborn and A. Day gave, respectively, $0{\cdot}0_59173$ and $0{\cdot}0_8336$ between 0° and 300°. W. Wimmer gave $\beta=0{\cdot}000011$ at 20°, and 0·0000093 at −180°. According to L. Holborn and A. Day, the expansion with wrought iron can be represented by $(11{,}705\theta+5{\cdot}254\theta^2)\times10^{-9}$, and with a high-carbon steel, $(9173\theta+8{\cdot}336\theta^2)\times10^{-9}$. J. R. Benoit found the expansion of a slowly cooled steel to be $1+\alpha\theta+\beta\theta^2$, where α is $0{\cdot}0_410354$ to $0{\cdot}0_410457$, and β is $0{\cdot}0_8523$ to $0{\cdot}0_8520$. W. Voigt gave for steel $\alpha=\{11{\cdot}47+0{\cdot}0519(\theta-30)\}\times10^{-6}$ between 26° and 58°;

and for iron, $a=\{11{\cdot}58+0{\cdot}048(\theta-30)\}\times10^{-6}$ between 24° and 68°. E. Grüneisen observed for temp. between :

	−190° to 16°	16° to 250°	250° to 375°	375° to 500°	500° to 625°	625° to 750°
δl . . .	1·87	3·04	1·88	1·98	2·02	2·02

for a metre rod at 0°, and $\delta l=1000\times0{\cdot}0_6679\ (T_2^{1{\cdot}43}-T_1^{1{\cdot}43})$ mm., or $\delta l=1000\{0{\cdot}0_611557(\theta_2-\theta_1)+0{\cdot}0_8517(\theta_2^2-\theta_1^2)\}$.

J. Driesen's results for $a\times10^8$ are summarized in Table XXXVI. The A_1- and A_3-arrests appear as minima ; the A_1-minimum remains constant, but the A_3-minimum falls with increasing proportions of carbon. The results for higher proportions of carbon are shown in Table XXXVI. Cast iron is a mixture of graphite, the phosphide eutectic, cementite, and ferrite, and each of these constituents has its own thermal expansion. C. Benedicks and H. Löfquist also observed that when 1 per cent. of combined carbon is changed into graphite, the volume of the casting increases 2·04 per cent. Consequently the thermal expansion of cast iron depends on a number of secondary effects, and is quite a complicated phenomenon. Thus, E. Morgan showed that a cast iron with 3·5 per cent. of carbon and 2 per cent. of silicon will expand uniformly up to 550° when it is heated at the rate of 30° per minute. Above 550°, in addition to the ordinary thermal expansion, graphitization occurs and this causes an increase in vol. dependent on the degree of graphitization. At the Ac_1-critical point, there is (*a*) a contraction due to the change of *a*- into *γ*-iron ; and (*b*) the dissolution of some carbide not decomposed below the Ac_1-point, and this involves an expansion. As a rule, all the undecomposed carbide does not dissolve at the Ac_1-point, because the heating it has received at the lower temp. causes the grains to become coarser, and to dissolve less rapidly in the austenite. The rate of expansion of austenite with temp. is different from that of iron below the Ac_1-arrest. This expansion is also modified by the dis-

TABLE XXXVI.—COEFFICIENTS OF THERMAL EXPANSION FOR CARBON STEELS.

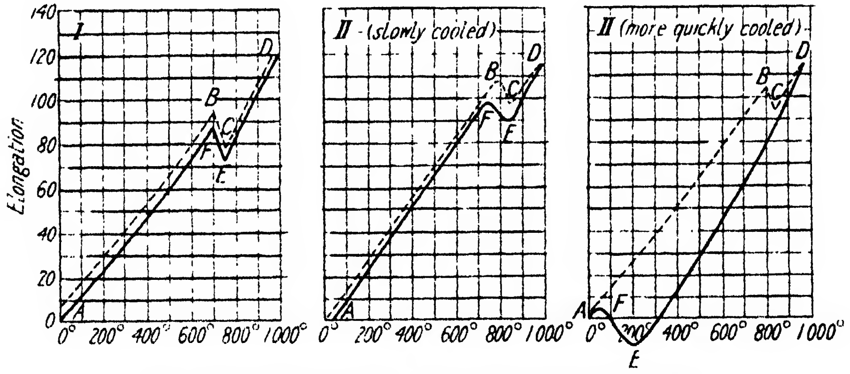
TABLE XXXVII.—COEFFICIENT OF THERMAL EXPANSION OF CAST IRON.

Temperature range	Percentage of carbon			
	1·97	2·24	3·66	3·80
20°–100°	994	961	851	871
120°–200°	997	967	794	793
200°–300°	1325	1336	1277	1298
300°–400°	1519	1541	1543	1548
400°–500°	1644	1697	1679	1679

solution of iron carbide in austenite as the temp. is raised. At still higher temp., some of the temper-carbon deposited at the lower temp. is re-absorbed. In the low-silicon cast irons, the carbide remains stable almost to the Ac_1-critical point; mottled irons are stable, but show a discontinuity at about 250° owing to a magnetic change; whilst the chromium cast irons at about 400° show a change in the expansion curve from about $0\cdot0_4130$ to $0\cdot0_4150$. The average thermal expansion of cast irons can be taken to be $0\cdot0_4140$. H. A. Schwartz found the coeff. of expansion of molten cast iron to be constant between 1375° and 1500°.

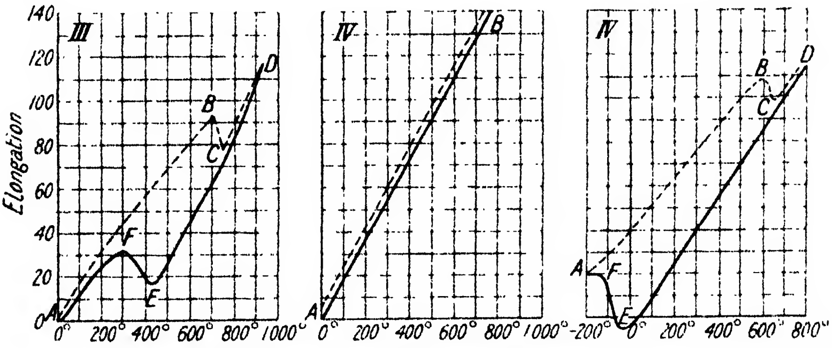
According to H. Esser, the thermal expansion curve of pure iron that has been de-gassed by repeated heating at 700° to 800° in vacuo, places the Ar_3-point at 898° and the Ac_3 at 904°; the Ac_1-arrest is detectable only when at least 0·06 per cent. of carbon is present in a steel, and the Ar_1-arrest when there is 0·20 per cent. With 0·86 per cent. of carbon, both the A_1- and A_3-arrests coincide, the Ar-arrests at 708°, and the Ac-arrests at 736°. The line joining the Ac_1-arrests of iron-carbon alloys containing up to 0·86 per cent. is horizontal at 736°, whereas that joining the Ar_1-arrests rise in a smooth curve from 685° with 0·1 per cent. to 708° with 0·86 per cent. The Ar_3- and Ac_3-lines fall steeply in smooth curves to join the A_1-lines at the eutectoid point.

G. Charpy and L. Grenet measured the elongation of various alloy steels at different temp., and the results are plotted in Figs. 235 to 240. *AB* represents the stable condition on heating from the ordinary temp., and it corresponds with the thermal expansion; *BC* represents a transformation which is accompanied by a contraction; *CD* represents the stable condition above the transformation temp., and it represents the thermal expansion; *DE* represents the contraction of the steel on cooling from, say, 950°; *EF* represents the transformation on cooling, and it is accompanied by an expansion; and *FA* represents the contraction as the steel cools from the transformation to ordinary temp. The alloy steels arrange themselves approximately into four groups: *Group I*, Fig. 235. These steels exhibit very nearly the same transformation temp. on heating and on cooling. The hysteresis effect with slow cooling is less than 150°. Examples are the carbon steels, and the majority of alloy steels used for structural purposes where the proportion of alloying metal is small. *Group II*, Figs. 236 and 237. These steels have nearly the same transformation temp. on slow cooling as on heating, but with moderately rapid rates of cooling the transformation on cooling is much lower than with heating. The interval of temp. depends on the maximum temp. attained, and on the time the steel is kept at this temp. Examples are the high-speed tool steels—the Cr-W, Cr-Mo, Cr-W-V, and Cr-W-V-Co steels. If these steels are not heated above a certain temp., the transformations are reversible; but if this temp. is exceeded, the transformation temp., with ordinary rates of cooling, generally drops from about 600° to 300°, or even to atm. temp., and there is no transforma-



FIGS. 235, 236, and 237.—Thermal Expansion Curves.

tion between these temp. By suitably selecting the temp., a portion of the transformation can be made to occur at 600°, and the remainder at 300°. *Group III*, Fig. 238. In these steels the transformation temp. with very slow rates of cooling differ from those on the heating curves. Examples are the nickel-chromium steels with from 3·5 to 6·0 per cent. of nickel, 1 to 2 per cent. of chromium, and less than 0·65 per cent. of carbon. The steels exhibit the same behaviour if the chromium is wholly or partly replaced by manganese, tungsten, or molybdenum. The lowering of the transformation temp. is not proportional to the amount of added metal. A small addition—say 5 to 6 per cent.—may depress the transformation temp. on cooling from, say, 600° to 200°, and further additions may produce only a slight effect. The transformation point of these steels is always lowered by cooling, and since any heating of the steel above the transformation temp. produces a hardening effect, these steels are softened by subjecting them to a form of tempering below the transformation temp. on heating. *Group IV*, Figs. 239 and 240. The transformation temp. of these steels is below the ordinary temp., and the steels between 0° and 950° show linear curves both on heating and on cooling. High-nickel, high-manganese, and high-nickel-manganese steels come under this category. In some cases the transformation may occur on cooling below atm. temp.



FIGS. 238, 239, and 240.—Thermal Expansion Curves.

E. Grüneisen found that for pressures, p kgrms. per sq. cm., the coeff. of expansion varies so that:

	$p=1$		$p=1000$	
	$-190°$ to $17°$	$17°$ to $100°$	$-190°$ to $17°$	$17°$ to $100°$
a	$0{\cdot}0_5907$	$0{\cdot}0_41189$	$0{\cdot}0_5903$	$0{\cdot}0_41182$

G. R. Dahlander studied the influence of a tension, p kgrms., on the coefficient of linear expansion, a, between 0° and 100°. He found for an iron wire of 0·878 mm. diameter, and with loads:

p	1·250	2·500	3·750	5·000
a	$0{\cdot}0_411902$	$0{\cdot}0_411956$	$0{\cdot}0_412074$	$0{\cdot}0_412253$

and for steel wire 1·249 mm. diameter, and loads 3·750, 6·250, and 10·0000 kgrms. at 17°, the values of a were respectively $0{\cdot}0_411296$, $0{\cdot}0_411409$, and $0{\cdot}0_411508$. For elastic limits E_1 and E_2 at the respective temp. θ_1 and θ_2 when the loads are respectively p_1 and p_2, and the coeff. of thermal expansion a_1 and a_2, the relations for a wire of cross-section a, are summarized by:

$$a_2-a_1=\frac{P_2-P_1}{a(\theta_2-\theta_1)}\left(\frac{1}{E_2}-\frac{1}{E_1}\right)$$

R. Mallet's observations on the sp. gr. of molten iron have been already discussed. He said that at the moment of solidification, molten iron does not expand, but rather contracts, so that the sp. gr. of liquid cast iron is 6·65, when that of the solid is 7·17, and that the coeff. of cubical expansion between 15° and 1315° is 0·00005994. F. Nies and A. Winkelmann made observations on this subject. T. Wrightson found that with grey Cleveland iron, the volume expands as the temp. rises until it is in the plastic state, when it has the sp. gr. 6·5, the cold iron having a sp. gr. 6·95. After this, a contraction occurs until the mass becomes liquid, when its sp. gr. is 6·88. Hence, if the vol. of liquid iron be taken as 100, that of plastic iron is 105·85, and that of solid iron at atm. temp., 98·98—*vide supra*, the sp. gr. of molten iron.

In preparing castings of cast iron, it is part of the moulder's craft, discussed by A. McWilliam and P. Longmuir,[2] and others, to deal with the **casting or cooling shrinkage** which renders necessary an allowance for the difference in size between pattern and casting. H. Moissan showed that whilst iron contracts on solidification, a sat. soln. of carbon in iron expands on solidification. E. Flachat said that the contraction with grey pig-iron is nearly 1 per cent.; and with white pig-iron, 2 to 2·5 per cent. The formation of pipe cavities in steel ingots, etc., is an example of liquid shrinkage. The *Hütte* gave a linear decrease of $\frac{1}{55}$th, with a low-carbon steel on cooling from the m.p. to ordinary temp. So far as the size of the casting goes, the net result is determined (i) by the change in vol. which occurs during the solidification of the liquid, (ii) by the thermal contraction of the metal during cooling, and (iii) by the changes attending the chemical and physical transformations which occur as the metal cools down from its f.p. Whatever condition affects the state of the cementite, etc., will naturally influence the shrinkage. Thus, the hotter the casting temp. of the metal, the greater the shrinkage. R. A. F. de Réaumur stated that cast iron expands on solidifying, but B. Kerl said that cast iron contracts in such a way that at the commencement of its solidification it first expands so as to fill up the smallest depressions and cavities of a mould, but after solidification, it contracts. R. Mallet opposed the view that cast iron expands during solidification, and although his curve showed a distinct expansion, corresponding with that shown by phosphoric, grey cast iron, he argued that the expansion was a freak result, or rather an experimental error, and thus missed a true phenomenon. W. C. Roberts-Austen and T. Wrightson, compared the sp. gr. of a number of metals during solidification, and found that a contraction occurred with cast iron. On the contrary, A. Ledebur said that there is a slight expansion at the moment of solidification. E. J. Ash and C. M. Saeger observed an expansion of 1·65 per cent. with grey cast iron, and a contraction of 5·85 per cent. with a low-carbon, low-silicon type of iron. F. Erbreich, T. Turner, S. G. Smith, F. Körber and G. Schitzkowsky, P. A. Russell, C. M. Saeger and E. J. Ash, R. Moldenke, and F. Busse made observations on this subject. T. D. West found that the harder grades of cast iron contract least on solidification owing to the segregation of graphite. W. J. Keep showed that iron alone contracts normally without showing any expansions; but when sufficient carbon is present to furnish tool steel, there is a considerable arrest in the contraction curve at a red-heat, and a distinct expansion occurs before the normal rate of contraction is resumed. With cast iron low in silicon, a slight expansion occurred immediately after solidification, this was succeeded by a normal contraction until, at a red-heat, another expansion occurred, and this was followed by a normal rate of contraction down to ordinary temp. With a cast iron containing 3·10 per cent. of carbon, and 3·85 per cent. of silicon, three expansions appeared in the curve. F. Osmond suggested that the first expansion may be at about 1100°, where the bulk of the graphite segregation occurs; that the second, probably at about 900°, is due to the presence of phosphorus; and that the third, probably at 700°, corresponds with the recalescence temp. T. Turner found that the volume changes on the cooling curves with iron containing:

	Carbon only	C and Si	C, Si, and P
First expansion . . .	Nearly absent	1135°	1060°
Second expansion . . .	Absent	Absent	900°
Third expansion . . .	665°	695°	730°

W. J. Keep also studied the effect of silicon. The first arrest observed by T. Turner is apparently raised by the presence of an increasing percentage of silicon, and lowered by the presence of phosphorus. The results confirm F. Osmond's hypotheses. The second expansion corresponds with the breaking down of the ternary eutectic of the system Fe–P–C, observed by J. E. Stead. The first expansion is negligibly small except when carbon is present; in that case, the separation of cementite from austenite accounts for the observed effect. The third expansion is connected with the transformation of the solid soln. or hardenite into pearlite. W. J. Keep also observed that some carbon segregates in this zone, and this would accentuate the expansion attending the pearlitic transformation. The effects produced by foreign elements are mainly due to their effects on the carbon segregation—thus, silicon increases the shrinkage; sulphur, and manganese increase the shrinkage; while phosphorus has very little influence. G. Hailstone showed that liquid contraction is accompanied by a lowering of the sp. gr. or density. If the metal is cast with iron hotter than will conduce to liquid contraction—say, between 1386° and 1428°—solid, dense castings result; liquid contraction occurs when the metal is cast at a medium heat; and if the temp. of the iron is too low, blow-holes appear. Conditions favouring a maximum solid contraction favour a maximum liquid contraction. A cast iron poured at its casting temp. shows a closer microstructure than otherwise, and the phosphide eutectic will collect in the network formation. Occluded gases appear to be held more tenaciously in cast iron poured at a high temp., and therefore a more solid casting is produced. Observations were also made by P. Bardenheuer and C. Ebbefeld, E. Bauer, O. Bauer, O. Bauer and K. Sipp, R. Buchanan, J. W. Donaldson, F. C. Edwards, H. Endo, H. O. Evans, J. E. Fletcher, J. Gray, A. Hanszel, F. Körber and G. Schitzkowsky, J. Longden, G. Masing, A. Messerschmitt, C. W. Meyer, A. L. Norbury, C. Pack, N. B. Pilling and T. E. Kihlgren, W. H. Pretty, R. T. Rolfe, R. T. Rolfe and J. Laing, C. M. Saeger and E. J. Ash, F. Sauerwald, F. Sauerwald and co-workers, H. A. Schwartz, O. Smalley, R. Stotz, D. J. Thomas, F. Wüst, and F. Wüst and G. Schitzkowsky. The general results show that the shrinkage which occurs on casting cast iron is conditioned by the chemical composition, the condition of the carbon, the casting temp., the rate of cooling, and the temp. gradient within the casting. The shrinkage of grey cast iron is less than that of white cast iron. K. Tanimura studied the effect of the melting temp. on low-carbon cast iron; and P. Bardenheuer and W. Bottenberg, the effect of the gas-content. H. I. Coe observed that there is an expansion during the solidification of white cast irons containing manganese. The curve shows minima corresponding with Fe_3C and no manganese; $8Fe_3C.Mn_3C$, or 5 per cent. Mn; $2Fe_3C.Mn_3C$, or 15·3 per cent. Mn; and $3Fe_3C.2Mn_3C$, or 19 per cent. Mn. There is also a depression corresponding with $4Fe_3C.Mn_3C$. The expansion with grey cast irons reaches a maximum with 10 per cent. Mn.

J. H. Andrew and co-workers observed that with steels during slow cooling, there are an evolution of heat and an increase in vol. at the $A_{3,2}$-arrest continuous with the Ar_1-arrest; and there is a sudden expansion with the evolution of heat at the Ar_1-arrest. The expansion depends on the carbon-content and the initial temp. Similar remarks apply to the arrest at 400° which occurs with nickel-chromium steels. The arrest between 150° and 160° in consequence of a small evolution of heat is attended by a large expansion, independent of the carbon-content. In tempering at 100°, there is a contraction, without the evolution of heat, when the proportion of carbon is greater than 0·6 per cent., and the steel has been quenched from above the Ac_3-,$_2$-,$_1$-arrest. No change in vol. occurs when heat is evolved at 150° to 300°. At 300° to 350°, heat is evolved if γ-iron be present, and a contraction is neutralized by the γ-iron present. No thermal change or abnormal change in vol. was observed at 500°. J. H. Andrew and co-workers concluded from their observations on the dilation of steels:

The change in vol. which occurs at the normal transformation points, is the resultant of two changes working in opposition—(*a*) an allotropic change, and (*b*) a change due to carbide. The latter change in steels of high carbon-content is not completed at the ferrite, carbide, or *SE*-line, but continues to a temp. depending on its composition—particularly on the carbon-content—it increases with the carbon-content. The dilation is a measure of the mol. conc. of the carbide in soln., and controls the temp. at which the allotropic transformation takes place. Quenching merely stereotypes the condition of the carbide, which, in its turn, controls the allotropic change. This variation in the mol. conc. is explained by assuming that carbide dissociates at and above the temp. of the normal transformation point. Nickel-chromium steels behave in much the same way as carbon steels, excepting that in the latter the time factor necessary to produce the same changes in the carbide is of a much lower order. Martensite is a product formed when the allotropic change has been depressed by dissociated carbide, to a temp. at which the latter is able to exist as such in the α-iron formed. At the temp. of the normal transformation point martensite is not formed as an intermediate phase between austenite and pearlite. When the mol. conc. of the carbide is such that the allotropic change is depressed below atm. temp., the resulting product will be austenite, *i.e.* the iron is retained in the γ-state. By tempering austenite in such a way that the carbide becomes partially associated, the allotropic change is able to take place on re-cooling, forming martensite, and the phenomenon of secondary hardening results. Dilation measurements enable the proportions of α- and γ-iron in the quenched product of any steel to be determined. In carbon steels quenched at 1000°, the iron in the product is in the α-state. In alloy steels γ-iron is present in various proportions, particularly with high carbon-content. In extreme cases, α-iron is entirely absent.

L. Aitchison and G. R. Woodvine observed that with nickel-chromium steels, the expansion that should be produced at the critical range during the cooling from the hardening temp. is not completed during the slow cooling in air; re-heating to quite low temp. induces a further expansion; further re-heating to low temp. brings about a contraction; prolonged heating at low temp. induces still further contraction; re-heating to intermediate temp. (300° to 500°) induces a similar initial expansion and then a contraction; re-heating to 600° induces a contraction; the smaller initial expansion at the intermediate temp. is likely to be the resultant of the expansion and contraction proceeding simultaneously; the total contraction brought about at temp. up to 200° by repeated heating and cooling is less than that similarly produced at higher temp.; and the maximum contraction brought about in any way, at all the different temp., is the same in amount. They found that the longitudinal and lateral expansions are the same. The exposure of steel to a higher temp. for a long time produces a metal which expands less on cooling, quickly or slowly. The expansion depends on the production of a stable austenite, which changes to martensite reluctantly and hence produces a smaller expansion. Air-hardened nickel-chromium steels when heat-treated in the ordinary way, are not in a stable volume condition. The tempering for volume stability requires a long time. For the changes in vol. during the ageing of steel, *vide supra*. The change in length of steels during tempering is a combined effect of tempering and temp.; K. Tamura eliminated the effect of temp. by measuring the increase in length of the cold specimen. The results show that the length decreases at first rapidly, then slightly, and afterwards there is a gradual decrease in length as the tempering interval increases; and also that for a constant interval of tempering, 1 hour, there is a decrease in length from room temp. to 200°, owing to the transformation of α- into β-martensite, and also to a slow decomposition of the martensite to form cementite; the maximum, lying between 230° and 300°, is due to the transformation of residual austenite to β-martensite; and the rapid contraction between 260° and 340° is due to the decomposition of β-martensite. The decrease in length above 340° is very slow. G. M. Eaton discussed the dilation of steel by the formation of martensite during quenching. The changes in vol. which occur during the quenching of steel were discussed by A. A. Blue, F. Berger, D. K. Bullens, H. Brearley, P. J. Haler, A. Portevin and P. Chévenard, J. Seigle, A. Heller, J. F. Keller, O. E. Harder and co-workers, R. S. MacPherran and R. H. Krueger, J. W. Donaldson, D. Hattori, and C. U. Scott. I. Jaederström discussed the effects of carbon, silicon, sulphur, manganese, phosphorus, nickel, and chromium on the casting shrinkage of cast iron. O. Bauer and H. Sieglerschmidt observed that the addition of about half per cent of copper or of nickel to cast iron had no perceptible effect on the growth of the metal. A. Portevin discussed the deformation of steel during heat-treatment.

A. Bramley and co-workers found that in gaseous cementation, samples of iron increased in diameter but generally decreased in length. If the original specimen contained a high proportion of carbon, or if the carburization was conducted below 900°, the changes in dimensions were comparatively small.

In 1791, T. Beddoes[3] reported: "In annealing crude iron with or without charcoal, it is known to increase in all its dimensions. I have seen bars, originally straight, bent like an S when long exposed to heat in circumstances where they could not extend themselves." It is a common thing to find the **growth of cast iron** with grate bars, stove-pipes, kiln-bats, oven-plates, etc., on exposure to high temp. J. Prinsep noticed that the capacity of an iron retort increased with successive heatings. Observations were also reported by A. Guettier, P. W. Brix, A. Erman and P. Herter, and J. Percy on the permanent expansion of cast iron by exposure to long-continued heat at or above redness. A. E. Outerbridge showed that grey cast iron expands more rapidly than white cast iron; that the deposition of carbon owing to the dissociation of the carbide does not account for the change in vol.; and that wrought iron and steel contract slightly when subjected to the same treatment. C. H. Wingfield also observed that wrought iron contracts permanently with the same treatment.

C. Benedicks and H. Löfquist analyzed the phenomenon by showing that permanent changes in vol. can occur in metals in three ways: (i) *Changes due to internal, irreversible or monotropic reactions* like that involved in the transformation of cementite into ferrite and annealing or temper carbon, or graphite. T. Kikuta thought that this change might develop internal cracks, but C. Benedicks and H. Löfquist, and H. F. Rugan and H. C. H. Carpenter showed that the theoretical expansion so caused is in agreement with the calculated value, and the change is not accompanied by internal cracks. Another monotropic reaction is the increase in vol. attending the oxidation of silicon, manganese, and iron by the entry of oxygen through cracks in the metal—*vide infra.*

(ii) *Permanent changes of shape resulting from normal expansion and contraction.* J. H. Whiteley, and J. F. Keller showed that a homogeneous metal cylinder when repeatedly quenched in water from a glowing state undergoes a permanent shortening. C. Benedicks and H. Löfquist said:

> On immersing a hot cylinder in the water, the outer layer is, of course, quickly cooled, and is consequently subjected to a sudden contraction. This will exert a considerable contraction stress on the inner, still warm layers—provided the tensile strength of the metal be sufficient—which will be noticeable especially in the direction of the cylinder axis; the plasticity of the inner layers being considerable on account of their higher temp., these will partly yield, and the length of the cylinder after completely cooling will be somewhat less than before treatment. The length thus successively decreasing by sudden coolings, it is a necessary consequence that the diameter should simultaneously increase, as otherwise a successive increase in the sp. gr. of the metal would occur. The result will be a growth of the middle part of the cylinder, together with a simultaneous shortening of its length; after repeated quenchings the cylinder will thus finally approach to a spherical form. That this must be the case is easily understood in the following way: A sudden cooling of the peripheric portions produces a high hydrostatic press. in the inner portions of the cylinder; this must cause a deformation tending towards a spherical form, in the same way as the blowing up of a heated, irregularly formed, closed glass tube will give a more or less spherical ball. If, instead, the homogeneous cylinder is subjected to a very sudden heating, as, for instance, by immersion in a molten salt bath, the outer parts must exert a certain stretching influence on the underlying portions, with a tendency permanently to elongate the cylinder (and lessen the diameter of the middle part). As in this case the inner portions have a lower temp., it is evident that the resulting elongation of the cylinder will be less than the shortening on sudden cooling. On the other hand, if the metal contains embedded particles which reduce its tensile strength, the possibility of the *formation of cracks* must be taken into consideration. Accordingly, in the case of a material in which cracks are easily formed, the following will occur: On account of the tensile stress exerted by the outer portions on the inner ones, on sudden heating, cracks may arise in the interior. On sudden cooling, however, cracks will arise, especially in the outer portions

of the cylinder, on account of the stresses appearing there. As a matter of fact, the interior —even if already containing cracks—will offer a considerable resistance to compression, as explained above. Consequently, a series of sudden coolings will cause an increasing internal bursting or porosity, proceeding throughout the cylinder, and accompanied by an increase in volume. As this action is caused by the difference in expansion of adjacent layers of the specimen, it will, however, not be of any appreciable magnitude, except when the temp. change takes place very suddenly; the velocity of temp. change—and consequently of expansion—which may be attained by ordinary heating and cooling being rather insignificant, the phenomenon will be difficult to observe.

(iii) *Permanent increase resulting from anomalous expansion and contraction.* When a metal has an allotropic phase transformation point, at which a considerable anomalous change in length occurs, this is equivalent to an extremely high speed of normal expansion and contraction. From the above, it follows that in a heterogeneous material possessing an anomalous dilation point, and in which internal bursting may occur, repeated heatings with subsequent coolings will cause a sensible and permanent increase in vol., and this even if the changes in temp. are made very slowly. The expansion of iron at the Ar-transition temp. was studied by G. Charpy and L. Grenet, A. M. Portevin and P. Chévenard. For pure iron, the reversible contraction at the Ac-arrest amounts to about 0·3 per cent. of the length at room temp. corresponding to a vol. contraction of 0·9 per cent. when α-iron changes into γ-iron. Its intensity diminishes with increasing carbon-content, so that with 0·7 per cent. carbon, the vol. contraction is 0·45 per cent. This decrease is due to the fact that a given amount of carbon has a greater vol. when dissolved in γ-iron above the Ac-arrest than when combined with iron in cementite, below Ac. If, instead, the carbon below Ac is present as graphite, the vol. change must be even greater than for pure iron. Actually, when 0·7 per cent. of carbon passes from cementite into graphite, an increase of 1·43 per cent. occurs. Consequently, in an iron containing 0·7 per cent. of carbon in graphite, if this is entirely dissolved at the Ac-change, a decrease in vol. of 1·9 per cent. will occur. Again, if 0·7 per cent. of carbon is dissolved in γ-iron above Ar_1 and the carbon entirely precipitated as graphite, an increase in vol. of 1·9 per cent. will occur, and this corresponds to an increase in length of 0·63 per cent. This represents the maximum anomalous expansion which can occur in grey cast iron at Ar. If the silicon-content be high, the percentage of carbon passing into γ-soln. will presumably be less than 0·7 per cent.; further, the carbon may not all be precipitated as graphite, for part may be precipitated as cementite. In both cases, the vol. or length changes at Ar will be less than the maximum value.

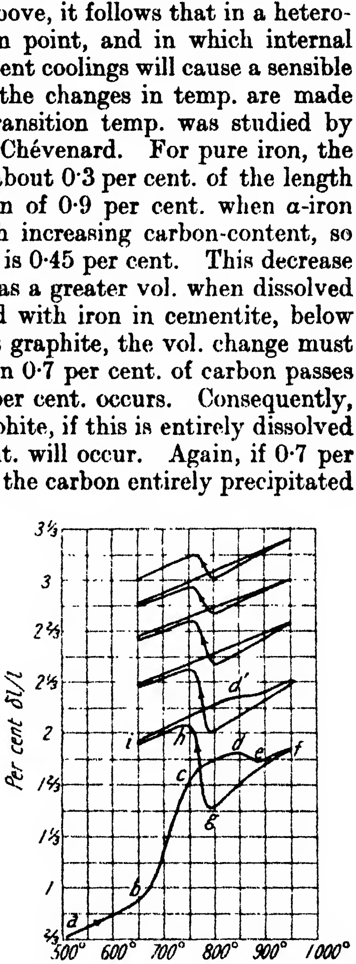


FIG. 241.—Curve showing the Permanent Increase in Length of Cast Iron during Repeated Heatings and Coolings.

Basing their hypothesis on the above considerations, C. Benedicks and H. Löfquist interpreted the phenomenon by a diagram, Fig. 241, resembling those obtained by T. Kikuta. The increase in the length, *l*, of a cylinder of cast iron will then be represented by a curve, *ab*, defined by the expansion coeff. of α-iron, namely, 12×10^{-6}, which increases slowly with temp. The coeff. of expansion of graphite cannot sensibly affect the result because the quantity present is so small. When the cementite begins to decompose, the vol. increases faster than is defined by the coeff. of thermal expansion. If 0·9 per cent. of combined carbon be present, the increase in vol. will be about 0·6 per cent., and the resultant expansion is represented by the curve *cd*, and the intermediate stage *bc*. T. Kikuta found that *b* is approximately at 700°. The formation of temper-carbon is complete at *c*.

The expansion proceeds along *cd* until Ac is attained, and if the proportion of silicon is high, the temp. is 850°. The transformation of the α- to the γ-state begins in the outer zone of the cylinder, and a linear contraction of about 0·63 per cent. occurs. This contraction will be opposed by the layer immediately below, which, like the whole of the interior, is still in the α-state. The metal here offers a great resistance to compression, so that the outer layer will be subjected to a severe strain giving rise to an internal bursting of the metal, which, on account of the contained graphite, possesses a very low tensile strength, and this results in a permanent lengthening. If thereby the tensile strength of the outer layer be very slight in comparison with the compression strength of the inner part, the outer layer, γ, would lengthen to exactly the same length still held by the inner part, α. The transformation having proceeded is this way until all is in the γ-state, no perceptible contraction of the cylinder would be observed. The metal, however, originally assumed to be devoid of cracks, possesses a certain tensile strength, so that on the first heating of the cylinder, a slight decrease in the resultant length may occur. If a quarter of the specific contraction takes place in this way, the resultant contraction, 0·16 per cent., will be that represented in Fig. 241 by the jump from *cd* to *ef* at 850°. The slope of *ef* is rather greater than that of *cd*, corresponding with the fact that γ-iron has a greater coeff. of expansion than α-iron. Since the graphite requires time to dissolve in the iron, a sudden jump will not occur, and *de* extending over an interval of, say, 50°, represents the region where the graphite is dissolving. The heating may now be continued up to 950°, represented by *f* in the diagram. On cooling, the contraction would follow the curve *fe*, but a certain dissolution of graphite would occur at this high temp., since a surplus of graphite is present, and this makes the backward curve *fg* slightly below *ef*.

The Ar-arrest is reached at about 800°. The transformation first occurs in the outer layer of the cylinder, which undergoes a strong anomalous expansion which, as indicated, attains a maximum of about 0·63 per cent. before the expansion of the underlying parts has begun. The outer layer is thus subjected to severe compression, and the inner part to strain. As a result, either the dilated outer layer is unable to produce any bursting of the interior layers, or the expansion of the outer layer will cause a certain bursting of the underlying layers. In the former case, the underlying layer will successively undergo the same expansion as the outer layer, and in the latter case, the underlying layers, after the transformation has taken place, will possess a somewhat larger vol. than that corresponding with the anomalous expansion itself. The latter case is the less probable, even if the tensile strength of the material be low, since the surface-layer, being very thin to begin with, cannot exert any considerable lengthening stress on the inner parts. In any case the resultant effect will be an expansion of the cylinder as a whole. Consequently, the expansion on the first passing of Ar may be assumed to amount to the theoretical maximum of 0·63 per cent. This increase in length corresponds with the passing of the curve from the point *g* to the curve *hi*. The change from *g* to *hi* does not take place suddenly, because the reaction cannot take place instantly; the precipitation of graphite occupies a certain time, especially as it is possible that a certain amount of cementite is formed primarily, and only later decomposed into graphite. The change, therefore, proceeds along the curve *gh* covering an interval of, say, 50°. The change in length during the subsequent cooling of the cylinder is represented by *hi*, and may continue until the point *i* is attained, say, 650°, when the cylinder is re-heated. The expansion may then proceed along *ih*, or rather along *id'*, because a slight continued precipitation of graphite may occur.

When the Ac-arrest is reached for the second time at *d'*, the prevailing circumstances are the same as before, with the difference that an internal bursting of the cylinder remains as a result of the previous heating. Making the necessary modifications for the residual effects of previous heatings and coolings, a series of loops is obtained as indicated in the diagram. The primary cause of the growth of cast iron is attributed to the fact that on account of internal bursting around the graphite lamellæ, the anomalous contraction at Ac decreases much more rapidly than the anomalous expansion at Ar. Every heating cycle consequently gives rise to a residual expansion. The repeated heating of the iron through Ac results in a continuous growth with an increased internal bursting. This bursting implies a lessened probability of the dissolution of graphite at Ac, etc. When heated in air, the cracks which are developed render possible a strong oxidation proceeding successively inwards. This phase of the subject was studied by H. F. Rugan and H. C. H. Carpenter, H. F. Rugan, J. H. Andrew and co-workers, J. E. Stead, C. E. Pearson, M. Horikiri and K. Uyeno, E. Richards, T. Terao, J. E. Hurst, H. Stäger, T. Wrightson, J. E. Fletcher, E. Honeggar, E. Scheil, J. Seigle, P. Bardenheuer, and F. K. Neath.

H. F. Rugan and H. C. H. Carpenter found that growth proper begins at about 650°, and it increases eightfold at 675°; it appears to reach a maximum at about 730°, and at 900° a further increase in volume was only just perceptible. They showed that alloys free from graphite do not grow, and that under suitable conditions, alloys containing graphite are capable of growing. With approximately constant carbon, the ultimate growth after repeated heating is approximately proportional to the percentage of silicon up to 6 per cent. The growth is far in excess of that caused by the transformation of combined into free carbon, and, in fact, growth was greatest in high-silicon alloys containing no carbon combined with iron. Two agencies thus appear at work: The internal press. of gas which the alloys contain in their original cast condition, and which is probably physical in character; the effect of external gas in contact with the alloys during their heat-treatment, which is probably partly physical and partly chemical in its nature. It was shown that the silicon is mainly responsible for the expansion, and that the expansion due to the precipitation of free carbon is relatively insignificant. There is an increase in weight which is approximately equal to the increase in the weight of iron and silicon oxidized minus the loss in weight due to the oxidation of carbon. The oxidation of silicon combined as FeSi is not sufficient to account for the gain in weight, and hence iron itself must also be oxidized. The carbon is oxidized to a greater extent in alloys containing least silicon; and in irons with least combined carbon, the oxidation of this element is at a minimum. It was inferred that when the metal is cooling, furnace gases penetrate to a certain depth in the metal, possibly along slits existing between the plates of carbon and the solid soln. of iron silicide, and through holes which exist here and there. The carbon oxides are assumed to oxidize the iron silicide, and during this period, growth and incipient disintegration occur. J. W. Donaldson found that the presence of chromium retards the growth of cast iron. The main cause of growth is the oxidation of the iron silicide. E. H. Saniter added that every time the metal is annealed and expanded, whether by the oxidation of the silicon or of the iron, the presence of the oxidation products prevent the metal from contracting to its original size when cooled. The process is repeated when the iron is again stretched by heating. H. F. Rugan and H. C. H. Carpenter were unable to expand iron-silicon alloys containing more than 0·20 per cent. of carbon; free carbon is necessary for the phenomenon. One specimen of metal shrank, if anything, when heated to 900° in vacuo, but when heated in furnace gases it expanded 67 per cent. Each time the metal is heated and cooled, the furnace gases penetrate a little deeper owing to the opening up of fresh avenues by the reactions just indicated. Each time the metal is heated and cooled the reactions are repeated, the iron is more and more disintegrated, and a further growth takes place. At the end of the process, the metal has lost the properties of cast iron; it has no mechanical strength, and may be sawn like chalk. H. C. H. Carpenter found that for grey cast iron the approximate percentage growths, with increasing proportions of silicon, were:

Si . .	1·0	1·50	2·0	2·5	3·0	3·5 per cent.
Growth .	15·0	21·5	27·0	31·0	34·0	37·0

Phosphorus tends to diminish the growth, since the growth was lessened about 3 per cent. by the presence of 0·3 per cent. of phosphorus, and still more with a higher percentage of phosphorus; the small amount of sulphur in commercial cast irons has but a slight influence in the direction of retardation; manganese retards the growth in all cases. Thus, alloys with 2·25 to 2·40 per cent. of carbon and 0·40 to 0·48 per cent. of silicon, as well as 0·510, 0·735, and 0·935 per cent. of manganese, after 151 heats, had respectively growths of 7·49, 6·06, and 3·09 per cent. Dissolved gases have no influence on the growth of an iron containing more than 3 per cent. of silicon; with between 1·75 and 3·00 per cent. silicon they may cause a growth of 1 to 2 per cent. Their most potent influence occurs when silicon does not exceed 1 per cent., and in such cases may be responsible for a growth of at least 10 per cent. An iron alloy with 2·66 per cent. of carbon, 0·587 per cent. of silicon, 1·64 per cent. of manganese showed no signs of growth after 150 heats, but rather about 0·13 per cent. contraction. The factors which lessen the growth sometimes act by lessening the intensity of the transformation—*e.g.* hydrogen, and nitrogen, observed by F. Wüst and O. Leihener, F. Osmond, W. C. Roberts-Austen, J. H. Andrew, H. S. Rawdon and co-workers; or by the stabilizing influence of different substances on cementite—*e.g.* phosphorus, observed by F. Wüst and co-workers, O. Bauer and K. Sipp, P. Oberhoffer, E. Schüz, H. C. H. Carpenter, J. H. Andrew and R. Higgins, etc., a subject discussed by W. H. Hatfield, and J. E. Hurst; sulphur, discussed by E. Schüz; chromium, by P. Goerens and A. Stadeler, and O. Bauer and K. Sipp. The case of aluminium was discussed by C. Benedicks and H. Löfquist, C. Geiger, and E. G. Odelstierna; of sulphur, by O. Bauer and K. Sipp; of nickel, by O. Bauer and K. Sipp; and of titanium, by B. Freise, and R. R. Kennedy and G. J. Oswald. In some cases the effect is due to the production of more finely-divided graphite which, as W. E. Remmers, and H. Hanemann have shown, increases the tensile strength of iron, and retards growth.

W. E. Remmers found that the alloying elements, silicon, aluminium, and, under certain conditions, titanium, and nickel, which favour the precipitation of carbon, tend to increase the growth, while such elements as chromium and manganese, which exert a stabilizing effect on the carbon, tend to decrease the growth. An increase in the total carbon increases the growth.

The general result is to show that the growth of cast iron when repeatedly heated is due to the physical changes at the Ac_1- and Ar_1-arrests, accompanied by bursting and cracking; as a result of the opening up of the iron, oxygen enters and produces the changes indicated by H. F. Rugan and H. C. H. Carpenter. T. Kikuta observed no sensible growth when the maximum temp. does not exceed the critical temp., though a considerable growth occurs on exceeding that region. Several instances of the growth of cast iron have been reported at temp., not exceeding Ac_1, and C. Benedicks and H. Löfquist added that the observed effect must be due to the formation of temper-carbon from cementite. F. Wüst and O. Leihener concluded that the influence of chemical composition on the growth of cast iron is obscured by other factors; that the growth in a neutral atm. cannot be explained by the decomposition of cementite; that the finer the state of subdivision of the graphite, the smaller the growth; that the growth in the middle zone is faster than in the border zone; and that the gas-content of the cast iron has an important influence on growth.

A. E. Outerbridge thought that the growth of cast iron is "an inherent quality of the metal, and has existed for all time. . . . The astonishing change in vol. is a molecular not a chemical process." H. F. Rugan and H. C. H. Carpenter showed that the phenomenon is a consequence of the oxidation of iron silicide. E. H. Saniter said that the phenomenon must have some relation to the thermal expansion of the metal because it is necessary to heat and cool the iron to make it increase so much in volume. T. Kikuta believed that the first growth on heating through 700° to 800° is partly due to the decomposition of the cementite, but the continued expansion of grey cast iron in vacuo during repeated heating and cooling is due to the differential expansion of the various constituents which produce numerous fissures or cavities in the neighbourhood of the plates of graphite. If the metal be now heated in air, these cavities serve as avenues for the entry of oxidizing gases in accord with the theory of H. F. Rugan and H. C. H. Carpenter. H. C. H. Carpenter did not obtain a growth in vacuo. C. E. Pearson suggested that any observed growth in vacuo is due to the influence of occluded gases; he found that the growth in hydrogen is inconsiderable. A. E. Outerbridge, J. E. Fletcher, and M. Okochi and N. Sato consider that the growth of cast iron by repeated heating and cooling through the Ar_1-range is caused by the press. of occluded gas. T. Kikuta said:

> The growth of grey cast iron during the first heating through 700° to 800°, is partly attributable to the decomposition of cementite. The continuous growth of grey cast iron in a vacuum during repeated heating and cooling through the A_1-range is the effect of the differential expansion at different microportions of the same specimen, numerous fissures or cavities being thus formed in the region of graphite flakes. In an oxidizing atmosphere, the growth is accelerated by oxides formed and filling the fissures or cavities during Ar_1-transformation. Thus the effect of oxidation on the growth of cast iron is indirect. The growth of white cast iron is almost completed in the first heating to 800°. About one-third of the whole expansion is due to the decomposition of eutectic and pearlitic cementites, and the other two-thirds to the minute fissures or cavities formed by the irreversible expansion in different microportions of the same specimen. The elongation observable at higher temperatures than the A_1-point is due to the pressure of occluded gases.

A. Campion and J. W. Donaldson observed an expansion up to 0·3 per cent. after 25 heatings at 450°; a definite growth was also observed at 550°. Observations on the subject were made by J. H. Andrew and R. Higgins, J. H. Andrew and H. Hyman, P. Bardenheuer and co-workers, O. Bauer and co-workers, W. H. Blackburn and J. W. Cobb, W. C. Bogenschutz, J. W. Cobb, J. W. Donaldson, J. S. Durn, J. Durand, W. Freytag, J. W. Gardom, W. H. Hatfield, H. M. Howe, T. E. Hull, F. H. Hurren, J. E. Hurst, D. H. Ingall and H. Field, R. L. Keynon, T. Kikuta, O. Leihener, A. Levi, O. Lellep, G. C. McCormick, R. S. MacPherran and R. H. Krueger, R. Mitsche, J. H. G. Monypenny, E. Morgan, A. L. Norbury and E. Morgan, P. Oberhoffer and E. Piwowarsky, M. Okochi and N. Sato, C. E. Pearson, E. Piwowarsky and O. Bornhofer, E. Piwowarsky and co-workers, W. H. Poole, W. E. Remmers, F. Roll, W. Schreck, W. Schwinning and H. Flössner, K. Sipp and F. Roll, R. Stumper, V. N. Svechnikoff, Y. Utida and M. Saito, T. Wrightson, F. Wüst and co-workers, and F. Wüst and O. Leihener studied the growth of cast iron under tension. According to J. Percy:

> Advantage has been taken of the permanent increase in volume which cast iron acquires by long exposure to a high temperature, in rendering cannon-shot serviceable which had been cast too small. The shot was heated in a charcoal fire, well embedded in the charcoal, and allowed to cool under charcoal dust. Their surface was bluish-grey, and did not require any cleaning to fit the shot for use; whereas in previously attempting to employ a hot-blast oven for the same purposes, the surface became coated with firmly adherent red oxide, so difficult to detach that it was found preferable to re-cast the shot than incur the labour and expense of cleaning them.

The observations of H. F. Rugan and H. C. H. Carpenter, W. H. Hatfield, and J. E. Stead show that the method of making over-shrunk castings grow to their proper size by re-heating, recommended by A. E. Outerbridge and others, can be employed only at the cost of some deterioration of the metal.

G. Wiedemann and R. Franz[4] said that if the **thermal conductivity** of silver is 100, that of iron is 11·6; L. Holborn and W. Wien said that if the conductivity of copper is 0·918, that of iron is 0·156, and steel 0·062 to 0·111. F. E. Neumann found the thermal conductivity of iron to be $k=0·1638$ cal. per cm. per second per degree; A. Berget gave 0·1587 above 0°; K. Angström, 0·1988 at 0°, and 0·1417 at 100°; L. R. Ingersoll, 0·1428 between 20° and 100°; L. Lorenz, 0·1665 at 0°, and 0·1627 at 100°; and H. Weber, 0·1485 at 39°. H. Masumoto extrapolated

0·1741 for the thermal conductivity of pure iron. J. D. Forbes obtained for wrought iron:

	0°	50°	100°	130°	200°	275°
k	0·2070	0·1772	0·1567	0·1447	0·1357	0·1240

R. W. Stewart gave for the thermal conductivity of iron, at 0°, $k=0{\cdot}172(1-0{\cdot}0011\theta)$. C. H. Lees gave 0·147 at 18°, and 0·152 at −160°. T. C. Baillie, P. G. Tait, P. Straneo, T. S. Taylor, and L. Ott made observations on this subject. For wrought iron, W. Jaeger and H. Diesselhorst gave 0·1436 at 18°, and 0·1420 at 100°; E. Grüneisen gave 0·171 at 18°; W. Beglinger, 0·111 to 0·150 at 8°; and E. H. Hall, 0·1528 at 28°. M. Jakob gave 0·135 for the best representative value of wrought iron. For cast iron, W. Beglinger gave 0·093 to 0·153 at 8°; and E. H. Hall and C. H. Ayres gave 0·1490 at 30°. M. Jakob gave 0·12 for the best representative value of cast iron. G. Kirchhoff and G. Hansemann gave 0·0964 at 15° for Bessemer steel with 0·52 per cent. C; and W. Beglinger, 0·0985 to 0·104 at 8°; and for Siemens-Martens steel, 0·133; while E. H. Hall, for similar steel with 0·1 per cent. of carbon, gave 0·1325 at 27·2°, and 0·1300 at 59·2°. G. Kirchhoff and G. Hansemann gave 0·1418 at 15° for puddled steel with 0·13 per cent. of carbon, and 0·1375 at 15° when 0·25 per cent. of carbon was present. W. Beglinger gave 0·123 at 8° for hard Thomas' steel, and 0·122 at 8° when the steel was softened; hard crucible steel has the value 0·108 at 8°; and the soft steel, 0·105 at 8°. F. Kohlrausch gave 0·062 for hard steel, and 0·111 for soft steel. E. Grüneisen gave 0·124 at 18° for steel with 0·57 per cent. of carbon, 0·123 for steel with 0·99 per cent. of carbon, and 0·119 for steel with 1·50 per cent. of carbon. W. Jaeger and H. Diesselhorst gave 0·1085 at 18° and 0·1076 at 100° for steel with 0·1 per cent. of carbon; and C. H. Lees, 0·115 at 18° and 0·113 at −160° for steel with 0·1 per cent. of carbon. Observations were also made by J. Mercier and P. Michoulier, H. J. French and O. Z. Klopsch, E. M. Bryant, G. Halliday, J. Hirsch, A. C. Kirk, M. Zittenberg, A. J. Durston, W. F. Barrett and co-workers, T. M. Barlow, J. W. Bolton, E. J. Janitzky, G. Graf, N. M. H. Lightfoot, A. L. Feild, P. Lejeune, J. W. Donaldson, T. J. Ess, H. Schmick, H. Thyssen and co-workers, J. Thoulet, R. C. Carpenter, D. Royce, A. Blechynden, J. G. Hudson, and W. Beglinger.

H. Masumoto found that in the case of cast iron, and steels, the thermal conductivity decreases rapidly at first, and then slowly as the proportion of carbon increases. The annealing of the cast iron raises the conductivity, but a subsequent annealing produces no change provided no graphitization occurs. Thus, with chill-cast and annealed (at 1000°) cast iron, the conductivities were:

	Carbon .	2·41	2·67	3·17	3·64	4·13	4·40	4·61 per cent.
k	Chill-cast .	0·0763	0·0702	0·0607	0·0513	0·0435	0·0350	0·0309
	Annealed .	0·0801	0·0760	0·0633	0·0540	0·0477	0·0390	0·0370

Graphitization decreases the thermal resistivity by about 3.99 for 1 per cent. of graphite. Thus, a sample with 4·35 per cent. of carbon with no graphite had a conductivity of 0·0347, and with 3·89 per cent. of the carbon as graphite, 0·1346; and a sample with 4·63 per cent. of carbon and no graphite had a conductivity of 0·0297, and with 4·55 per cent. of the carbon as graphite, 0·1332. By extrapolation, the thermal conductivity of cementite is 0·017 cal. per degree per cm. per second, when the corresponding value for iron is 0·1741 at 34°. C. Benedicks and co-workers represented the thermal resistivity, k^{-1}, the reciprocal of the thermal conductivity, by $k^{-1}=4{\cdot}4+8{\cdot}7\Sigma C$, where ΣC denotes the carbon value of a dissolved element, and it is obtained by multiplying the percentage proportion of the element by the ratio of the at. wt. of carbon to that of the element. H. Masumoto gave $k^{-1}=5{\cdot}744+2{\cdot}432[\mathrm{C}]+5{\cdot}081[\mathrm{Si}]+2{\cdot}461[\mathrm{Mn}]$.

J. W. Donaldson found that the thermal conductivity of grey cast iron varies from 0·11 to 0·137 cal. per sq. cm. per sec., and decreases as the temp. rises; *e.g.* one sample, with 0·65 per cent. Si, had a conductivity of 0·135 at 100° and 0·114 at 400°, and when the silicon was raised to 1·24 per cent., the corresponding values were 0·127 and 0·109. Silicon, nickel, vanadium, and manganese lower the conductivity—*vide infra*, the special steels—the influence of phosphorus is negligible; and chromium and tungsten raise the conductivity. Structure is of less importance than composition, though ferrite is a better conductor than eutectoidal pearlite. K. Honda and T. Simidu obtained the following results for Swedish iron, and for steels with different proportions of carbon, between the temp. named:

Swedish iron	30°	137°	234°	375°	516°	613°	710°	834°
	0·134	0·128	0·119	0·109	0·095	0·086	0·084	0·078

	0·086	0·086	0·087	0·085	0·083	0·074	0·074	0·066

K. Honda and T. Simidu observed that G. Wiedemann and R. Franz's law—**3**. 31, 5—holds for temp. up to about 900°; and L. Lorenz's law—**3**. 21, 5—applies for Swedish iron; but for steels, the conductivity-resistance curve does not pass through the absolute zero. The subject was discussed by A. Eucken and K. Dittrich. T. Simidu observed that for forged, quenched, and annealed steels, the products of the thermal and electrical conductivities are approximately constant, the mean value is 0·185 or $7{\cdot}75 \times 10^{10}$ in c.g.s. units. This is greater than the theoretical value $6{\cdot}5 \times 10^{10}$, and the discrepancy is attributed to a special molecular condition of the steels which is distinguished from that of other metals by their ferromagnetism. H. Masumoto found that the product of the electrical resistance and thermal conductivity of iron is a little greater than the theoretical; with increasing impurities the product increases slightly. With steels and cast iron, the products increase slightly with increasing carbon-content. Graphitization causes a large increase in the product. Extrapolation gives 0·24 for the product with cementite. The subject was discussed by G. Kirchhoff and G. Hansemann, F. Kohlrausch, A. C. Mitchell, E. Grüneisen, F. A. Schulze, E. D. Campbell and W. C. Dowd, E. Grüneisen and E. Goens, W. G. Kannuluik, R. Kikuchi, and F. A. Fahrenwald.

The "temperature" conductivity, represented by $a^2 = k/Dc$, where D denotes the sp. gr., and c the sp. ht., was found by G. Kirchhoff and G. Hansemann to be for puddled steel with 0·13 per cent. of carbon, $a^2 = 0{\cdot}1694 - 0{\cdot}00034\,(\theta - 15)$, and with 0·25 per cent. of carbon, $a^2 = 0{\cdot}1637 - 0{\cdot}00027\,(\theta - 15)$; and for Bessemer steel, $a^2 = 0{\cdot}1148 - 0{\cdot}00019\,(\theta - 15)$.

P. W. Bridgman found the press. coeff. for the thermal conductivity to be $-0{\cdot}0_63$ for press. between 0° and 12,000 kgrms. per sq. cm. For pressures up to 12,000 kgrms. per sq. cm., P. W. Bridgman found a 0·3 per cent. reduction in the thermal conductivity, so that the press. coeff. for the conductivity is $-0{\cdot}0_63$. For loads in tension of 2050 and 1025 kgrms. per sq. cm., P. W. Bridgman found the percentage change of thermal conductivity to be respectively $-0{\cdot}534$ and $-0{\cdot}32$; the proportional change of thermal conductivity, respectively $-2{\cdot}61 \times 10^{-6}$ and $-3{\cdot}08 \times 10^{-6}$; and the proportional change of sp. thermal conductivity, respectively $-1{\cdot}90 \times 10^{-6}$ and $2{\cdot}37 \times 10^{-6}$. A. Johnstone found that stretching increased the thermal conductivity about 0·5 per cent. for a tension of about 0·7 of the elastic limit, and when the tension was withdrawn the conductivity returned to its original value. H. M. Brown found that a longitudinal magnetic field of 10,000 gausses decreased the thermal conductivity 1·14 per cent., and a transverse field of 4000 gausses decreased it 0·4 per cent.—*vide infra*, magnetic properties of iron. C. Schwarz, A. M. Kuhlmann and A. D. Spillman, S. Saito, E. J. Janitzky, C. Benedicks and co-workers, and F. Riedel investigated the distribution of the temp. in the interior of masses of cooling steel.

The **specific heat** of iron was found by H. Tomlinson [5] to be 0·11302 between 0° and 100°; J. C. Wilcke gave 0·126; A. Crawford, 0·1269; W. Irvine, 0·143; P. L. Dulong and A. T. Petit, 0·1098 between 0° and 100°; 0·1150 between 0° and 200°; 0·1218 between 0° and 300°; and 0·1255 between 0° and 350°; H. V. Regnault gave 0·11352 between 19° and 98°, and 0·11380 at a red-heat. E. Bède gave 0·1123 between 15° and 100°; 0·1153 between 16° and 142°; and 0·1233 between 20° and 274°. L. Lorenz gave 0·1050 at 0°, 0·1107 at 50°, and 0·1136 at 75°; A. Naccari, 0·1091 at 15°, 0·1151 at 100°, 0·1249 at 200°, and 0·1376 at 300°. J. Pionchon gave 0·17654 at 500°, 0·32431 at 700°, 0·218 between 720° and 1000°, and 0·19887 between 1000° and 2000°. E. Grüneisen gave c_p=0·0851 between −190° and 17°, and c_p=0·112 between 17° and 100°. The sp. ht. of iron increases rapidly with a rise of temp.; and the metal undergoes a change between 660° and 720°, since the sp. ht. at 700° is greater than it is at 720°. W. N. Hartley gave 0·213 for the sp. ht. between 750° and 1000°, 0·218 between 954° and 1006°, and 0·19887 between 1050° and 1700°. P. Oberhoffer said that the mean sp. ht. of iron increases from 0·1221 at 250° to 0·1675 at 750° and then remains practically constant up to 500°. O. Byrström gave for the sp. ht. of purified iron:

	0°	50°	100°	150°	200°	250°	300°
Iron .	0·111641	0·112359	0·113795	0·115950	0·118821	0·122410	0·126719

P. L. Dulong and A. T. Petit represented the effect of temp. on the true sp. ht. by $0\cdot1062+0\cdot0_{4}56\theta+0\cdot0_{6}24\theta^{2}$, and on the mean sp. ht. by $0\cdot1062+0\cdot0_{4}28\theta+0\cdot0_{7}8\theta^{2}$. O. Byrström, on the true sp. ht. by $0\cdot11164+0\cdot0_{5}718\theta+0\cdot0_{6}1436\theta^{2}$, and on the mean sp. ht. between 0° and 660°, J. Pionchon gave $0\cdot11012+0\cdot0_{4}25\theta+0\cdot0_{7}547\theta^{2}$; between 660° and 720°, $0\cdot57803-0\cdot001436\theta+0\cdot0_{5}1195\theta^{2}$; between 720° and 1000°, $0\cdot218-39\theta^{-1}$; and between 1050° and 1160°, $0\cdot19887-23\cdot44\theta^{-1}$. W. A. Roth and W. Bertram gave for the sp. ht., c, of α-iron up to 720°, $c=0\cdot1060+0\cdot0_{4}6003(\theta-20)$; and for the true at. ht.:

	100°	200°	300°	400°	500°	600°	700°
c .	6·46	7·13	7·80	8·47	9·14	9·81	10·48

J. A. Harker found the mean sp. ht. of iron—containing 0·01 per cent. of carbon, 0·02 per cent. silicon, 0·03 per cent. sulphur, and 0·04 per cent. phosphorus—between 0° and

	200°	500°	750°	850°	900°	1050°	1100°
c .	0·1175	0·1338	0·1537	0·1647	0·1644	0·1512	0·1534
C .	—	7·47	8·58	9·20	9·18	8·44	8·57

W. Jaeger and H. Diesselhorst gave 0·1054 for the sp. ht. of iron at 18°, and 0·1185 at 100°; P. Schübel, 0·1096 between 18° and 100°, 0·1201 between 18° and 300°, and 0·1351 between 18° and 600°; and W. A. Tilden, 0·10983 between 17° and 100°; and H. Schimpff, 0·1098 between 17° and 100°.

H. A. Jones and co-workers represented the at. ht. at T° K. by $C_p=4\cdot39+0\cdot00405T$. W. H. Dearden found the sp. ht. of iron—with 0·04 per cent. of carbon; 0·006, S; 0·006, Si; and 0·069, P—to rise from 0·0852 at 17° to a maximum of 0·1942 at 108°, and then to fall to about 0·12 in the range of 150° to 200°, and it then rises again. This has not been confirmed. The high value at about 110° is said to correspond with other abnormalities, sonorousness, resistance, and mechanical properties. E. Lecher reported a maximum at about 740°. H. Klinkhardt found the A_2-arrest approximates to 760° with a step-down of rather more than 8 cals. per gram-atom per degree. He gave for the minimum value approximately 10·3 cals. per gram-atom per degree for β-iron, and 8·6 for γ-iron. Observations were made by J. B. Austin, F. K. Bailey, L. F. Bates, A. I. Brodsky, H. Klinkhardt, F. Morawe, J. F. Shadgen, N. Stücker, and M. Stupakoff. For W. Gerlach's curve of the temp. coeff. of the sp. ht., *vide infra*, the electrical resistance of iron.

P. Weiss and co-workers investigated the heat changes which occur through the ranges where iron is losing its magnetization, and they found that the sp. ht. increased to a maximum as the substance approached the Curie point; there was then an abrupt drop in the curve to a low value characteristic of paramagnetic substances. The magnetic transformation is thus associated with a comparatively large change in the internal energy, which is manifested by the excess of sp. ht. over what was normally expected. This excess falls off with diminishing temp. below the Curie point, but it is still sensible at room temp. so that it alters the shape of the sp. ht. curve. P. Weiss and P. N. Beck gave:

	170°	202·7°	453°	598°	711°	753°	777·7°	806°	844·3°	873·7°
c .	0·1012	0·1168	0·1458	0·1756	0·2185	0·3136	0·2280	0·2179	0·2206	0·2503

F. Wüst and co-workers obtained confirmatory results, but they smoothed their curve so that the deviations were either eliminated or averaged. F. Wüst and co-workers gave for the mean sp. ht. of purified iron, $0·10545+0·0_4 5684\theta$ between 0° and 725°; $0·1592-1·63\theta^{-1}$ between 785° and 919°; $0·14472+18·31\theta^{-1}+0·0_7 5\theta$ between 919° and 1404·5°; $0·21416-77·18\theta^{-1}$ between 1404·5° and 1528°; and $0·15012+70·03\theta^{-1}$ between 1528° and 1600°. For the sp. ht., they also gave $0·10545+0·00011368\theta$ between 0° and 725°; and $0·14472+0·0_6 10\theta$ between 919° and 1404·5. R. Durrer gave the sp. ht., *c*, and the at. ht., *C*, of electrolytic iron, between 0° and

	Solid							Molten	
	725°	785°	918°	920°	1404°	1405°	1528°	1528°	1600°
c .	0·1467	0·1571	0·1574	0·1647	0·1578	0·1592	0·1637	0·1959	0·1939
C .	8·19	8·77	8·79	9·20	8·81	8·89	9·14	10·94	10·83

Discontinuities in the curve at 1404° and 919° correspond with the A_4- and A_3-arrests, respectively. The character of the curve at the A_2-arrest between 725° and 785° is different from the others, and it is attributed to the reversible transformation α-Fe$\rightleftharpoons\beta$-Fe. S. Umino found the mean and true sp. hts. of iron with 0·04 per cent. of carbon to be:

	100°	200°	400°	600°	700°	750°	800°	850°
Mean .	0·1102	0·1133	0·1226	0·1347	0·1436	0·1494	0·1578	0·1645
True .	0·113	0·121	0·144	0·178	0·215	0·251	0·273	0·262
	900°	1100°	1200°	1300°	1400°	1500°	1570°	1630°
Mean .	0·1682	0·1699	0·1696	0·1698	0·1725	0·1726	0·1570	0·1630
True .	0·170	0·176	0·180	0·182	0·186	0·188	0·222	0·222

The abnormal values for the true sp. ht., in the range of the ferromagnetic change, are shown up by the curves. The sp. ht. of the molten metal does not change in the range of temp. examined. S. Umino measured the sp. ht. of electrolytic iron, and obtained for the true sp. ht., *c*:

	850°	900°	950°	1000°	1200°	1350°	1450°	1500°	1560°
c .	0·185	0·185	0·161	0·163	0·172	0·179	0·185	0·185	0·194

The results are plotted in Fig. 242, along with values for the mean sp. ht. There are abrupt changes at the A_3- and A_4-arrests, and at the m.p. In the other ranges of temp., the sp. ht. increases linearly with temp. Above the A_2-point, the sp. ht. remains constant until the A_3-point is reached, when there is a discontinuous decrease, but afterwards, an increase with rise of temp. up to the A_4-point, where a discontinuous increase again occurs, and then remains constant. During fusion there is a marked increase. The two portions of the true sp. ht. curve, lying above and below the curve for γ-iron, probably fall on the same straight line. A. Mallock observed no discontinuity in the sp. ht. between 1400° and 1500°, but the sp. ht. at ordinary temp. is about three times as great as it is above the recalescence point.

J. Maydel gave for the at. ht., $A=8\cdot803-938\cdot9(\theta+330)^{-1}$. A. Eucken and H. Werth gave for the at. hts. at constant vol. and constant press., and for Θ, the characteristic temp. in Debye's function—**1.** 13, 15—for electrolytic iron:

$T°$ K.	16·90°	26·80°	40·00°	84·00°	109·90°	148·52°	189·64°	205·59°
C_p .	0·03732	0·1125	0·3673	2·182	3·200	4·312	5·015	5·245
C_v .	0·03732	0·1125	0·3673	2·178	3·189	4·286	4·970	5·182
Θ .	392	431	430	420	417	395	368	350

F. M. Jäger gave 5·89 Cals. for the at. ht. of α-iron at 0°; 21·0 Cals. at 756°; 8·89 Cals. at 790° (β-iron), and it remains constant at 8·086 Cals. between 919° and 1200°; at 1404·5° it becomes about 12 Cals., and quickly falls to 8·382 Cals. (δ-iron), which value it retains up to the m.p.

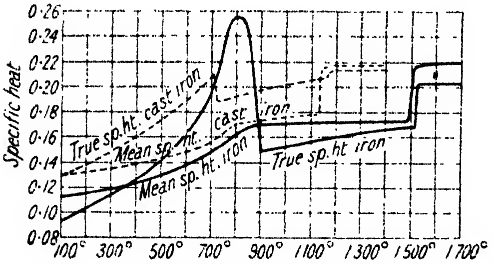

FIG. 242.—The Specific Heats of Iron (0·04 per cent. of Carbon) and of Cast Iron (4·12 per cent. of Carbon).

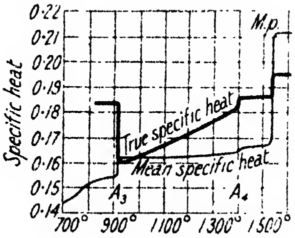

FIG. 243.—The Effect of Temperature on the Specific Heat of Iron.

For temp. below atmospheric, U. Behn gave 0·0721 between −186° and −79°, and 0·0999 between −79° and 18°; P. Ewald, 0·0697 at −135°, 0·1001 at −38°, and 0·1062 at 28°; P. Nordmeyer and A. L. Bernoulli, 0·095 between −185° and 20°; T. W. Richards and F. G. Jackson, 0·0859 between 20° and −188°; and J. Dewar, 0·0175 between −253° and −196°. E. H. and E. Griffiths' results down to −223°, and P. Günther's for still lower temp., are as follow:

	97·5°	20·5°	0°	−63°	−163°	−223°	−231·1°	−237·9°	−241·1°
c .	0·1137	0·1078	0·1046	0·0960	0·0621	0·0176	0·0058	0·0043	0·0027
C .	6·35	6·02	5·84	5·36	3·47	0·98	0·325	0·244	0·152

W. H. Rodebush and J. C. Michalek gave 0·0326 at −200·2°; 0·0491 at −182·7°; and 0·096 at −75·1°; and M. Kawakami, 0·1133 between 30° and 172·3°; 0·1148 between 30° and 205·8°; and 0·1170 between 30° and 250°. Observations on sp. ht. were also made by F. A. Fahrenwald, J. W. Richards, H. Klinkhardt, H. E. Schmitz, and M. Pirani.

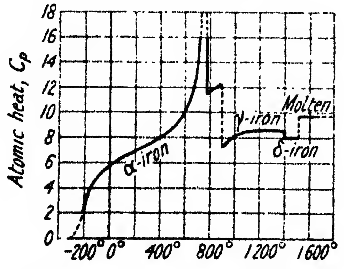

FIG. 244.—The True Specific Heat of Iron.

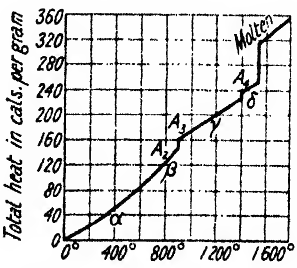

FIG. 245.—The Thermal Capacity of Iron.

The data were collected by O. C. Ralston, and the results for the sp. ht. and the thermal capacity of iron are summarized in Figs. 244, 245. The sp. ht. rises from absolute zero and, as ordinary temp. is approached, it turns off to a horizontal asymptote as in the case of most substances. The effect of the magnetic component of the sp. ht. now appears bending the sp. ht. curve upward until a peak is reached where the magnetic change proceeds for test. After the Curie point, A_2, is reached, the sp. ht. of paramagnetic α-iron, *i.e.* β-iron, is nearly constant, and then abruptly changes at the A_3-arrest and remains nearly constant in the range of stability of γ-iron. There is another break at the A_4-arrest as δ-iron is formed, and, according to P. Oberhoffer and W. Grosse, the value for δ-iron is a continuation of the curve for normal α-iron. There is another break at the m.p., and the sp. ht. of molten iron then remains constant. The thermal capacity curve, Fig. 245, explains itself. A gram of cold iron requires 252·3 cals. to bring it to the m.p., and 317·2 cals. to produce a gram of liquid iron from cold iron; and it also follows that at the b.p. of iron, it requires 613·6 cals. to produce a gram of liquid iron at the b.p., or 2403·6 cals. to produce a gram of iron gas at its b.p. It is assumed that the sp. ht. of molten iron is constant 0·176, and that the latent heat of vaporization is near 100 Cals. per gram-atom. The thermal capacity curve for ferromagnetic α-iron is not a straight line, but rather a curve of increasing slope which culminates in the A_2-arrest. The energy required to raise the temp. is expended in increasing the thermal motions of atoms or groups of atoms in the space-lattice, in increasing the distance between the atoms in the space-lattice, in overcoming the tendency of the atoms to orient themselves magnetically, and in electronic displacements.

P. Weiss, on the basis of his theory of an internal field, showed that a ferromagnetic substance should exhibit characteristic changes in the neighbourhood of its magnetic critical point. The argument runs somewhat as follows:

The magnetic energy per c.c. of a ferromagnetic substance is $W=-\frac{1}{2}HI$, where I is the intensity of magnetization, and H is the molecular field. It is assumed that $H=nI$, where n is a constant dependent on the nature of the material. Hence, $W=-\frac{1}{2}nI^2$, and $dW/dt=-\frac{1}{2}nd(I^2)/dT$, where T is the temp. dW/dt will contribute to the sp. heat of the substance which will become equal to $S=s+(1/\rho J)(dW/dI)$, where s denotes the sp. ht. neglecting the magnetic contribution; S, the total sp. ht.; ρ, the density; and J, the mechanical eq. of heat. Consequently, $S=s-(n/2\rho J)d(I^2)/dT$.

From the shape of the magnetization-temperature curves, P. Weiss concluded that the sp. ht. should rise to a maximum at the critical temp., and then decrease discontinuously owing to the disappearance of the magnetic term. The results of observations with iron found by P. Weiss and co-workers, A. Piccard and A. Carrard, were not wholly in agreement with the theory. The best results were obtained with nickel, but the observations of W. Sucksmith and H. H. Potter with Heusler's alloy and with nickel were not in agreement with P. Weiss' theory of the sp. ht. of ferromagnetic substances. Similarly with L. F. Bates' observations with manganese arsenide.

A. Weinhold gave for the sp. ht. of wrought iron, between θ°_2 and θ°_1, $c=0{\cdot}105907+0{\cdot}00003269(\theta_2-\theta_1)+0{\cdot}0_722159(\theta_2-\theta_1)^2+0{\cdot}0_3110795(\theta_2-\theta_1)^3$; A. Naccari, $c=0{\cdot}10440+0{\cdot}0001075\theta$; and E. Bède, $c=0{\cdot}1053+0{\cdot}000071\theta$. H. V. Regnault found for hardened steel of sp. gr. 7·7982, 0·1175 between ordinary temp. and 100°, and for annealed steel of sp. gr. 7·8609, 0·1165. C. Chappell and M. Levin observed no difference, within the limits of experimental error, between the sp. ht. of cold-drawn metals, before and after annealing. The sp. ht. of mild steel was 0·1117 to 0·1120, and that of hard steel 0·1132 to 0·1134 in the two conditions respectively. O. Byrström's values for the sp. hts. of cast iron and of cast steel are:

	0°	50°	100°	150°	200°	250°	300°
Cast steel .	0·11782	0·11850	0·11986	0·12190	0·12462	0·12802	0·13211
Cast iron .	0·12768	0·12830	0·12954	0·13140	0·13388	0·13698	0·14070

O. Petterson and E. Hedelius gave for wrought iron 0·108079 between 4° and 27°. H. V. Regnault gave 0·12983 for white cast iron, 0·12728 for cast iron, and 0·11848 for cast steel. W. Schmidt found the sp. ht. of pig-iron with approximately the eutectic proportion, 4·35 per cent. of carbon, was 0·3136 between 1175° and 1275°, and 0·3216 from 1275° to 1375°. S. Umino found the mean and true sp. hts. of cast iron with 4·12 per cent. of carbon to have the values:

	100°	200°	400°	500°	600°	700°	800°	900°
Mean . .	0·1308	0·1341	0·1400	0·1417	0·1482	0·1542	0·1679	0·1712
True . .	0·131	0·139	0·159	0·172	0·187	0·207	0·194	0·198

	1000°	1050°	1100°	1150°	1200°	1250°	1300°	1350°
Mean . .	0·1748	0·1773	0·1776	0·1791	0·2191	0·2188	0·2185	0·2185
True . .	0·202	—	0·207	—	0·215	0·215	—	0·215

W. Brown found an increase in the sp. ht. of iron with 0·0089 per cent. of carbon; and for steels with about 0·1 per cent. of silicon, 0·14 to 0·32 per cent. of manganese, and

Carbon . . .	0·028	0·05	0·14	0·89	1·23 per cent.
Sp. ht. . . .	0·1134	0·1136	0·1144	0·1192	0·1234

whilst for steels with about 0·48 per cent. of silicon, 0·58 per cent. of manganese, and 0·58, 1·00, and 1·25 per cent. of carbon, the sp. hts. were respectively 0·1170, 0·1220, and 0·1225. While A. Meuthen found breaks at 1·0 per cent. of carbon in the curves for the sp. ht. of steels with different proportions of carbon, M. Levin and H. Schottky obtained only a linear relation. K. Honda gave for forged and annealed steels between 20° and 150°:

Carbon .	0·00	0·10	0·20	0·50	0·70	0·89	1·11	1·29	1·48 per cent.
Forged .	0·1126	0·1135	0·1145	0·1179	0·1195	0·1219	0·1225	0·1230	0·1233
Annealed	—	0·1131	0·1129	0·1144	0·1167	0·1187	0·1190	0·1197	0·1212

for quenched steel, 0·1188; and when annealed, 0·1176; and for cast iron, 0·1371 when cast; annealed at 670° for 5 mins., 0·1345; for 10 mins., 0·1316; and for 60 mins., 0·1158.

The sp. ht. of steel should be the sum of the sp. hts. of the contained ferrite and cementite, so that the relation between the percentage of carbon and the sp. ht. should be linear. A. Meuthen, however, found that the curve between 0° and 700° consists of two straight lines intersecting at the eutectoid composition. G. Tammann said that this peculiarity is due to a difference in the size of the cementite grains. M. Levin and H. Schottky observed that with annealed steels there is a linear relation between the sp. ht. and the carbon concentration at room temp. as well as at temp. below the A_1-point. K. Honda showed that the sp. ht. of iron is not a linear function of the proportion of carbon, but is modified by the presence of stresses. The decrease in the sp. ht. of quenched steels produced by a prolonged annealing at 650° is partly due to the release of the strain, and partly to the decomposition of the cementite during the annealing. A high degree of strain in a metal is accompanied by an internal or a molecular disorder, which is equivalent to a small degree of freedom, and hence causes an increase in the sp. ht.

The sp. ht. of cementite has been worked out by S. Umino, who found the true sp. ht., c_p, and the mol. ht., C_p, to be

	0°	200°	220°	300°	500°	600°	700°	800°	900°
c_p	0·1475	0·1495	0·1497	0·1225	0·1660	0·1785	0·1925	0·2100	0·2264
C_p	26·9	51·5	100·4(17·9)	21·1	29·6	35·9	37·7	—	—

The results were plotted as a smoothed curve by S. Umino, but O. C. Ralston showed that the curve has the form shown in Fig. 246, where the break is the A_0-arrest, that is, the temp. of magnetic transformation, or the Curie point of cementite. Obviously, in determining the sp. ht. of steels at elevated temp. by quenching, the hot metal in the liquid of the calorimeter may alter the nature of the constituents. If quenched from below 720°, the thermal capacity will be a function of the carbon-content, but if quenched in the calorimeter from higher temp. the thermal capacity will be a function of the proportion of austenite, martensite, troostite, sorbite, or pearlite. The energy changes involved in passing from austenite to martensite, and from martensite to pearlite have been studied by N. Yamada, S. Umino, and A. Meuthen—*vide infra.* S. Umino's values for the sp. ht. of electrolytic iron and different steels are shown in Fig. 247.

E. Grüneisen found the effect of pressure, p, on the sp. ht., c_p, of iron to be $dc_p/c_pdp=-0{\cdot}0_641$; and $dv/vdp=0{\cdot}0_660$. J. Russner, B. V. Hill, and J. R. Ashworth discussed the relation between the thermal and magnetic constants of iron; E. Grüneisen and E. Goens, the sp. ht. and sp. resistance—*vide infra,* electrical resistance; and J. Russner, and A. H. Stuart, the relation between the sp. ht. and the mechanical constants. According to J. Stefan, and A. Wassmuth, the sp. ht. of magnetized iron is greater than that of unmagnetized iron. J. W. Richards, and J. Maydel discussed some relationships of the sp. ht.; and K. Försterling, the relationship between the lattice energy and the sp. ht. E. D. Eastman and co-workers calculated $C_p-C_v=0{\cdot}10$ Cal. per degree per mol.

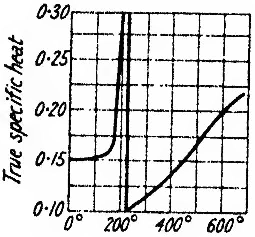

FIG. 246.—The Specific Heat of Cementite.

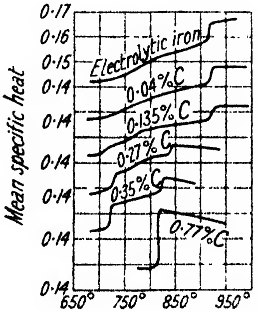

FIG. 247.—Mean Specific Heat Curves of Iron and Steel at Different Temperatures.

Amongst the older determinations of the **melting-point** of iron there is one by L. B. G. de Morveau [6] at 175° on the Wedgwood scale, and one by G. S. Mackenzie at 158° on the same scale. J. F. Daniell gave 1587°; C. S. M. Pouillet, 1500°; T. Carnelley, 1804°; R. Pictet, 1600°; F. Osmond, 1520°; and W. C. Roberts-Austen, 1600°. W. R. Mott gave 1507° for the m.p. of iron; C. Brisker, 1500°; F. Wüst and co-workers, 1528°; S. Umino, 1535°; P. Oberhoffer and W. Grosse, 1528°; H. C. H. Carpenter and B. F. E. Keeling, 1505°; A. Müller, 1485° to 1525° on the heating curve, and 1505° to 1485° on the cooling curve. For purified iron, B. Saklatwalla gave 1510°; H. Harkort, 1501°, and 1504°; D. Hanson and J. R. Freeman, and E. M. Terry, 1530°; R. Sahmen, 1532°; A. G. C. Gwyer, 1515°; R. Ruer and E. Schütz, 1502°; E. Isaac and G. Tammann, 1524° to 1527°; W. Guertler and G. Tammann, 1492°; C. Benedicks and co-workers, 1525°; and when 0·1 per cent. of carbon is present, 1480°; R. Ruer and R. Klesper, and R. Ruer and F. Goerens, 1528°; J. H. Andrew and D. Binnie, 1537°; F. S. Tritton and D. Hanson, 1535°±5°; K. Honda and H. Endo, 1530°; W. Gontermann, 1525°; N. S. Konstantinoff, 1514°; G. K. Burgess, 1507°; G. K. Burgess and R. G. Waltenberg, 1533°, for electrolytic iron with 0·012 per cent. of carbon, 0·072, H; 0·013, Si; and 0·004, P. C. H. M. Jenkins and M. L. V. Gayler gave 1527±3° for the m.p. of 99·98 to 99·99 per cent. iron; this value is based on the assumption that the m.p. of palladium is 1555°, and that of gold, 1063°. The observation of H. C. H. Carpenter and B. F. E. Keeling is based on the m.p. of platinum, 1710°; more recent determinations place the m.p. of platinum 45° to 65° above this value, and hence H. C. H. Carpenter and B. F. E. Keeling's value should probably be 20° to 30° above 1505°. L. I. Dana and P. D. Foote, and W. Guertler and M. Pirani gave for the best representative value, 1530°; H. C. H. Carpenter, 1505°; and

O. C. Ralston, 1537°. A. Mallock studied this subject. T. Carnelley discussed the relation between the m.p. and the coeff. of thermal expansion; W. Crossley, the relation between the m.p. and the at. vol.; K. Honda and H. Masumoto, and L. P. Sieg, the relation between the elastic constants and the m.p.; and G. Moressée, the relation between the m.p., the at. wt., and the latent heat of fusion.

The liquidus and solidus curves for iron and carbon alloys were measured by H. C. H. Carpenter and B. F. E. Keeling, R. Ruer and R. Klesper, S. Kaya, R. Moldenke, J. H. Andrew and D. Binnie, and K. Honda and H. Endo—*vide supra*, the equilibrium diagrams. R. A. Hadfield gave 1135° for the m.p. of Swedish iron with 4 per cent. of carbon; 1220° for grey foundry iron with 3·5 per cent. of carbon (1·75 per cent. Si, and 0·5 per cent. P); 1410° for steel with 0·90 per cent. of carbon; 1453° for steel with 0·30 per cent. of carbon; and 1475° for steel with 0·10 per cent. of carbon. E. Widawsky and F. Sauerwald gave for the liquidus temp. of the iron-carbon alloys:

Carbon .	0·0	0·5	1·0	1·5	2·0	2·5	3·0	3·5	4·0	4·5 per cent.
Liquidus .	1533°	1480°	1458°	1422°	1382°	1341°	1290°	1232°	1170°	1150°

W. Schmidt said that temp. discontinuities at T° K. in the various physical properties of iron conform with the relation $T=nT_m/m$, where T_m, the m.p. of iron, is taken as 1803° K., $m=14$, and n is an integer less than 14. The effect of press. on the m.p. obtained by Clapeyron's equation—1. 6, 4—for $dv=0{\cdot}2735$ c.c., and one atm. press., is $dT=0{\cdot}00330$, meaning that the change in the m.p. is 0·0033° per atm., or 1° per 300 atm. The effect of press. on the A_3- and A_4-arrests has been previously discussed. Z. Herrmann studied the energy at the m.p.; and E. Kordes gave 1·52 for the entropy change on melting.

Most metals pass abruptly from the solid to the liquid state, and are in some cases brittle and easily pulverized near the temp. of incipient fusion, and even if there is a temp. at which the metal becomes viscid before melting, the range between that temp. and the m.p. is very narrow. Ordinary iron is remarkable in developing a viscid character through a considerable range of temp. below its m.p. Thus, at a bright red-heat, the iron is soft enough to be forged; and at a white-heat, it is so pasty that two pieces when pressed together unite intimately and firmly, as also in the operation of *welding*. Platinum, like iron, is a weldable metal. T. Scheerer said that if the iron be quite free from carbon, or nearly so, it can only be imperfectly welded, and even that with great difficulty; he considered that the carbon is necessary to prevent the formation of a layer of oxide on the surface, which prevents adhesion. J. Percy questions the fact and the explanation. The welding may be effected by the extrusion of the melted scale, but if the scale be not liquid the iron will not weld. T. Wrightson compared the phenomenon of welding in iron to the regelation of ice. Wrought iron at a welding temp. possesses the same property of cooling under pressure as exists with freezing water, and on which the accepted theory of regelation depends. The process of melting together, and the process of welding differ in that the latter occurs at a temp. much below the m.p. As in the case of the regelation of ice, the property of welding in iron depends upon a critical condition existing over a limited range of temp. between the molten and the plastic state. T. Turner discussed the semi-fluid state of iron. F. J. R. Carulla noted that the interior of a block of mild steel may be raised to the fusing point whilst the exterior remains solid, and if the surface be pierced the molten interior can be drained off leaving an empty shell. G. J. Snelus thought that the surface had become decarburized by air. R. Wright and R. C. Smith, and R. C. Smith found that reduced iron sinters at 750° to 850°, and precipitated iron at 750°; and B. Garre showed that at about 700° the metal diffuses from particle to particle in the solid state so that the tensile strength of iron powder, compressed at 3000 kgrms. per sq. cm., is raised from 10 to 19·4 kgrms. per sq. mm. after being heated to 700°. The sintering of powdered iron was studied by L. Schlecht and co-workers.

According to R. Hare,[7] if an electric current be passed by means of charcoal points through iron, in vacuo, there is formed a quantity of the vapour of iron which burns with a flash on admitting air, and deposits a yellow film on the glass. H. Pellat said that steel acts on a photographic plate even when separated by a sheet of cardboard, but not when separated by a sheet of glass; the action is attributed to the **volatilization** of the metal at ordinary temp. R. Colson obtained negative results with iron. Possibly the effect was due to the escape of occluded reducing gases. W. Crookes said that the comparative volatility of electrically heated wires of iron is 5·50 when that of gold is 100. According to A. Knocke, the volatilization of iron is sufficiently great to be detected at 755° in vacuo. G. W. C. Kaye and D. Ewen found that when iron is heated to 950° in an inert atm., particles are emitted at right-angles to the surface, leaving the surface etched and pitted. The effect is distinct from volatilization. E. Botolfsen found that iron can be sublimed in a high vacuum at temp. below its m.p. The effect is independent of the origin of the iron and of the presence of certain substances likely to act as catalysts, and at 1300° its rate is of the order of 0·07 per cent. per hr. The sublimate takes the form of a thick deposit of metallic crystals, and is almost pure. J. W. Mellor has noticed a similar effect on the surface of glass and vitreous porcelain if heated rapidly; in this case the effect is probably a mechanical disintegration produced by occluded gases. O. Ruff and W. Bormann gave 2450° for the **boiling-point** of iron; H. A. Jones and co-workers, 3202°; O. P. Watts, 2600°; H. C. Greenwood, 2723° to 2925°; E. Mack and co-workers, 2723°; and W. R. Mott, 3000°. H. Moissan found that iron can be readily volatilized in the electric arc furnace. A sublimate or distillate of iron can be obtained as a grey powder mixed with brilliant malleable scales. The distillation of iron by this process is difficult owing to the violent frothing produced by occluded gases. O. Ruff and co-workers studied the b.p. of soln. saturated with carbon. H. A. Jones and co-workers gave for the **rate of evaporation,** m, of iron, $\log_{10}m=40{\cdot}231/4{\cdot}577-(86350+240)/4{\cdot}577T-(0{\cdot}971/4{\cdot}577)\log_{10}T-0{\cdot}00203T/4{\cdot}577-2675/(4{\cdot}577\times3475)$; and for the **vapour pressure,** p mm., $\log_{10}p=40{\cdot}231/4{\cdot}977+3{\cdot}486-2675/(4{\cdot}577\times1808)-(86350+240)/4{\cdot}577T-(0{\cdot}971-0{\cdot}5)\log_{10}T-0{\cdot}00203T/4{\cdot}577$; or

$T°$ K. .	600°	1000°	1500°	2000°	2600°	3000°	3600°
p. .	$2{\cdot}48\times10^{-20}$	$1{\cdot}76\times10^{-7}$	$3{\cdot}60\times10^{-1}$	$3{\cdot}9\times10^{2}$	$3{\cdot}5\times10^{4}$	$2{\cdot}2\times10^{5}$	$1{\cdot}0\times10^{6}$

H. C. Greenwood estimated a vap. press. of 760 mm. at 2450°. J. Johnston gave for the vap. press. $\log p=-17000T^{-1}+9{\cdot}10$; and R. W. Millar, p mm., of liquid iron, $\log p=1{\cdot}7151\log T-18440T^{-1}+14{\cdot}221$; and for the b.p. at different press.:

p . .	760	500	300	100	50	10	1	0·1 mm.
B.p. .	3235	3097	2930	2670	2520	2225	1900	1655

L. E. Gruner[8] gave for the **heat of fusion** of white cast iron 32 to 34 cals. per gram, or 1·8 to 1·9 Cals. per gram-atom; and for grey cast iron, 23 cals. per gram, or 1·3 Cals. per gram-atom. For purified iron, at 1528°, F. Wüst and co-workers gave 49·4 cals. per gram, or 2·75 Cals. per gram-atom; R. Durrer, 49·35 cals. per gram; Y. Chu-Phay, 66·4 cals.; W. Schmidt, 59 cals. per gram, or 3·3 Cals. per gram-atom; S. Umino, 65·65 cals.; and P. Oberhoffer and W. Grosse, 64·38 cals. C. Brisker based a calculation on assumptions as to the state of carbon in soln., and from the equation for the lowering of the f.p., obtained 31·6 cals. per gram, or 1·765 cals. per gram-atom, or when re-calculated by O. C. Ralston, 57·50 cals. per gram, or 3·210 cals. per gram-atom—the results are poor. C. P. Yap calculated 64·4 cals. per gram for the heat of fusion of α-iron, and 66·4 cals. per gram for that of γ-iron. The subject was discussed by E. Kordes. E. Rabinowitsch and E. Thilo gave for the heat of fusion, 0·12 volt; for the heat of vaporization, 4·09 volts; and for the heat of sublimation at the m.p., 4·21 volts when 1 volt=23 Cals. N. M. H. Lightfoot discussed the effect of the latent heat on the solidification of steel ingots; W. Herz discussed the relation between the heat of fusion and the vibration frequency; and G. Moressée, the thermodynamics of the latent heat of fusion. If L denotes the m.p. at T_m° K.; and A, the at. wt., then $L=3T_m°/A$.

J. Johnston gave 77,800 cals. per mol. for the **heat of vaporization.** H. C. Greenwood gave 88,900 to 94,300 cals. per gram-atom, and E. Mack and co-workers, 71,400 cals. per gram-atom. O. C. Ralston calculated 100,000 cals. per gram-atom, and obtained from Trouton's rule, 77,000 cals. per gram-atom. H. A. Jones and co-workers gave for the latent heat of vaporization, 89,025 cals. at about 1000°. They gave $LT^{-1}=40{\cdot}231-0{\cdot}971 \log_{10}T-4{\cdot}577 \log_{10}m-0{\cdot}00203T-240T^{-1}$.

The **transformation points** of iron are discussed elsewhere. G. Sirovich [9] found an arrest occurs at 370° where the supposed α_1-Fe changes into α_2-Fe—*vide supra*, allotropes of iron. For the A_2-arrest where $\beta\text{-Fe}\rightleftharpoons\alpha\text{-Fe}$, W. C. Roberts-Austen gave 770° on the heating curve; H. Harkort, 764° to 759° on the cooling curve, and 691° to 763° on the heating curve; A. Müller, 765° to 774° on the heating curve, and 766° and 759° on the cooling curve; G. Charpy, 730° on the cooling curve, and 740° on the heating curve; F. Osmond, 780° on the cooling curve, and 800° on the heating curve; H. C. H. Carpenter and B. F. E. Keeling, 790° on the cooling curve; R. Sahmen, 840° on the heating, and 800° on the cooling curves; R. Ruer and E. Schütz, 780° on the heating, and 773° on the cooling curves; E. Isaac and G. Tammann, 740° on the cooling curve; W. Gontermann, 770° on the cooling curve; R. Ruer and R. Klesper, 769° on the cooling and heating curves; A. Westgren and G. Phragmen, 770°; and G. K. Burgess and J. J. Crowe gave 768° on the heating and cooling curves. P. Weiss and P. N. Beck gave 753°; P. Weiss and co-workers, 784°; F. Wüst and co-workers, 755°; P. Oberhoffer and W. Grosse, 785°; S. Umino, 820° to 825°; F. Wever, and R. Ruer and K. Bode, 763°. Observations were made by R. Averdieck, A. Mallock, and C. H. M. Jenkins and M. L. V. Gayler.

W. C. Roberts-Austen placed the *A_3-point* where $\gamma\text{-Fe}\rightleftharpoons\beta\text{-Fe}$ at 895° on the cooling curve; A. Müller gave 894° on the cooling curve, and 917° on the heating curve; H. C. H. Carpenter and B. F. E. Keeling, 900° on the cooling curve; H. Harkort, 888° to 875° on the cooling curve, and 910° to 917° on the heating curve; G. Charpy, 840° on the cooling curve, and 865° on the heating curve; F. Osmond, 880° on the cooling curve, and 905° on the heating curve; R. Sahmen, 888° on the cooling curve; E. Isaac and G. Tammann, 832° on the cooling curve; W. Gontermann, 852° on the cooling curve; F. Wever, 900°; G. K. Burgess and J. J. Crowe, 909° on the heating curve, and 898° on the cooling curve; and R. Ruer and R. Klesper, 898° on the cooling, and 906° on the heating curves. F. Wüst and co-workers gave 919°; P. Oberhoffer and W. Grosse, 906°; S. Umino, 906°; E. M. Terry, 903°; T. Ishiwara, 890°; and K. Honda and H. Takagi, 889° to 898°. Observations were made by C. H. M. Jenkins and M. L. V. Gayler. H. Quinney found that the time-temp. curve of single crystals falls about 4° below that for polycrystals, but the Ac_3-arrest is the same in both cases. According to W. Rosenhain, of the work performed during the plastic deformation of a mild steel under tensile stresses, 10 per cent. is dissipated as heat, and the remainder is expended in doing internal work; this work is assumed to involve a change of phase from the crystalline to the plastic state.

For the A_4-arrest, where $\delta\text{-Fe}\rightleftharpoons\gamma\text{-Fe}$, R. Ruer and R. Klesper gave 1401°, F. Wever, and W. Gontermann, 1411°, on the heating and cooling curves. R. Ruer and K. Kaneko gave 1420°; D. Hanson and J. R. Freeman, 1400°; P. Weiss and G. Foëx, 1395°; T. Ishiwara, 1390°; and E. M. Terry, 1406°. Observations were made by C. H. M. Jenkins and M. L. V. Gayler.

R. Ruer and F. Goerens, G. K. Burgess and J. J. Crowe, E. Maurer, and H. le Chatelier discussed the effect of the *speed of heating and cooling* on the transition points, and the effect of other influences have been previously described. G. Tammann said that at 770°, α-iron passes into the β-form, which at 890° is transformed with contraction into the γ-form. These transformations are reversible, and the influence of press. on the transition temp. may be calculated by aid of the formula,

$dT/dp=\delta T/Rp$. In the transformation of the α- into the β-form, the value $dT/dp=0$, that is, the temp. of the transformation, is independent of the press. At 770°, under a press. of 12,000 kgrms. per sq. cm., the transition curves of the α- into the β-form and of the β- into γ-form cut one another at a triple point, where α-, β-, and γ-iron are in equilibrium. Observations were made by H. Hort, and F. K. Bailey.

Lord Kelvin (W. Thomson) pointed out that the theory of the mutual convertibility of heat and mechanical work in reversible operations when applied to these phenomena proves (i) that a piece of soft iron at a moderate or low red-heat, when drawn gently away from a magnet experiences a cooling effect, and when allowed to approach a magnet experiences a heating effect; that nickel and cobalt at high temp., within some definite range below that of melting copper, experience the same kind of effects when subjected to similar magnetic operations. (ii) That cobalt at ordinary atm. temp., and at all temp. upwards to its temp. of maximum inductive capacity, experiences a cooling effect when allowed to approach a magnet slowly, and a heating effect when drawn away.

W. C. Roberts-Austen estimated 2·86 cals. for the **heat of transformation** of γ-iron into β-iron; and 1·00 Cal. for β-iron into α-iron; P. N. Laschtschenko gave 5 cals. per gram, or 0·28 Cal. per gram-atom, for the former, and 6·1 cals. per gram, or 0·38 Cal. per gram-atom, for the latter. W. Schneider gave 13·2 cals. per gram for the heat of transformation of γ-iron into α-iron, and said that the value decreases linearly with increasing proportions of carbon up to 6·68 per cent., when it disappears. S. Evershed calculated for a change at 700° an absorption of 4·5 cals. per gram; at 770° to 810°, when α-iron changes to β-iron with the loss of magnetism, an absorption of 1·4 cals. per gram; at 919°, when β-iron changes to γ-iron, an absorption of 6·7 cals. per gram; at 1405°, when γ-iron changes to δ-iron, an absorption of 1·9 cals. per gram; and at 1528°, when solid iron becomes liquid, an absorption of 49·3 cals. per gram.

C. P. Yap calculated 2·0 cals. per gram for the heat of transformation of γ-iron to δ-iron; and Y. Chu-Phay, 2·2 cals. per gram, and for α-iron to γ-iron, 5·5 cals. per gram. R. Durrer found 6·56 cals. per gram for the heat of transformation at the A_2-arrest. W. A. Roth and W. Bertram gave 0·324 Cal. per gram-atom for the heat of the transformation at 750°. Estimates of the heat of transformation at the A_2-arrest were made by F. Osmond, 1·3 cals. per gram; A. S. Stansfield gave 1·0 cal.; J. Pionchön, 5·3 cals.; F. Wüst and co-workers, and S. Umino, 3·65 cals. S. Umino gave 3·1 to 5·60 cals. per gram for the heat of transformation at the A_3-point. F. Osmond gave 3·8 cals.; A. S. Stansfield, 2·86 cals.; F. Wüst and co-workers, 6·56 cals.; P. Oberhoffer and W. Grosse, 5·6 to 6·765 cals. R. Durrer, 6·67 cals.; and A. Meuthen, 3·0 cals. W. Bertram gave 0·324 Cal. per gram-atom at 750°. S. Umino gave 2·53 cals. per gram for the heat of the A_4-transformation; F. Wüst and co-workers, 1·94 cals.; P. Oberhoffer and W. Grosse, 2·531, and R. Durrer, 1·94 cals.

S. Umino gave for the heat of fusion of the eutectic, at 1135° with 4·25 per cent. of carbon, 46·63 to 47·0 cals. per gram of alloy. W. Schmidt gave 59 cals. per gram for 4·35 per cent. carbon. The other heats of transformation are not unique. S. Umino's value for the Curie point, at A_0, is 9·72 cals. per gram of cementite at 150° to 220°. The following may tentatively be taken as the best representative values for the heats of transformation, Q cals. per gram, of iron:

	A_2	A_3	A_4	M.p.	B.p.
Q	3·65	5·0	2·5	65·0	1660

The thermal changes during the transformations of the constituents of the iron-carbon alloys.—N. Yamada, and S. Umino studied the rapid quenching of steels in order to obtain the maximum amount of martensite with as little undecomposed austenite as possible. The thermal capacity of the result represents the normal thermal capacity together with the energy involved in passing across the

A_1-line from austenite to martensite. The quenching prevents the formation of pearlite, so that the result is definite and is represented by the *austenite-martensite* curve, Fig. 248. The *martensite-pearlite* curve—*vide supra,* martensite—was obtained by quenching samples from the austenite field, tempering one at 500° whilst the other remained in the martensite condition, and heating them separately in a calorimeter at 350° to 400°. The difference represented the heat of transformation of martensite to pearlite—excepting that hypereutectoid steels also contained austenite. The hypereutectoid samples on the martensite-pearlite line were quenched from temp. below the cementite solubility line, whilst the hypereutectoid samples quenched from within the austenite field form an upward continuation of the hypoeutectoid martensite-pearlite line. The difference is supposed to represent the heat of precipitation of cementite from austenite; it is represented in Fig. 248 by the *austenite-cementite* above the A_1 curve. The total thermal capacity curves in passing from A_3 down to A_1, represent the heat involved in passing these points, which correspond with the A_3+A_2+*austenite-martensite* curve in the diagram. By extrapolation to zero carbon, the A_3-heat is 12 cals. per gram. For hypereutectoid steels it corresponds with the austenite-martensite transformation alone. S. Umino also arranged for the austenite to be transformed into pearlite instead of martensite, and so obtained the *austenite-pearlite* curve—*vide supra,* martensite. Subtracting the martensite-pearlite heats from the austenite-pearlite heats gives the heats indicated in the *austenite-martensite* curve — *vide supra,* martensite. Eutectoidal steel, having 0·9 per cent. of carbon, furnishes only one thermal anomaly as the austenite passes into 100 per cent. pearlite. At this temp. the heat involved represents the transformation of austenite to α-iron and cementite from the supersaturated solid soln. of α-iron plus the heat of the A_3-transformation. By arranging for the γ-iron to have been transformed into α-iron, the heat of the austenite-martensite transformation is eliminated, and for hypoeutectoid steels, the heat involved is proportional to the carbon or cementite content, and it represents the heat of precipitation of cementite from its soln. in α-iron, or, conversely, the heat of dissolution of cementite in α-iron—N. Yamada gave 75·3 cals. per gram of cementite, and S. Umino, 75·9 cals. The austenite-pearlite curve also enables the heat of precipitation of cementite from γ-iron to be calculated—A. Meuthen gave 118·5 cals. per gram of cementite, and S. Umino, 120 cals. N. Yamada obtained 83·6 cals. for the heat of precipitation of cementite in hypereutectoid steels above the A_1-arrest. This datum is intermediate between the values for α- and γ-iron, and it is taken to mean that, in quenching, from temp. intermediate between A_1 and the cementite solubility curve, some austenite survived, and only part was converted into martensite. The heat effects involved in the mild tempering of martensite to furnish atomically-displaced carbon—troostite—or, on further tempering, to furnish dispersed cementite—sorbite—and on further tempering, crystallized cementite—pearlite — are probably summated in the difference between the heats of the austenite-martensite and the austenite-pearlite transformations. According to M. Kawakami, the heat of precipitation of cementite from α-martensite is 3·7 cals. per gram, and it is about half as large as is that from β-martensite.

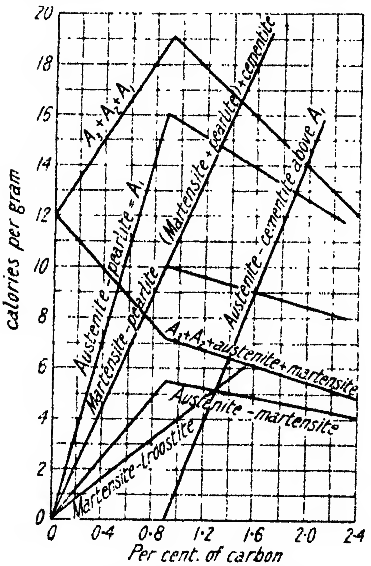

FIG. 248.—Heat Changes in the Transformations of Steels.

M. Kawakami, assuming that there are two forms of martensite, α and β—*vide supra*—and that heating to 200° decomposes only the α-form, leaving the β-form which requires for decomposition a temp. of 370°, measured the heat involved, and obtained the results indicated in the *martensite-troostite* curve, Fig. 248. The heat involved in tempering eutectoid steel at 200° is 3·7 cals. per gram. If troostite is formed by the conversion of a super-saturated solid soln. of cementite in α-iron into atomically-dispersed carbon in α-iron, the heat effect is 410 cals. per gram of carbon, or 4920 cals. per gram-atom; but if troostite is cementite precipitated from a supersaturated solid soln. in α-iron, the heat effect is 27·4 cals. per gram of cementite, or 4920 cals. per mol. O. C. Ralston summarized, in Table XXXVIII, the heat changes in eutectoidal steels with 0·9 per cent. of carbon.

TABLE XXXVIII.—THE THERMAL VALUES OF THE TRANSFORMATION IN EUTECTOID STEELS.

Metallographic change	Supposed chemical change	Heat liberated (in calories)		
		per gram of pearlite	per gram of cementite	per mol. of cementite
Austenite→martensite	Solution α-Fe→solution α-Fe	5·9	43·8	7,870
Martensite→troostite	Solution α-Fe→α-Fe+carbon	3·7	27·4	4,920
Troostite→pearlite	α-Fe+carbon→α-Fe+Fe_3C	6·2	46·0	8,260
Martensite→pearlite	Solution α-Fe→α-Fe+Fe_3C	9·9	73·0	13,170
Austenite→pearlite	Solution γ-Fe→α-Fe+Fe_3C	15·8	117·2	21,040

H. Esser and W. Grass gave for the austenite→pearlite transformation, 21·22 cals. per gram, and R. Averdieck, 22·54 cals. A. Meuthen's value, 3·0 cals., for the pearlite transformation is rather low. S. Umino also calculated thermal values, in calories, for the A_1-, A_2-, and A_3-arrests, and obtained:

	Electrolytic iron	Percentage of carbon in steel				
		0·040	0·135	0·270	0·350	0·770
A_1 . .	0·00	0·67	2·40	4·70	6·00	13·60
A_2 . .	3·63	3·55	3·50	3·36	3·23	3·18
A_3 . .	5·35	5·00	5·48	3·66	3·50	0·80

A. Meuthen obtained for iron alone, A_2=5·60 cals. and A_3=3·0 cals.; and the results are nearly equivalent to a reversal of S. Umino's results. S. Umino traced the A_2 transformation as far as 0·770 per cent. of carbon; and he traced the effects of the magnetic component of the sp. ht. as low as 130° below the A_2-transformation, and a slight disturbance probably occurs very much below this. The extrapolation of the A_3-arrest to 0·9 per cent. carbon, 100 per cent. pearlite, gives zero for the thermal value of the A_3-transformation, whilst the A_1-transformation takes 15·95 cals. The thermal value of the A_2-transformation is not added to that of the A_1-transformation, because the A_2-change is not a discontinuity in the thermal capacity curve, Fig. 249, but only a change of direction, for the sp. ht. is the change in the thermal capacity, Q, with temp. θ, namely, $dQ/d\theta$. According to A. McCance, Q=3·2 cals. is the mean value of the A_3-transformation. Where the A_2- and A_3-arrests are merged into one, and Q_m denotes the energy of demagnetization, and A. McCance calculated:

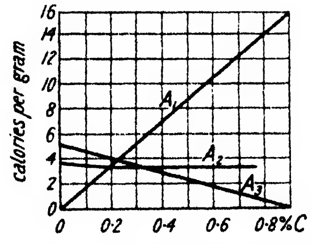

FIG. 249.—The Thermal Values of the A_1-, A_2-, and A_3-Transformations.

	752°	742°	732°	716°	700°
Q_m . . .	0·23	0·93	2·10	3·74	4·95 cals.
Q' . . .	3·4	4·1	5·3	6·9	8·1 ,,

The A_2-point for the steel with 0·77 per cent. carbon is higher than the A_3-point, because the A_3S-line, Fig. 249, crosses the A_2-line at about 0·6 per cent. of carbon. These results may all be regarded as first approximations to the truth in a very difficult quest. The subject was studied by F. Stäblein and H. Jäger.

According to N. Yamada, the heat of dissolution of carbon in iron, measured by the difference of the heat of dissolution of quenched and tempered carbon steels in molten alkali nitrate, is as follows :

Carbon . .	0·38	0·52	0·65	0·70	1·30	1·7 per cent.
Heat dissolution.	4·3	6·2	8·0	8·2	14·4	19·5 cals.

and for the two last hypereutectoid steels, quenched at 750°, the values were respectively 9·3 and 8·8 cals.—*vide* Fig. 250. This shows that the heat of dissolution of carbon in iron increases linearly with the contents of carbon in the steel, and amounts to 1130 cals. per gram of carbon, or 75·3 cals. per gram of cementite ; and the mol. ht. of dissolution of carbon or cementite is then 13·6 Cals. W. Schneider gave 33·2 cals. per gram for the heat of solid soln. of Fe_3C in α-iron.

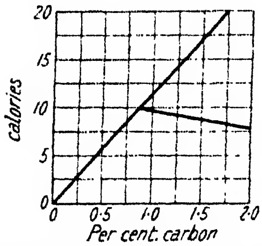

Fig. 250.—Heats of Dissolution of Carbon in Iron.

E. D. Eastman,[10] and G. N. Lewis and co-workers calculated the **entropy** of iron atoms by two different methods to be 6·5 to 7·0 cals. per degree at 25°. The subject was discussed by W. Herz, K. K. Kelley, R. D. Kleeman, B. Bruzs, and W. M. Latimer. Some results calculated by W. H. Rodebush and J. C. Michalek, and O. C. Ralston from the results of plotting the true at. ht. against the natural logarithms of the absolute temp., gave for the entropy, in cals. per gram :

	0°	25°	100°	200°	400°	600°	720°	800°	900°
Entropy .	6·36	6·87	8·24	9·78	12·45	14·74	16·00	17·41	18·47
	906°	906°	1000°	1200°	1400°	1400°	1535°	1535°	1600°
Entropy .	18·63	18·86	19·39	20·68	21·71	21·77	22·41	24·00	24·39

O. C. Ralston calculated 66·74 units for the absolute entropy of cementite at 700°, and 31·94 units at 25°, he also gave for the relative entropy of cementite :

	0°	100°	200°	220°	300°	400°	600°	700°	720°
Entropy .	0	5·79	12·92	16·90	18·94	23·40	31·01	34·8	35·68

J. B. Austin gave for the entropy, S ; heat capacity, Q Cals. for gram-atom ; and free energy, F, of α-iron :

	−273·1°	−123·1°	0°	100°	500°	1000°	1535°
S .	0	2·83	6·10	8·10	13·72	19·27	22·88
Q .	0	290	950	1566	4689	10280	15945
F .	0	−134	−715	−1455	−5911	−14251	−25400

and for γ-iron :

	−273·1°	−100°	0°	100°	500°	1000°	1500°
S .	0	4·98	7·90	9·94	15·60	19·86	22·92
Q .	0	538	1185	1880	5016	9411	14048
F .	960	636	−12	−867	−6083	−14911	−25630

A. Eucken and H. Werth calculated for the entropy at the transition point $\alpha \rightleftharpoons \gamma$ at 1181° K., 19·35 cals. per gram-atom for α-iron, and 18·59 cals. per gram-atom for γ-iron ; and W. M. Latimer and R. M. Buffington, values for the relative entropy of $Fe^{\cdots}$-ions. R. Dallwitz-Wegener discussed the **free energy** of the element.

§ 20. Optical Properties of Iron and Iron-Carbon Alloys.

Powdered iron obtained by reducing the heated oxide in hydrogen at a comparatively low temp., is a powder which is dull grey or black in **colour**, and it acquires a silver-white lustre under the burnisher ; according to G. Magnus,[1] if reduced at a higher temp., the powder is greyish-white. J. L. C. Schroeder van der Kolk found that the streak of iron on a biscuit tile is brownish, like that of graphite. M. Faraday said that thin films are dark brown by transparent light, and steel-grey by reflected light. B. Dessau obtained thin films which were grey in transmitted light; and G. T. Beilby, blue by reflected light. A. W. Wright observed that a thin film of iron in transmitted light appears of a neutral tint with a faint brownish tinge, and E. van Aubel, and L. Houllevigue added that thin films deposited on glass by cathode spluttering, or electrolysis, are transparent, and brown. For layers 31 to $72\mu\mu$ thick, L. Houllevigue found the transparency to be an exponential function of the thickness. G. le Bon observed that ordinary light contains waves, which he called *la lumière noire*, which will traverse thin sheet iron and produce photographic effects. G. Govi found that films of red-hot iron up to 0·4 mm. thickness are opaque. C. A. Skinner and A. Q. Tool said that films obtained by rapid cathode spluttering appear deep black by reflected light, and yellowish-brown by transmitted light; whereas those obtained more slowly have a metallic lustre, and are opaque. G B. Rizzo, and P. Secchi discussed the colour of thin films; W. C. Sabine discussed the selective absorption of films of steel for ultra-violet light. W. L. Dudley found that the incandescent vapour is greenish-blue. E. M. Péligot observed that the iron obtained by reducing the chloride in hydrogen is filamentous, compact, malleable, and is almost as white as silver. J. J. Berzelius observed that wrought-iron filings melted under ferrous oxide, in a luted fireclay crucible, furnish a button with crystalline fracture, greyish-white in colour. Electrodeposited iron, by E. A. Jacquin's or R. Böttger's processes, has a bright lustre, and, according to E. Lenz, it has the colour of platinum after it has been heated in vacuo. E. F. Dürre discussed the colour and lustre of different varieties of iron, and also the fracture, and texture of the metal. W. Ramsay said that it seemed as if it were possible to see objects through a regular stream of the molten cast iron, and they appeared to be of a yellow colour, but the transparency of molten cast iron was denied by T. Turner.

M. White and F. W. Taylor gave for the colours of iron at high temperatures: 532°, dark blood-red, black-red, incipient red, and *rouge naissant*; 566°, dark red, blood-red, low red, and *rouge sombre*; 635°, dark cherry-red, incipient cherry-red, and *cerise naissant*; 682°, medium cherry-red; 746°, cherry-red, full red, and *cerise*; 835°, light cherry, bright cherry, scaling heat, light red, and *cerise clair*; 899°, orange, salmon, free scaling heat, and *orange foncée*; 941°, light orange, light salmon, and *orange clair*; 996°, yellow; 1079°, light yellow; and 1205°, white, and *blanc*. The results agree with those of H. M. Howe, but they differ from those C. S. M. Pouillet obtained in 1836.

The crystalline characteristics have been previously described. T. Turner discussed the colour of the tarnish films of iron—*vide infra*, temper colours—and W. Biltz, and J. Meisenheimer, the colour of iron compounds.

H. E. J. G. du Bois and H. Rubens[2] found the **index of refraction,** μ, of precipitated iron to be for wave-length, λ:

λ . . .	4310	4860	5893	6440	6700
μ . . .	2·05	2·43	2·72	3·06	3·12

P. A. Ross gave 1·48 for $\lambda=4500$; 1·85 for $\lambda=5893$; and 2·1 for $\lambda=6200$, with electrolytic iron; and C. Statescu, 2·182 for $\lambda=5880$. Observations on the refractive index were also made by A. Beer, A. L. Bernoulli, H. E. J. G. du Bois and H. Rubens, P. Drude, L. R. Ingersoll, H. Knoblauch, A. Kundt, W. Meier, R. S. Minor, A. Pflüger, D. Shea, C. A. Skinner and A. Q. Tool, J. T. Tate, A. Q. Tool, and W. Voigt. The refractive index for the X-rays was measured by R. L. Doan, A. Gouy, J. A. Prins, and A. Winkelmann and R. Straubel. A. Kundt found that for red-light at 18°, 20°, 102°, and 106°, the refractive indices were respectively 0·66, 1·92, 2·54, and 3·69. W. Linnik and W. Laschkareff measured the refractive index of steel and iron for X-rays. C. V. Raman and K. S. Krishnan discussed the colour, intensity, and polarization of light diffracted through large angles by steel wedges and screens with polished edges. A. J. Ferreira da Silva found that with iron salts, the **atomic refraction** of bivalent iron is 11·6, and of tervalent iron, 20·1; for long waves, A. Heydweiller gave 5·07 and 7·97 respectively for bi- and ter-valent iron; and A. Hauke gave for the **refraction equivalents,** calculated from the refractive indices of aq. soln. of iron salts by the μ-formula, and for bivalent and tervalent iron respectively 11·6 and 20·6, and by the μ^2-formula, 4·75 and 5·83 respectively. W. J. Pope gave 13·38 for the refraction equivalent of bivalent iron, and 23·03 for tervalent iron; and J. H. Gladstone, respectively 11·6 and 19·4. The **anomalous dispersion** of iron was studied by S. Albrecht, P. Drude, H. Giesler, A. S. King, J. A. Prins, L. Puccianti, and W. Voigt. The double refraction of iron was discussed by H. Behrens, and S. Procopiu. M. Cau observed that thin films of iron, formed by the condensation of iron vapour, exhibit a **birefringence** accompanied by **dichroism,** the principal directions of which are parallel and perpendicular, respectively, to that of the original wire. The effect ceases when the deposit is removed, and is due to the magnetic field of the heating current, in which the atoms of vapour tend to orient themselves in positions which are retained after deposition and are unaffected by a magnetic field placed parallel to the deposit. The component of the vibration parallel to the axis is less absorbed than the normal component by the birefringent dichroic layers of iron. In the middle of the spectrum, the dispersion is normal for the ellipticity, and abnormal for the rotation of the emergent vibration. C. Statescu gave for the **extinction coefficient** of electrolytic iron, k=2·716; A. Kundt, μ=1·52 for blue-light, μ=1·73 for white-light, and μ=1·81 for red-light; whilst A. Pflüger gave μ=3·66 for red-light. W. Meier found for electrolytic iron, the following values for the index of refraction, μ, the extinction coeff., k, and the percentage **reflecting power,** R:

λ	2573	2749	2981	3255	3611	3982	4413	4678	6080	5893	6680
μ	1·01	0·95	0·92	0·99	1·04	1·17	1·28	1·34	1·38	1·51	1·70
k	0·88	0·80	0·83	0·91	1·10	1·29	1·37	1·45	1·50	1·63	1·84
R	16·2	14·4	16·0	17·4	22·4	26·7	27·7	29·2	30·2	32·6	36·2

P. Drude found for massive iron, λ=5890, k=320, μ=2·36, and R=56·1; and W. W. Coblentz gave for the reflecting power of massive iron for λ=5000, 6000, 7000, and 8000, R=55·0, 57·5, 59·5, and 61·5 respectively. He also gave:

λ	0·5	1·0	2·0	3·0	5·0	7·0	8·0	9·0 μ
R	55·0	65·0	78·0	84·5	91·5	94·0	94·0	93·0

I. C. Gardner, and F. von Fragstein measured the reflecting power in the ultraviolet. Observations on the optical constants of steel were made by A. L. Bernoulli, G. Breithaupt, J. Clavier, P. Drude, F. A. Fahrenwald, P. Glan, E. Hagen and H. Rubens, S. Haughton, H. Hauschild, R. Hennig, E. O. Hulbert, L. R. Ingersoll, J. Jamin, J. T. Littleton, M. Luckiesh, W. Meier, R. S. Minor, G. Pfestorf, G. Quincke, J. T. Tate, A. Q. Tool, and V. S. M. van der Willigen. The following is a selection from the results:

λ	1880	2265	3255	4000	5000	6200	7000	8700
k	—	1·64	2·09	1·73	3·15	3·30	3·47	4·08
μ	—	1·30	1·37	1·68	2·09	2·58	2·73	3·02
R	22	34·8	44·8	53·9	56·9	56·8	58·0	63·2

λ	1·0	1·25	1·50	1·75	2·00	2·25	8·80	14·0μ
k	4·43	5·08	5·75	6·32	6·88	7·41	—	—
μ	3·19	3·45	3·71	3·88	4·02	4·14	—	—
R	65·5	69·7	73·1	75·6	77·7	79·7	93·0	96·0

M. Chikaschige and D. Uno measured the reflecting power of the iron-carbon alloys. For alloys with the pearlitic structure—normalized at 1000°, and annealed at 700°—the reflecting powers with different spectral lines are indicated in Fig. 251. The fact that the curves are nearly parallel shows that the colour is independent of the proportion of carbon. The dotted lines, which merge into the continuous lines of Fig. 251, refer to martensite—normalized at 1000° and quenched in water from 800°. Fig. 252 shows the reflecting powers of a 0·9 per cent. carbon steel normalized at 1000°; quenched at 800° in water at 20°; and then annealed at the temp. indicated—350° for troostite; 550° for sorbite; and 700° for pearlite. The results show that the reflecting powers of the constituents decrease in the order: martensite, troostite, sorbite, ferrite, and pearlite. W. Arkadieff studied the reflection of electromagnetic waves; E. Gerold, the lustre of iron; and E. Rupp, the optical properties of iron before and after exposure to hydrogen, nitrogen, and hydrogen sulphide; and W. Bruch found that the optical properties indicated that cast iron is isotropic.

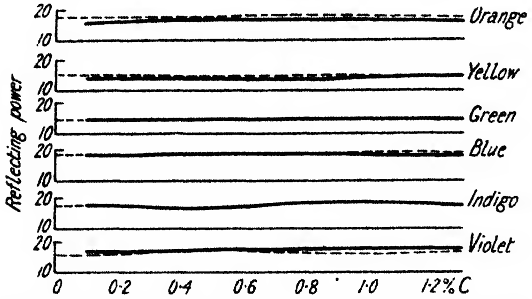

Fig. 251.—Reflecting Powers of Martensite (dotted) and Pearlitic Iron-Carbon Alloys.

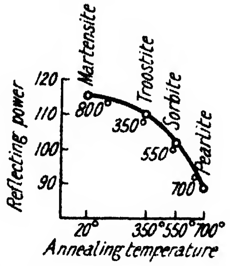

Fig. 252.—The Effect of Annealing Temperature on the Reflecting Power of Steel.

W. Meier, and G. Jaffé calculated values for the optical constants based on the theory of electrons: S. Nakamura studied the relation between the optical constants and the permanent mechanical expansion of steel; J. T. Littleton, the relation between the optical constants and the carbon-content and heat-treatment of steel; L. R. Ingersoll and J. T. Littleton, the optical constants of steel in the ultra-red; and G. Jung, W. H. J. Vernon, and H. Freundlich and co-workers, the relation between the optical constants and the tarnish colours.

Observations on the reflecting power of the visible rays were made by A. L. Bernoulli, P. Drude, E. O. Hulbert, L. R. Ingersoll, J. Jamin, S. Rösch, R. S. Minor, G. Quincke, J. T. Tate, and A. Q. Tool; on the reflecting power of the ultra-violet rays, by R. Hamer; on the reflecting power for the heat rays, by H. Rubens and E. F. Nichols, and A. Trowbridge; on the reflecting power for the ultra-red rays, by H. Rubens and co-workers, and L. R. Ingersoll and J. T. Littleton; the effect of temp. on the reflecting power, by W. R. Grove, E. Hagen and H. Rubens, and R. Sissingh; on the reflecting power of iron under water, by J. Conroy, and P. Drude; and on the reflecting power of the active and passive forms of iron—*vide infra*, passive iron—by F. Haber and F. Goldschmidt, P. Krassa, F. J. Micheli, and W. J. Müller and J. Königsberger. A. Gouy, W. Wien, and C. V. Raman and K. S. Krishnan studied the reflection and diffraction colours of iron.

E. Hagen and H. Rubens measured the **emissivity** of steel for long waves, and they also measured the effect of temp. on the emissivity. According to H. F. Weber, heated iron begins to emit greyish light when the temp. has risen to 377° or 378°; and for polished iron, R. Emden gave 405°. G. Malander said that even at ordinary temp., hardened steel emits weak ultra-violet rays. C. C. Bidwell compared the apparent temp. with the true black body temp. of iron surfaces, and found that the relative emissivity of bright, clean iron, radiating freely into air, varied from as low as 28 per cent. of that of a black body at 700°, through 30 per cent. at 1300°, to 48 per cent. at 1700°. M. Möller and co-workers found that the relative emissivity is 43·5 per cent. for polished iron, and 80 per cent. for an oxidized surface at 700° to 1100°. G. K. Burgess and P. D. Foote also obtained a relative emissivity of 80 to 85 per cent. for an oxidized surface of iron at 700° to 1100°. Optical and total radiation pyrometers thus require corrections according as bright or oxidized surfaces of iron are involved. Observations were made by E. R. Binkley, G. R. Greenslade, K. Lubowsky, and A. L. Helfgott. G. Naeser, and R. Hase measured the emissivity of liquid iron; H. T. Wensel and W. F. Röser found in measuring the temp. of molten cast iron that there is a change in the emissivity in the neighbourhood of 1375° from 0·7 to 0·4, and this is attributed to the formation of a film of oxide which renders a correction necessary in reading the temp. with an optical pyrometer.

V. A. Suydam measured the total radiation energy of iron, and found, for $T°$ K., the following values of the energy E, in watts per sq. cm.:

Temp. °K.	696°	805°	915°	1083°	1180°	1233°	1303°
E	0·2230	0·4362	0·7952	2·1810	3·3628	4·7000	7·880

He represented the results by Wien's law, $E=cT^5$, where the constant c ranged from $2{\cdot}99\times10^{-17}$ to $3{\cdot}99\times10^{-17}$. The press. was 0·0002 mm. The wave-length of the maximum energy, E, emitted from smooth, solid iron is shifted in the direction of the shorter wave-length as the absolute temp. rises in accord with Wien's law. Matt, slag-free iron, emits the grey radiation approaching the black body condition as the temp. rises. The heat spectrum of liquid iron closely resembles that of the smooth metal with respect to energy and spectral distribution. R. Hase's results are summarized in Fig. 253. G. R. Greenslade studied the radiation energy between 782° and 1312°. The subject has been discussed by C. B. Thwing, M. Kahanowicz, I. Langmuir, G. Moressée, F. Wamsler, A. R. Meyer, K. Lubowsky, F. Paschen, C. P. Randolph and M. J. Overholser, V. Polak, E. Schmidt, E. Furthmann, C. C. Bidwell, and M. Möller and co-workers. E. Hagen and H. Rubens measured the relation between the emissivity and the electrical conductivity; M. Kahanowicz, the effect of a magnetic field, and of oxidation films on the emissivity; and H. P. Gurney, the relation between the emission and absorption of heat rays for different kinds of iron.

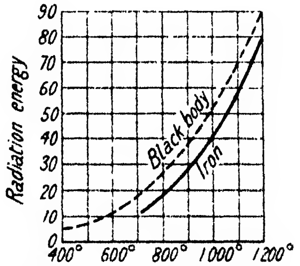

FIG. 253.—The Radiant Energy from Iron.

K. Endell and H. Hanemann[3] studied the polarization of light reflected from iron. The magnetic rotation of the plane of polarized light by iron was discovered by J. Kerr, and it is called the **Kerr effect.** The phenomenon was studied by E. van Aubel, S. G. Barker, H. Behrens, H. E. J. G. du Bois, M. Cau, P. D. Foote, L. Houllevigue and co-workers, L. R. Ingersoll, A. Kundt, J. G. Leathem, W. Lobach, P. Martin, H. Ollivier, B. Pogany, and C. Snow. The gyromagnetic value of iron was studied by S. J. Barnett. The so-called **Faraday effect,** that is, the rotation and elliptical polarization of light by passage through thin films of iron in a magnetic field, was studied by J. Becquerel and W. J. de Haas, H. Behrens, M. Cau, J. Dorfman, C. J. Gorter, W. D. Harris, E. Hirsch, H. R. Hulme, L. R. Ingersoll, H. Poritsky, R. W. Roberts and co-workers, C. A. Skinner and A. Q. Tool, C. Snow, and W. Voigt. Luminescent iron vapour, or a precipitated film of iron on glass produced in a magnetic field, emits polarized rays, and the phenomenon is called the **Thomson effect.** It was studied by E. Thomson,[4] O. J. Lodge, and R. Whytlaw-Gray and J. B. Speakman.

Neither ferrous nor ferric salts show a **flame spectrum** which is sufficiently characteristic for recognition tests. There are lines which are feeble in the oxy-hydrogen flame, but which appear strengthened in the Bunsen flame. G. A. Hemsalech and C. de Watteville,[5] and C. de Watteville found that the flame spectrum extends far into the ultra-violet. J. N. Lockyer observed that in the oxy-coal gas flame there are present a line and fluted band spectrum. G. A. Hemsalech and C. de Watteville observed that in the oxy-acetylene flame, there are present lines which appear in the oxy-hydrogen flame, and the strengthened lines of the Bunsen flame. W. N. Hartley observed a series of lines, and a band between 554 and 593$\mu\mu$ in the oxy-hydrogen flame, and J. N. Lockyer and H. E. Goodson, and J. Meunier observed that the lines in the oxy-hydrogen flame can be arranged in three classes according as they are stronger, weaker, or of the same intensity as the lines of the arc-spectrum. G. A. Hemsalech, and A. de Gramont found that in the mantle of the flame there are lines at 3860, 4119, 4957 A., and in the cone there are the lines 3936, 4119, and 4957 A., whilst there are triplets at 4046 and 4384 A. which are intense in the cone and feeble in the mantle. The subject was studied by A. Gouy, R. Eisenschitz and A. Reis, and A. Hagenbach and H. Konen. H. Auerbach observed numerous lines in the Bunsen flame, and in the oxy-coal gas flame, but not in the coal gas flame with a blast of air; and M. Adam, in the hydrogen flame. J. M. Eder and E. Valenta observed a band at 4400 A. in the flame spectrum of ferric chloride. E. N. da C. Andrade studied the spectra of iron in the flame of chlorine, bromine, and iodine. The flame with chlorine is coloured yellow, due, it is supposed, to the presence of undissociated ferric chloride which is able to maintain its existence in the presence of an excess of chlorine. A. Mitscherlich examined the spectra produced by the vapours of ferric chloride and iodide in the hydrogen flame. E. L. Nichols and H. S. Howes observed the spectrum of iron when a ferruginous bead of sodium pyrophosphate, or borax, is heated in hydrogen; and G. D. Liveing and J. Dewar, T. Hori, and S. Kalandyk and co-workers, when detonating gas is exploded in an iron tube. A. S. King studied the spectrum of iron heated in the electric furnace and found that the result at 2400° agrees with the flame spectrum; but above 2400°, the spectrum resembles that of the low-voltage arc. H. Schüler observed that the vapour electrically excited shows lines resembling that of the arc spectrum. Observations were also made by E. Carter and A. S. King, and by G. A. Hemsalech.

When soln. of the iron salts are sparked by the aid of a condenser, they give a complicated **spark spectrum** containing thousands of lines. A. Masson, D. Alter, and G. Kirchhoff were among the first to study the spark spectrum of iron. E. Formanek regarded the following as the more important lines in the simple spark spectrum of iron: in the orange-yellow, 6462, 6400, 6350, 6095, and 5916; in the yellow, 5762, 5714, 5708, and 5614; in the green, 5601, 5594, 5586, 5571, 5455, 5444, 5429, 5370 (ϵ, Fig. 254), the triple lines 5326, 5266, and 5232 (α, Fig. 254), the pale green lines 5192, 5168, 5139, and 5004 (δ, Fig. 254), and the stronger green lines 4959, and 4923 (β, Fig. 254); the blue lines 4891, and 4874 (ζ, Fig. 254), 4531, 4404, and 4382 (γ, Fig. 254), 4325 and 4307 (η Fig. 254), and, finally, 4271, and 4251. The sets α (5326, 5266, and 5232), β (4959, and 4923), ζ (4891, and 4874), and γ (4404, and 4383) are said to be characteristic in the spectral detection of iron. A. de Gramont gave as characteristic of iron and ferruginous minerals the lines 4960 in the green; 4415 in the blue; and 4404, 4383, 4271, 4260, and 4071 in the indigo.

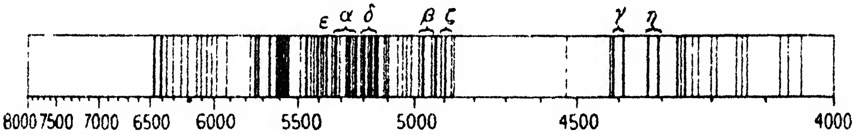

FIG. 254.—The Spark Spectrum of Iron.

Observations on the spark spectrum of iron were also made by W. A. Miller, H. D. Babcock, E. O. Hulbert, E. Carter and A. S. King, L. and E. Bloch, D. Alter, A. Masson, G. Kirchhoff, T. R. Robinson, W. E. Adeney, J. L. Schönn, T. Takamine and S. Nitta, R. A. Millikan and co-workers, T. R. Robinson, W. Finkelnburg, W. Huggins, R. Thalén, L. de Boisbaudran, A. Gouy, R. Capron, E. Carter, E. Carter and A. S. King, F. Müller, G. S. Monk, O. Stuhlman, J. B. van Milaan, G. Ciamician, J. Parry and A. E. Tucker, W. N. Hartley and co-workers, G. D. Liveing and J. Dewar, F. McClean, J. M. Eder, J. M. Eder and E. Valenta, F. Papenfus, J. H. Pollok, A. S. King, J. Wilsing, F. Exner and E. Haschek, H. Konen, A. Hagenbach and H. Konen, J. N. Lockyer, G. E. Hale and N. A. Kent, G. E. Hale, G. A. Hemsalech and C. de Watteville, H. W. Morse, O. Lohse, and H. Finger.

W. B. Anderson discussed the effect of variations in the experimental conditions on the spark spectrum; H. R. von Traubenberg, the effect of the surrounding gaseous atmosphere: (i) oxidizing—oxygen, carbon dioxide, nitrous oxide, or sulphur dioxide; (ii) reducing—hydrogen, methane, acetylene, and carbon monoxide. The spectrum of wires exploded by the disruptive discharge was examined by J. A. Anderson, S. Smith, R. Déchène, A. C. Menzies, A. S. King, T. Hori, and H. Nagaoka and co-workers; and the spectrum of the disruptive discharge, by H. Nagaoka and co-workers. The spark discharge in a capillary tube filled with gas was found by J. Trowbridge to show no iron lines. J. H. Pollok found that the discharge in the vacuum tube with ferric chloride has an iron spectrum corresponding with the spark spectrum. P. E. Robinson, F. Grünbaum, L. Janicki, L. Janicki and R. Seeliger, and K. L. Wolf studied the spectrum of the spark discharge in the vacuum tube. According to G. A. Hemsalech, the velocity with which luminous particles are emitted by the iron electrode is 27·2 metres per sec.; the duration of the luminosity in the spark discharge is between 40×10^{-3} and 282×10^{-3} sec.—it increases with the capacity; it is proportional to the intensity of the lines; and it decreases in a magnetic field. The spark spectrum of the discharge in water was observed by E. von Angerer and G. Joos, L. and E. Bloch, L. de Boisbaudran, G. Ciamician, H. Finger, W. H. Fulweiler and J. Barnes, G. E. Hale, G. E. Hale and N. A. Kent, E. O. Hulbert, H. Konen, H. Konen and H. Finger, J. N. Lockyer, W. F. Meggers and F. M. Walters, A. L. Narayan and K. R. Rao, J. Parry and A. E. Tucker, B. Setna, H. Stücklen, N. K. Sur, and J. Wilsing. T. Tucholsky, and H. Nagaoka and co-workers observed the change in the wave-length and intensity of iron lines by the disruptive discharge. A portion of the **arc spectrum** by A. S. King is shown in Fig. 254.

The arc spectrum was examined by K. Behner, E. G. Bilham, Lord Blythswood and W. A. Scoble, P. H. Broderson, H. Buisson and C. Fabry, K. Burns, K. Burns and F. M. Walters, R. Capron, W. Clarkson, A. Cornu, H. Crew, H. Crew and B. J. Spence, W. G. Duffield, J. M. Eder and E. Valenta, E. J. Evans, F. Exner and E. Haschek, C. Fabry and co-workers, F. Goos, A. Hagenbach and H. Konen, A. Hagenbach and K. Langbein, S. Hamm, J. Hartmann, G. A. Hemsalech and C. de Watteville, H. Hertenstein, A. Hilger, W. J. Humphreys, C. V. Jackson, L. Janicki, C. E. St. John and H. D. Babcock, H. Kayser and C. Runge, A. S. King, W. Kleinewefers, E. A. Kochen, J. Lang, G. D. Liveing and J. Dewar, J. N. Lockyer, P. Maring, W. F. Meggers and C. C. Kiess, P. W. Merrill, J. B. van Milaan, G. S. Monk, C. E. Moore and H. N. Russell, J. E. Petavel and R. S. Hutton, M. Pirani and R. Rompe, R. A. Porter, H. Pressentin, S. P. de Rubies, H. Schumacher, A. Secchi, A. Sellerio, R. Thalén, and H. Viefhaus.

The so-called *normal spectrum* was discussed by W. E. Adeney, S. Albrecht, H. D. Babcock, F. L. Brown, H. Buisson and C. Fabry, K. Burns and co-workers, J. M. Eder, J. M. Eder and E. Valenta, P. Eversheim, C. Fabry and A. Pérot, L. Glaser, F. Goos, J. Hartmann, S. Hoeltzenbein, L. Janicki, C. E. St. John and co-workers, H. Kayser, H. Kayser and co-workers, C. C. Kiess, J. Lang, F. McClean, W. F. Meggers and co-workers, K. W. Meissner, G. S. Monk, F. Müller, H. Nagaoka, F. Papenfus, A. H. Pfund, H. Pickhan, H. A. Rowland, H. Schumacher, H. Viefhaus, P. Wallerath, and H. Werner.

The *intensity* of the spectral lines was studied by P. H. Broderson, R. Frerichs, O. Laporte, J. B. van Milaan, and L. S. Ornstein; the relative intensity of arc and spark lines, by G. Nakamura; and the *selective reflection* of the lines in the arc spectrum, by R. W. Wood. H. Crew and B. J. Spence studied the effect of different phases of an *alternating current arc* on the spectrum; C. Fabry and H. Buisson, the effect of the potential difference between the electrodes; H. Crew, and G. D. Liveing and J. Dewar, the effect of an atmosphere of hydrogen; R. A. Porter, the effect of an atmosphere of hydrogen, oxygen, or ammonia; M. la Rosa, and E. Donek, the effect of an atmosphere of oxygen; H. Nagaoka, the displacement of the lines as a result of press., potential difference, and speeds of ions and electrons - the so-called *pole effect;* P. W. Merrill, the strengthening of the lines at the positive pole; H. Konen, the arc spectrum under water; M. Pierucci, the spraying of iron salts in the carbon arc light; E. G. Bilham, K. Burns, W. G. Cady, W. R. Mott, H. Nagaoka and Y. Sugiura, Siemens-Schuckertwerke, the effect of electrodes containing various other metals, carbon, oxides, etc.; and A. Hagenbach and K. Langbein, and H. Buisson and C. Fabry, the temp. of the arc. The effect of *pressure* was discussed by W. S. Adams, H. D. Babcock, H. Buisson and C. Fabry, M. A. Catalan, W. G. Duffield, G. E. Hale and W. S. Adams, W. J. Humphreys, C. Keller, A. S. King, P. Maring, J. F. Mohler, A. Pérot, J. E. Petavel and R. S. Hutton, and R. Rossi; and the *magnetic field*—**Zeeman effect**—by J. S. Ames and co-workers, H. D. Babcock, A. E. Becker, H. Becquerel and H. Deslandres, H. B. van Bilderbeek van Meurs, A. Dufour, J. M. Graftdyk, G. E. Hale, W. Hartmann, G. A. Hemsalech, N. A. Kent, A. S. King, O. Lüttig, A. A. Michelson, H. Nagaoka, H. Nagaoka and Y. Sugiura, T. Preston, H. M. Reese, Y. Takahashi, J. H. van Vleck and A. Frank, K. Yamada, and P. Zeeman. Using a magnetic field equivalent to 37,000 gauss., H. Nagaoka, and Y. Takahashi observed that of the nine strong violet lines seven were found to give separations proportional to the field, while two gave larger separations in stronger fields. Of the weaker lines some give larger separations than usual, which are not proportional to the field. The effect of an *electric field*—the **Stark effect**—on the spectrum of iron was examined by M. Adam, J. A. Anderson, H. Nagaoka and Y. Sugiura, and T. Takamine; the *self-induction*, by G. A. Hemsalech, B. Eginitis, E. Néculcéa, P. E. Robinson, and G. Berndt; *reversed lines*, by G. D. Liveing and J. Dewar; *anomalous dispersion*, by H. Ebert, L. Puccianti, and H. Geisler; *enhanced lines*, by J. N. Lockyer, J. N. Lockyer and F. E. Baxandall, F. E. Baxandall, W. G. Duffield, P. W. Merrill, G. E. Hale and W. S. Adams, C. Fabry and H. Buisson, and A. Fowler. *Les raies ultimes*, the *ultimate or residual rays*, and the *sensitiveness* of the spectrum of iron were studied by E. Bayle and L. Amy, F. Brasack, A. de Gramont, W. N. Hartley and H. W. Moss, W. Kraemer, J. H. Pollok, J. H. Pollok and A. G. G. Leonard, and D. M. Smith. A. de Gramont said that the last lines to be visible are in the group 2767·6 to 2737·0, and also 3020·8; with ocular observations, 4404 and 4383; and with photographic observations, 4045, 3820, 3737, 3570, 3565, 2755, 2749, 2739, 2395, and 2382. The lines 2395·7, and 2382·2 are visible with a dilution of 1 : 1,000,000; 2755·8, 2749·4, 2739·6, 2599·5, and 2598·5, with a dilution of 1 : 100,000; and 3737·5, and 3735·0, with a dilution of 1 : 10,000. W. N. Hartley and H. W. Moss gave 3886·4, 3860·0, 3824·5, 3749·6, 3745·7, 3735·0, 3733·4, 3722·6, and 3720·0 for the ultimate lines of iron in the oxy-hydrogen flame; 2753·4, 2749·4, 2747·1, 2746·6, 2743·2, 2739·6, 2825·8, 2628·4, 2599·5, and 2598·5 for the ultimate lines of the spark spectrum between iron electrodes. F. Twyman and co-workers, T. Negresco, W. Kraemer, A. Schleicher, and J. R. Green discussed the spectral analyses of metals in quantitative and qualitative analyses.

The **ultra-violet spectrum** was examined by J. L. Schönn, G. D. Liveing and J. Dewar, F. Exner and E. Haschek, J. Thibaud, V. Schumann, R. J. Lang, T. Royds, T. Takamine and S. Nitta, S. Hamm, J. C. McLennan and co-workers, P. Maring, S. P. de Rubies, O. Stuhlman, C. C. Kiess, R. A. Millikan and co-workers, and L. and E. Bloch; and the **ultra-red spectrum,** by H. Becquerel, J. Querbach, H. Lehmann, W. W. Coblentz, K. W. Meissner, W. F. Meggers and C. C. Kiess, W. de W. Abney, E. A. Kochen, E. J. Evans, L. Geiger, H. M. Randall and E. F. Barker, and J. C. McLennan and co-workers. The electrodic **luminescence spectrum** was studied by W. von Bolton; the luminescence spectrum produced by the action of cathode rays on the vapour of iron, by E. Carter and A. S. King; and the spectrum of the luminescence of iron vapour in nitrogen, by P. Lewis. The existence of iron lines in the **solar spectrum** was discussed by J. von Fraunhofer, S. A. Mitchell, H. von Klüber, A. Cornu, J. Wilsing, H. Ebert, J. N. Lockyer and F. E. Baxandall, J. N. Lockyer, A. S. King, C. Fabry and co-workers, R. Woolley,

S. Albrecht, H. A. Rowland, H. Deslandres, A. de Gramont, C. E. Moore and H. N. Russell, and H. W. Vogel; and in **stellar spectra,** by A. de Gramont, G. P. Merrill, P. W. Merrill, W. W. Morgan and co-workers, O. Struve, O. Struve and P. Swings, and G. P. Merrill and C. G. Burwell, S. Albrecht, J. N. Lockyer and F. E. Baxandall, R. Furnhjelm, and H. Ludendorff; and the spectra of meteorites, by W. Crookes—*vide supra,* the occurrence of iron. R. Gans studied the absorption spectrum of a *colloidal* soln. of iron; and J. N. Lockyer, and J. Parry, the possible dissociation of iron at high temp.

The **absorption spectrum** of the *vapour* of iron was discussed by K. L. Wolf, H. Gieseler and W. Grotrian, A. S. King, J. C. McLennan and A. B. McLay, W. F. Meggers, J. N. Lockyer and W. C. Roberts-Austen, G. D. Liveing and J. Dewar, J. A. Anderson, and E. von Angerer and G. Joos. A. S. King's results with the vapour at different temp. are indicated in Fig. 255.

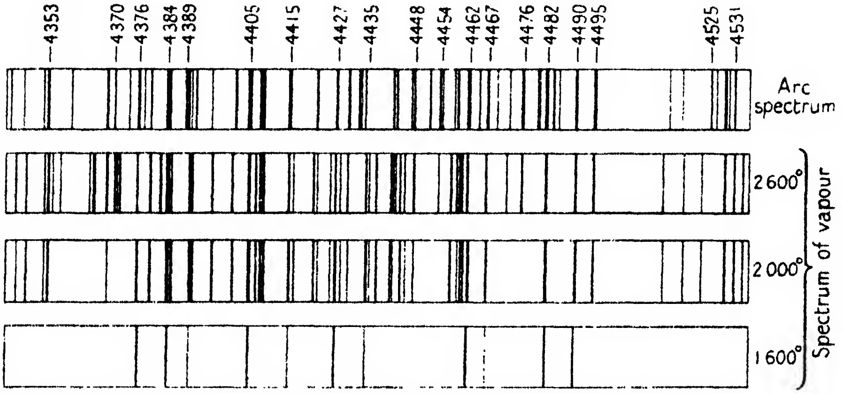

FIG. 255.—The Spectra of Iron Vapour at Different Temperatures.

According to J. Formanek, coloured solutions of iron salts do not furnish absorption spectra suitable for analytical purposes. The ferrous salts absorb more or less red rays, and the ferric salts, blue or violet rays —*vide infra,* the special salts. The absorption spectrum of ferric thiocyanate in amyl alcohol is shown in Fig. 256. Soln. of ferric salts react with alkanna tincture, and with neutral aq. soln. the liquid first becomes bluish-grey, and afterwards dirty green. This liquid has a strip at 4955, and a band in the blue. The addition of a drop of ammonia to the liquor precipitates the iron compound, and the absorption spectrum disappears; but if a trace only of ammonia be added, the liquor becomes grass-green, and a strong absorption appears at 6645, and a feeble one at 6030. Alkanna tincture acts similarly on soln. of ferrous salts, but the colour is bluish-violet. If ammonia be added as before, the colour becomes reddish-brown, and shows bands in the green and blue, and two strips at 5895 and 5475. After the liquid has stood for some time it becomes dirty green, and turbid, and the spectrum disappears. Observations were made by J. Plotnikoff and M. Karschulin, R. Samuel, and H. I. Schlesinger and H. B. van Valkenburgh. M. Luckiesh, and T. Dreisch studied the special transmission of glasses coloured with iron.

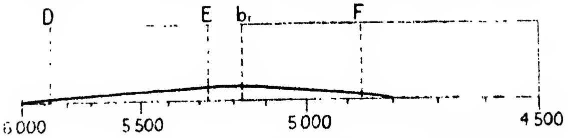

FIG. 256.—The Absorption Spectrum of Solutions of Ferric Thiocyanate.

Regularities in the spectra and **series spectra** of iron were examined by A. Schuster, and W. N. Hartley. A. S. King arranged the lines in different classes, according to their behaviour with respect to temp., one class was well developed at 1600°, another at 2000°, and another at 2300°; and G. E. Hale and W. S. Adams also found that the lines could be arranged in classes according to their behaviour with respect to press. The subject was also discussed by M. A. Catalan, E. Gehrcke, A. de Gramont, A. Hagenbach and H. Schumacher, G. A. Hemsalech, J. N. Lockyer and co-workers, and J. Meunier. H. D. Babcock discussed the changes of energy involved in the passage from one class to another. The multiplets—doublets, triplets, quartets, and sextets—were examined by E. von Angerer and G. Joos, N. Bohr and D. Coster, W. M. Cady, M. A. Catalan and co-workers, W. Clarkson, D. Coster, R. Frerichs, E. Gehrcke, R. C. Gibbs and H. E. White, H. Gieseler and W. Grotrian, S. Goudsmit and co-workers, A. de Gramont, W. Grotrian, S. Hoeltzenbein, F. Hund, C. E. St. John, M. Kahanowicz, P. K. Kichlu, C. C. Kiess and O. Laporte, M. Kimura and G. Nakamura, O. Laporte, E. M. Lindsay, J. C. McLennan and A. B. McLay, W. F. Meggers, W. F. Meggers and O. Laporte, J. B. van Milaan, H. Nagaoka and Y. Sugiura, A. L. Narayan and K. R. Rao, P. G. Nutting, L. S. Ornstein and H. C. Burger, E. Paulson, A. Rubinowicz, R. Rudy, H. N. Russell, M. Sawada, N. K. Sur, F. M. Walters, H. E. White, and A. T. Williams.

There are supposed to be rings or shells of electrons connected respectively with the emission and absorption of the K-, L-, M-, and N-series of the X-rays; while with the heavier atoms like uranium and thorium, there may be six such shells—denominated K, L, M, N, O, and P groups, beginning with the innermost—the K-group has 1 member; the L-group, 3; the M-group, 5; the N-group, 7; the O-group, 5; and the P-group 3. According to N. Bohr's theory,[6] the electrons in any given shell move in orbits more or less elliptical, and spatially arranged so as not to be co-planar. Owing to variations in the eccentricity, the orbits of the electrons in different shells are interpenetrating so that electrons in the exterior shells may approach closely to the nucleus at perihelion of the highly elliptical orbits. Consequently, the force acting on an electron in an elliptical orbit may undergo enormous variations in each revolution, so that the inverse square rule is approached only in the exterior parts of the orbits. In certain cases, the binding force on the electrons in exterior shells may be greater than that acting on the electrons in the interior shells. With the more simple pictures of the Bohr atom, the K-rays are due to electrons whose quantum number, n, decreases to 1, and such an electron drops into the K-ring, orbit, or shell; when the quantum number of the electron has dropped to 2, it gives off L-rays, and the electron is said to have dropped into the L-ring, shell, or orbit. J. Palacios and M. Velasco studied the fine structure of the X-ray absorption spectrum.

J. Laub assumed that hard X-rays furnish a *J-series* of **X-ray spectra,** but M. Siegbahn could not confirm this. The *K-series* of X-ray spectra were found by H. G. J. Moseley, and E. Wagner to furnish $\alpha=1{\cdot}946$, and $\beta=1{\cdot}765$. A. Larsson gave $\alpha_1=1{\cdot}932066$, $\alpha_2=1{\cdot}935987$, $\alpha_{3:4}=1{\cdot}92330$; there are also $\beta'=1{\cdot}75646$, and $\beta'''=1{\cdot}7371$, as well as $\beta_1=1{\cdot}753013$, $\beta_2=1{\cdot}74076$. Measurements were made by U. Andrewes and co-workers, M. Balderston, J. A. Bearden, H. Beuthe, S. Björek, D. M. Bose, W. Bothe and co-workers, M. de Broglie, C. T. Chu, D. Coster and co-workers, A. Dauvillier, A. C. Davies and F. Horton, B. Davis and H. Purks, G. B. Deodhar, V. Dolejsek, V. Dolejsek and co-workers, M. J. Druyvesteyn, W. Duane and co-workers, S. Eriksson, J. D. Hanawalt, E. Hjalmar, S. Idei, A. Karlsson, S. Kawata, G. Kettmann, B. Kievit and G. A. Lindsay, E. H. Kurth, K. Lang, A. Larsson, A. E. Lindh, G. A. Lindsay and H. R. Voorhees, H. Mark and L. Szilard, L. H. Martin, H. T. Meyer, F. L. Mohler and P. D. Foote, B. C. Mukherjee and B. B. Ray, G. Ortner, T. H. Osgood, S. Pastorello, R. L. Petry, M. Privault, B. B. Ray, O. W. Richardson and F. C. Chalklin, M. Sawada, N. Seljakoff and co-workers, M. Siegbahn, M. Siegbahn and co-workers, M. Siegbahn and B. B. Ray, M. Siegbahn and W. Stenström, M. Siegbahn and M. Zacek, N. Stensson, E. C. Stoner, R. Thoraeus, J. Valasek, A. P. R. Wadlund, B. Walter, F. Wever, F. J. von Wisniewsky, Y. H. Woo, and S. Yoshida. The limit of absorption of the K-series was placed by V. Dolejsek at 1·7395; by W. Duane and co-workers at 1·7396; and by E. Wagner at 1·7377. The absorption of the

K-series was also studied by W. Duane, W. Duane and H. Fricke, J. L. Glasson, and R. Thoraeus. A. E. Lindh found for the absorption limit with elemental iron, 1·7405; for Fe_2O_3, 1·7373; for $Fe(OH)_3$, 1·7371; for $FeCl_3$, 1·7372; for $(NH_4)_2Fe(SO_4)_2$, 1·7371; for FeS, 1·7389; for $FeSO_4$, 1·7383; for $Fe_2(SO_4)_3$, 1·7371; and for $FeSO_4$, 1·7371. The relation between the electronic structure and the K-series was discussed by G. A. Lindsay and H. R. Voorhees, and B. B. Ray; and the electronic energy, by R. Whiddington, and G. W. C. Kaye. The *L-series* includes the lines α=17·66, $\alpha_{1,2}$=17·58, β=17·33, β_1=1722, $\beta_{4,3}$=15·61, ϵ=20·12, and η=19·63. The *L-series* was studied by S. Björek, N. Bohr and D. Coster, A. Dauvillier, M. J. Druyvesteyn, H. Hirata, C. E. Howe, F. L. Hunt, A. Karlsson, G. Kellström, E. H. Kurth, B. C. Mukherjee and B. B. Ray, F. P. Mulder, O. W. Richardson and F. C. Chalklin, G. K. Rollefson, M. Siegbahn and co-workers, A. Sommerfeld, E. C. Stoner, J. Thibaud and A. Soltan, C. H. Thomas, R. Thoraeus, B. Walter, and R. B. Witmer and J. M. Cook. The *M-series* was studied by U. Andrewes and co-workers, F. L. Mohler and P. D. Foote, B. C. Mukherjee and B. B. Ray, J. A. Prins and A. J. Takens, R. L. Petry, B. B. Ray and R. C. Mazumdar, O. W. Richardson and F. C. Chalklin, G. K. Rollefson, O. Stuhlman, and C. H. Thomas. The *N-series* was studied by E. H. Kurth. H. Stintzing, and O. Eisenhut and E. Kaupp attempted the analysis of iron by X-ray spectra.

The **absorption coefficients**, μ, for the K-series of X-rays was found by C. G. Barkla and V. Collier to be 0·0202 for air; 0·204 for H_2S; 0·24 for SO_2; 0·112 for ethyl chloride; and 0·384 for ethyl bromide; and E. A. Owen gave μ=0·0254 for air; 0·0456 for CO_2; and 0·2673 for SO_2. C. W. Hewlett gave for the relative mass absorption coeff. for wave-lengths λ A.:

λ . .	0·130	0·210	0·324	0·471	0·666	0·861	1·006
μ/D .	0·437	1 16	3·76	11·22	31·05	60·60	91·70

and C. G. Barkla and C. A. Sadler, and C. A. Sadler and A. J. Steven gave for the absorption of the K-series of radiations from

	Cu	Ag	Zn	Tl	As	Se	Cr	Fe	Co	Ni
μ/D .	268	17·4	221	173	134	116·3	103·8	66·1	67·2	314

J. A. Becker found that the absorption coeff. of iron for X-rays of short wave-length were very little affected by a magnetic field of 18,000 gauss. Observations were made by S. J. M. Allen, T. E. Aurén, C. G. Barkla and co-workers, H. R. Voorhees and G. A. Lindsay, R. A. Houstoun, L. H. Martin and K. C. Lang, L. M. Alexander, J. A. Prins, N. Ahmad, L. Bastings, J. A. Bearden, W. H. Bragg and co-workers, F. Dessauer and B. Winawer, W. Duane and H. Fricke, C. W. Hewlett, J. A. Becker, H. Hädicke, H. S. Read, J. Palacios and M. Velasco, A. H. Compton, M. Ishino and S. Kawata, G. W. C. Kaye, J. Laub, L. H. Martin, F. K. Richtmyer and co-workers, M. Siegbahn, O. Stelling, and K. A. Wingardh. W. Kossel discussed the relation between the absorption coeff. of Cu, Zn, Fe, and Ni; J. Veldkamp, the effect of lattice structure on the X-radiograms; J. A. Becker, the effect of magnetization on the absorption of X-rays; and B. Rossi, the absorption and diffusion of penetrating corpuscular radiation in iron.

C. H. Thomas, U. Nakaya, F. C. Chalklin, H. Kulenkampff, G. Shearer, and C. T. Chu studied the emission of soft X-rays; O. W. Richardson and F. S. Robertson, L. P. Davies, and U. Nakaya, the effect of oxidation on the emission of soft X-rays; R. Whiddington, the velocity of the X-rays; L. H. Martin, the efficiency of the emission of the K-series of Z-rays; and H. S. Read, the effect of temp. on the absorption of X-rays; W. Arkadieff, the magnetic absorption spectrum. The absorption of polarized X-rays in a magnetic field was examined by J. A. Becker, J. C. Chapman, A. H. Forman. P. H. Brodersen studied the intensity of X-rays; R. W. G. Wyckoff, E. N. Coade, S. J. M. Allen, A. A. Claassen, A. J. Bradley and R. A. H. Hope, R. W. James and G. W. Brindley, C. W. Hewlett, E. N. Coade, and

R. J. Havighurst, and E. A. Owen, the scattering of X-rays; A. H. Armstrong, the diffraction of X-rays; R. Glocker and K. Schäfer, the dispersion of X-rays; P. Günther and G. Wilcke, the analysis of mixtures of iron and cobalt by X-radiograms; E. Rupp, the diffraction of electrons; S. Pastorello, iron as a deflection lattice for X-rays; R. L. Doan, W. Ehrenberg and F. Jentzsch, J. E. Henderson and E. R. Laird, and R. W. G. Wyckoff, the reflections of X-rays; and H. Haas detected no polarization of the K-rays with a voltage of 7·4 to 12·6 kilovolts. C. E. Eddy and T. H. Laby, and O. Eisenhut and E. Kaupp studied the analysis of iron by means of the Lenard rays; and G. R. Fonda and G. B. Collins, by means of the X-ray spectrum. W. A. Wood observed that manganese deposited on aluminium will remove the β-rays by selective absorption from the characteristic radiation of iron. The production of the K-series of X-rays by α-rays was studied by W. Bothe and co-workers. The secondary X-rays of iron were studied by C. G. Barkla, C. D. Cooksey, W. Kaufmann, and C. A. Sadler. The production of X-ray fluorescence was studied by M. Balderston, W. Bothe and co-workers, M. I. Harms, W. Kossel, L. H. Martin, and V. Posejpal. C. G. Barkla and A. J. Philpot, and E. A. Owen, measured the ionization coeff. of the $K\alpha$-rays in their passage through hydrogen, oxygen, carbon monoxide, carbon dioxide, hydrogen sulphide, sulphur dioxide, hydrogen selenide, and ethyl bromide and iodide. M. von Laue and G. Siljeholm found that near the A_3-arrest, the changes in the thermal electron emission are related with those occurring in the thermal energy; and E. Rupp and E. Schmid found maxima for V 20, 110, 175, and 230 in the voltage-intensity of the electronic reflexion curve. W. Arkadieff studied the magnetic and electric spectra of electromagnetic waves. G. Fournier, and E. Rupp studied the **absorption of electrons**; J. Thibaud and F. D. la Tour, and P. Auger, the **absorption of neutron rays**; W. Espe, S. R. Rao, H. Hase, and H. E. Farnsworth, the distribution of energy and the **emission of electrons** from iron; H. E. Farnsworth, and G. A. Carse and D. Jark, the emission of electrons from magnetized and unmagnetized iron when no appreciable difference could be detected; E. Rupp, and E. Rupp and E. Schmid, the **diffraction of electrons**; and W. Boas and E. Rupp, the diffraction of electrons by purified and passive iron. W. Ehrenberg and F. Jentzsch, the **reflection of electrons**; C. H. Kunsman, M. N. Davis, H. B. Wahlin, F. Simon, A. Goetz, L. R. L. Barnes, G. Siljeholm, F. M. Penning, and M. von Laue, the **emission of positive ions** from heated iron; A. K. Brewer, the effect of ammonia; and, according to A. Goetz, there is no displacement, but there is a change in the direction of the curve of electronic emission at different temp. on passing through the transition points of iron; F. E. Myers and R. T. Cox tried to detect the polarization of electrons passing through magnetized iron-foil, and G. A. Carse and D. Jark observed no difference in the emission of electrons from magnetized and unmagnetized iron excited by the X-rays. A. Nodon observed the permeability of iron to the penetrating ultra-radiations of the sun. R. Robl observed no luminescence in ultra-violet light. B. Rossi measured the absorption of corpuscular radiations. H. R. von Traubenberg found the range of the α-particles in iron to be $18{\cdot}7\times10^{-4}$ cm. G. P. Thomson discussed the diffraction of the **cathode rays.** R. Holoubek studied the tracks of the H-particles from iron bombarded by α-**rays**; A. Wegerich studied the effect of bombarding iron with α-particles—*vide infra*, the atomic disintegration of iron. H. Robinson and W. F. Rawlinson investigated the emission of β-**rays** from iron; K. W. F. Kohlrausch, E. Stahel and H. Ketelaar, H. Herszfinkiel, L. H. Gray and G. T. P. Tarrant, and A. H. Compton, the absorption of the γ-**rays** of radium; and E. J. Workman, and H. Herszfinkiel, secondary ionization by hard γ-rays. According to R. F. Mehl and C. S. Barrett, the penetration limit of the γ-rays through steel is about twice as great as that of the X-rays. H. Schindler studied the effects of ultra-penetrating radiation. N. Piltschikoff observed that iron emits the so-called Moser rays which are capable of passing through thin layers of paper, celluloid, gelatin, or aluminium; and which can decompose silver bromide.

J. Lifschitz studied the Becquerel effect. W. G. Guy, and I. I. Borgman observed no evidence of the **radioactivity of iron.** N. R. Campbell calculated from the ionization of air by iron that the radioactivity, if present, is but $1\cdot7\times10^{-12}$ times as strong as is that of radium. Y. H. Woo studied the Compton effect.

The **critical potentials** found by U. Andrewes and co-workers were 73 and 166 volts; H. N. Russell gave 7·83 and 16·5 volts respectively for the series and ionization potentials of iron. A. V. Douglas gave 6·6 volts for the ionization potential of iron deduced from astronomical data; and G. B. Kistiakowsky, 11 to 13 volts. O. Laporte gave 5·9 volts for the ionization potential, and 3·20 volts for the first excitation potential. R. Hamer and S. Singh found critical potentials with 3·7, 7·15, 11·2, 16·3, 19·4, 24·5, 29·0, 33·9, 38·8, 42·1, 45·7, 48·4, 51·4, 54·8, 61·6, 72·7, 89·6, 103·1, 111·6, and 125·8 volts. G. K. Rollefson found that in the range 40 to 175 volts, the critical radiation potentials of the M-series are 3·46, 6·03, 7·05, 8·21, 9·63, 10·40, 10·88, 11·33, and 11·83 volts; and the values for the L-series in the range 60 to 70 volts are 45·5, 47·0, and 51·5 volts. In the range from 600 to 700 volts, O. W. Richardson and F. C. Chalklin found critical voltages at 608·1, 640·0, and 689·7 volts; C. H. Thomas, 639 and 704·3 volts; and G. K. Rollefson, 618, 637, and 697 volts. R. L. Petry observed critical potentials for the secondary electron emission of iron at 6·7, 9·0, 13·5, 26, 34, 39, 42·8, 48·3, 54·6, 66·7, 80·5, 92·7, 740, 810, and 1010 volts. There is a long range of voltages below 200 volts observed by O. W. Richardson and F. C. Chalklin, G. K. Rollefson, A. V. Douglas, M. de Broglie, S. C. Roy, D. R. Hartree, C. H. Thomas, S. C. Biswas, R. N. Ghosh, E. H. Kurth, U. Andrewes and co-workers, and C. T. Chu; the critical voltages follow the series $V=180-2420n^2$, where $n=4, 5, 6, 7, 8, 9, 10, 11, 12$. Observations on the series and critical potentials were also made by S. C. Biswas, A. C. Davies and co-workers, E. H. Hall, U. Andrewes and co-workers, F. Hund, O. Laporte, R. L. Petry, B. B. Ray and R. C. Mazumdar, O. Stuhlman, C. H. Thomas, and F. M. Walters. W. Grotrian represented graphically the energy stages, volts, for atoms of iron for different groups of spectral lines by Fig. 257. W. Herz gave $8\cdot25\times10^{-12}$, and J. E. P. Wagstaff, $0\cdot67\times10^{-12}$ for the **vibration frequency** of iron—*vide* 1. 13, 19. J. B. Austin gave between $7\cdot0\times10^{-12}$ and $9\cdot7\times10^{-12}$.

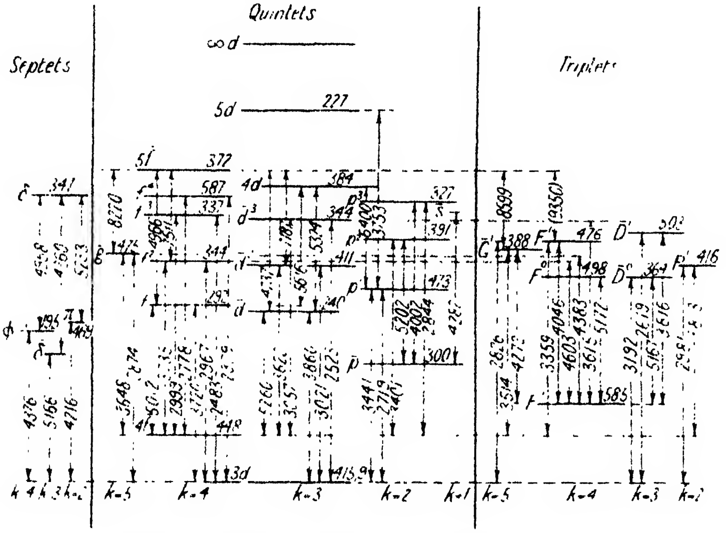

FIG. 257.—Energy Stages in the Spectra of Iron.

The **photoelectric effect** with iron was studied by G. B. Bandopadhyaya, A. K. Brewer, A. B. Cardwell, L. P. Davies, G. N. Glasoe, G. L. Locher, R. Hamer, G. B. Kistiakowsky, T. H. Osgood, T. Pavolini, G. Reboul, O. W. Richardson and

F. S. Robertson, and J. J. Weigle. According to G. B. Welch, the photoelectric effect is in the threshold of 3155 A.; R. Hamer gave 3425 A. A. K. Brewer, and U. Nakaya discussed the influence of adsorbed gas on the photoelectric effect. A. B. Cardwell observed the effect of removing the occluded gas on the photoelectric effect, and found that a thoroughly outgassed specimen showed no fatigue for 12 hrs. after treatment. When this state was reached, the strength of the photoelectric current depended on the rate of cooling of the iron filament. The photoelectric sensitiveness thus increases if the specimen be annealed in vacuo. There was a decrease in the photoelectric sensitivity if a filament heated above 910° was suddenly cooled, this being due to the retention of part of the γ-iron. The variation of the photoelectric current with temp. of the filament was investigated for iron which had been outgassed by heat-treatment for 150 hrs. The variation is complex. Between about 475° and 768° there is a decrease in photoelectric current due to a pure temp. effect. At 768° (where there is a transition of α- to β-iron) the sensitivity remains constant or increases slightly. Near 910° (transition of β- to γ-iron) there is an abrupt decrease in the sensitivity. The thermionic current was also measured and plotted against heating current. There is an abrupt change in the curve at 910°. The long wave-length limit for thoroughly outgassed iron lies between 2580 and 2652 A. The work function, obtained by substituting these values in Einstein's photoelectric equation, is $4{\cdot}72 \pm 0{\cdot}07$ volts. S. Chandrasekhar studied the photoelectric absorption by iron. The subject was studied by W. Frese; the effect of magnetization, by G. Polvani; and the effect of polishing with iron the metals copper, silver, gold, and platinum, by R. F. Hanstock; the effect of gases, by R. Dümpelmann; and the effect of magnetization, by J. H. J. Poole. F. Ehrenhaft found that iron particles show positive and negative **photophoresis** in that they move both with and against the direction of an incident beam of light.

§ 21. Electrical Properties of Iron and Iron-Carbon Alloys.

P. E. Shaw and C. S. Jex,[1] A. Coehn and A. Lotz, A. Lafay, J. B. Seth and co-workers, H. F. Richards, and P. A. Mainstone studied the **triboelectricity** or friction electricity produced when iron is rubbed against glass, etc. R. F. Hanstock studied the effect of cold-work on the triboelectric effect.

Many observations on the **electrical conductivity** of iron and steel have been reported. Thus, A. Matthiessen and C. Vogt gave for the electrical conductivity, K, of electrolytic iron ignited in hydrogen, $K=16{\cdot}810-0{\cdot}519\theta+0{\cdot}00134\theta^2$; and ignited in air, $K=16{\cdot}810-0{\cdot}509\theta+0{\cdot}00127\theta^2$ when the value for K_0 for silver is 100; they also found for pianoforte wire, $K=13{\cdot}293-0{\cdot}425\theta+0{\cdot}00092\theta^2$; and for commercial iron, $K=18{\cdot}774-0{\cdot}428\theta+0{\cdot}000090\theta^2$. C. W. Siemens gave for iron, 8·3401 at 0° when the conductivity of mercury is unity; R. Benoit, 7·861; A. Berget, 7·88; L. Lorenz, 9·685 at 0°, and 6·189 at 100°; W. Kohlrausch, 8·405 at room temp. for electrolytic iron, 0·8913 at a red-heat, 0·8196 at a yellow-heat, and 0·7949 when the iron is non-magnetic. Observations were also made by A. Arndtsen, C. Barus, E. Becquerel, T. Berglund and A. Johansson, L. Cailletet and E. Bouty, J. A. Capp, O. Chwolson, A. Emo, J. A. Fleming, P. Fournel, C. A. Hering, W. H. Johnson, G. C. Knott, A. Macfarlane, A. Matthiessen and C. Vogt, A. R. Meyer, J. R. A. Mousson, J. Müller, A. Oberbeck and J. Bergmann, J. H. Partridge, M. Pirani, W. H. Preece, P. T. Riess, C. M. Smith and co-workers, H. Tomlinson, C. Villiers, A. von Waltenhofen, H. Wedding, etc. J. Dewar and J. A. Fleming, and E. Dickson gave for the electrical conductivity in mhos of purified, and annealed iron:

	−205·3°	−78°	0°	98·5°	196·1°
Mhos × 10^{-4} .	153·40	18·80	11·30	5·62	4·65

W. Meissner and B. Voigt also made observations between −271·8° and 0°; and found for the ratio, r, of the resistance, R, at the given temp. to the resistance, R_0, at 0°, for a sample, I, of electrolytic iron, and a sample, II, of iron with 0·001 per cent. Mn, 0·004 per cent. of copper, 0·0049 per cent. of nickel, etc., and tempered, when the resistance of I was $R_0=0{\cdot}0067$ ohm at 0°, and that of II, $R_0=0{\cdot}160$, and the calculated values of the ratios for the pure metals, r_{red}:

		0·16°	−185·58°	−194·15°	−252·60°	−268·79°	−271·62°
I	r . . .	1	0·1169	0·09194	0·02282	0·02160	0·02156
	r_{red} . .	1	0·09745	0·07194	0·00130	0·00005	0·00001
II	r . . .	1	—	0·0756	0·00892	0·00818	—
	r_{red} . .	1	—	0·06797	0·00075	0·00000	—

L. Guillet found the electrical resistance of annealed electrolytic iron to be 10·22 microhms per cm. cube at 20°, and since the only measurable impurities were 0·025 per cent. of phosphorus, and 0·011 per cent. of arsenic, A. L. Norbury estimated that by allowing for an increased resistivity of 0·32 microhm from these sources, the corrected value is 9·90 microhms per cm. cube at 20°. F. C. Thompson and co-workers gave 7·3 microhms for the sp. resistance of pure iron. T. D. Yensen gave 9·96 microhms per cm. cube for the resistance at 20° of annealed, doubly refined electrolytic iron, melted in vacuo. The only impurities were carbon, 0·006 per cent., and silicon, 0·01 per cent. Allowing for these, A. L. Norbury estimated the resistance to be 9·81 microhms, and F. Ribbeck, 9·62 microhms, per cm. cube at 20°. E. Gumlich and P. Goerens gave 9·94 microhms for the electrical resistance of purified iron at 20°. F. Stäblein gave 10 microhms for the sp. resistance of pure iron; 14·7 microhms for that of the eutectoid with 0·9 per cent. of carbon, and 70 microhms for cementite. G. Niccolai, and L. Holborn obtained 10 microhms per cm. cube for the resistance of iron near 0°; H. Masumoto, 10·44 microhms; and G. K. Burgess and I. N. Kellberg, 9·713 microhms per cm. cube. These investigators also obtained for the resistance of iron in ohms × 10^{-5} per cm. cube:

	−253°	−192°	−78°	0°	100°	200°	300°	400°
R . .	—	0·237	0·691	1·000	1·557	2·240	3·069	4·058
H . .	0·0113	0·0878	0·5794	1·000	1·6476	(2·4726)	3·4738	(4·6536)
B and *K* .	—	·	...	0·9713	1·5880	—	3·40	4·61

	500°	600°	700°	750°	800°	900°	900°	950°
B and *K* .	6·05	7·61	9·51	10·67	11·60	12·16	12·24	12·41

Measurements were made by P. Saldau; E. Grüneisen and E. Goens, and W. Rohn. J. C. McLennan and co-workers gave 8·85 for the sp. resistance of iron at 0°, and 0·101 for the value at 252·4°, whilst W. Meissner gave:

	0·20°	−185·57°	−194·14°	−252·60°	−268·79°	−271·66°
R	1	0·1169	0·09194	0·02282	0·02160	0·02156

or, by extrapolation, 0·02155 at −273°. W. Tuijn and H. K. Onnes found that iron did not show superconductivity at low temp.; and V. A. Suydam gave for the resistance, *R*, at *T*° K., taking the value at 0° or 273° as unity:

	273°	411°	588°	694°	851°	983°	1177°	1290°	1363°
R .	1·000	1·777	2·945	3·871	5·491	7·322	9·361	9·937	10·632

The observations of K. Honda and Y. Ogura, summarized by the light curve, Fig. 258, show a marked change in direction at 798°, or the A_2-arrest. G. K. Burgess and I. N. Kellberg observed no such change, but rather obtained a continuous curve in which the greatest change in the resistance, per degree rise of temp., occurred in the vicinity of the A_2-arrest. W. Broniewsky also observed perceptible singularities in the resistance curve at about 750°, 850°, and 950°, but W. Heraeus showed that the method of measurement was unsatisfactory, and the results improbable. The resistance of non-magnetic *α*- or *β*-iron is a continuous function of that of the ferromagnetic variety without exhibiting any sharp change. G. K. Burgess and I. N. Kellberg took observations at intervals of 2° or 3°, and found that the curves on a rising and on a falling temp. did not quite coincide, especially near the A_3-point. The observations of L. Holborn at low temp. fall on the curve, and indicate that the resistance approaches zero at about −253°. The resistance data of A. R. Meyer fall on or near the curve of G. K. Burgess and I. N. Kellberg. W. Conrad found that the electrical conductivity of molten steel is two hundred times worse than that of the same steel at ordinary temp. W. Jaeger and H. Diesselhorst obtained for iron with 0·1 per cent. carbon, $8·36 \times 10^4$ mhos at 18°, and $5·95 \times 10^4$ mhos at 100°; and for iron with 0·1 per cent. carbon, 0·2, Si, and 0·1, Mn, $7·17 \times 10^4$ mhos at 18°, and $5·31 \times 10^4$ mhos at 100°. V. Strouhal and C. Barus gave at 0°, $8·30 \times 10^4$ mhos for iron; $1·02 \times 10^4$ mhos for hard cast iron; $1·34 \times 10^4$ mhos for soft cast iron; forgeable cast iron in its original state—$4·10 \times 10^4$ mhos, hard, and $3·06 \times 10^4$ mhos, soft—$4·35 \times 10^4$ mhos for piano wire; $8·47 \times 10^4$ mhos for glass-hard steel; $3·46 \times 10^4$ mhos for that steel tempered at a yellow-heat; and $4·88 \times 10^4$ mhos when tempered at a blue-heat. H. Pécheux gave for very soft steel, with a little silicon, $8·50 \times 10^4$ mhos, and with more silicon, $7·40 \times 10^4$ mhos, while for semi-hard steel he gave $8·39 \times 10^4$ mhos, and for hard steel with a little silicon, $6·48 \times 10^4$ mhos; G. Kirchhoff and G. Hansemann, $7·11 \times 10^4$ mhos for puddled steel, and $4·31 \times 10^4$ mhos for Bessemer steel. W. Jaeger and H. Diesselhorst gave for steel with 1 per cent. of carbon, $5·02 \times 10^4$ mhos at 18°, and $3·91 \times 10^4$ mhos at 100°; J. Hopkinson, for magnetic steel with 25 per cent. of nickel, $1·92 \times 10^4$ mhos at 20°, and when non-magnetic, $1·39 \times 10^4$ mhos; and H. le Chatelier, for steel at 15° with 13 per cent. of manganese, $0·78 \times 10^4$ mhos when magnetic, and $0·61 \times 10^4$ mhos when non-magnetic. M. Mathieu studied the resistance of iron to an alternating current of 50 cycles.

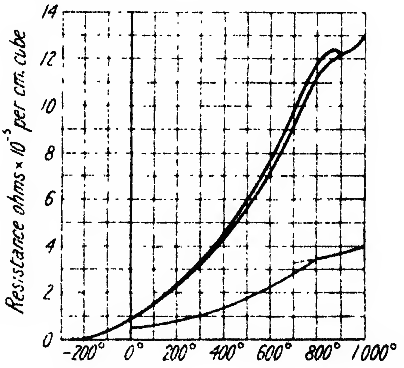

Fig. 258.—The Electrical Resistance of Iron.

The use of iron in place of copper conductors for electrical cables was discussed by W. T. Ryan, L. P. Perry, M. D. Leslie, H. B. Dwight, C. H. Risdale, W. Peukert, H. Pinsl, T. A. Worcester, W. Esch, and A. E. Kennelly. According to L. W. W. Morrow, the resistance rapidly increases with the current owing to the skin effect. The comparative resistances, R, in ohms per mile of single wire were :

Current	5	15	25 amperes
R Copper	1·172	1·172	1·172
R Iron (steel)	8·12	9·96	13·40
	9·35	9·96	11·10

The temp. coeff., a, of the resistance, was found by L. Cailletet and E. Bouty to correspond with $R=R_0(1+0\cdot004900\theta)$ between $-100°$ and $0°$. J. Dewar and J. A. Fleming gave for the resistance of soft, annealed iron, $R=R_0(1-0\cdot005310\theta)$ between $-100°$ and $0°$, and $R=R_0(1+0\cdot006250\theta)$ between $0°$ and $100°$, whilst for iron with 0·25 per cent. of manganese, and 0·01 per cent. of silicon, $R=R_0(1-0\cdot005440\theta)$ between $0°$ and $100°$. W. Jaeger and H. Diesselhorst gave $R=0\cdot0_410512(1-0\cdot005440\theta)$ for annealed iron with 0·25 per cent. manganese, and 0·01 per cent. of sulphur, between $-197°$ and $0°$, and for the hot-drawn metal, $R=0\cdot0_59065(1-0\cdot006250\theta)$. In the latter case :

	−39·2°	−81·9°	−197·1°	−217°	−222·2°
R	$0\cdot0_57168$	$0\cdot0_55318$	$0\cdot0_51220$	$0\cdot0_6725$	$0\cdot0_6660$

For iron with 0·1 per cent. of carbon, $R=R_0(1-0\cdot004610\theta)$, and for iron with 1·0 per cent. of carbon, $R=R_0(1-0\cdot0051310\theta)$. G. Niccolai gave $R=R_0(1-0\cdot0055700\theta)$ for the temp. coeff. between $0°$ and $100°$; P. W. Bridgman, $R=R_0(1-0\cdot0062060\theta)$ for iron with 0·03 per cent. of impurity, and at temp. between $0°$ and $100°$; L. Holborn, and A. R. Meyer gave $R=R_0(1-0\cdot006570\theta)$; G. K. Burgess and I. N. Kellberg, $R=R_0(1-0\cdot006350\theta)$; and E. P. Harrison gave for the resistance of iron up to $500°$, $R=0\cdot3318+0\cdot0012300\theta+0\cdot0_52209\theta^2$. A. Arndtsen gave $R=R_0(1-0\cdot0041300\theta+0\cdot0_411788\theta^2)$ between $5°$ and $156°$; H. F. Lenz, $R=R_0(1-0\cdot0017200\theta+0\cdot0_584670\theta^2)$ between $0°$ and $200°$; H. Tomlinson, $R=R_0(1-0\cdot0051310\theta+0\cdot0_581520\theta^2)$ for iron between $18°$ and $100°$; J. Hopkinson, $R=R_0(1-0\cdot00480\theta)$ at ordinary temp., $R=R_0(1-0\cdot00180\theta)$ at $855°$, and $R=R_0(1-0\cdot00670\theta)$ above $855°$; and R. Benoit, $R=R_0(1-0\cdot004516\theta+0\cdot0_51457\theta^2)$ between $100°$ and $860°$. A. A. Somerville gave for the purified metal, $R=R_0(1-a\theta)$:

	25°	100°	200°	400°	600°	750°	800°	1000°
$a\times10^4$	52	68	90	133	170	250	120	05

H. Pécheux found for very soft steel with a little silicon, $R=R_0(1-0\cdot00650\theta+0\cdot0_543\theta^2)$, steel with a little more silicon, $R=R_0(1-0\cdot00870\theta+0\cdot0_574\theta^2)$, for semi-hard steel, $R=R_0(1-0\cdot00490\theta+0\cdot0_589\theta^2)$, and for hard steel with silicon, $R=R_0(1-0\cdot00400\theta+0\cdot0_554\theta^2)$. V. Strouhal and C. Barus found for steel between $10°$ and $35°$, $R=R_0(1-0\cdot001610\theta)$ when glass-hard, $R=R_0(1-0\cdot002440\theta)$ when tempered at a pale yellow-heat, $R=R_0(1-0\cdot003300\theta)$ when tempered at a blue-heat, $R=R_0(1-0\cdot004230\theta)$ for soft steel, and $R=R_0(1-0\cdot00420\theta)$ for piano wire ; R. Benoit gave $R=0\cdot1149(1-0\cdot0049780\theta+0\cdot0_57430\theta^2)$ for soft steel between $100°$ and $860°$, and for soft iron, $R=0\cdot1272(1+0\cdot004520\theta+0\cdot0_5580\theta^2)$. J. A. Fleming gave $R=R_0(1-0\cdot001320\theta)$ for 24 per cent. nickel steel at $20°$, and $R=R_0(1-0\cdot0040\theta)$ at $600°$, whilst for manganese steel, he gave $R=R_0(1-0\cdot00120\theta)$.

T. Kase studied the change of electrical resistance of cast iron in the vicinity of the eutectic temp., and the results for white pig-iron with 3·52 per cent. of carbon, cooled from 1380°, are summarized in Fig. 259 ; analogous results were obtained with grey pig-iron. He found that the electrical resistance of the molten cast iron gradually decreases from 1380° down to the liquidus temp., 1210°, *AB*, and the slope of the curve then changes down to the eutectic temp., 1130°, *BC*, when the eutectic begins to separate ; the electrical resistance decreases abruptly at this temp., CD_2, and then decreases slowly, *DE*, Fig. 259. The ordinates at *D* and *C* are respectively 2·23 and 2·76, showing that at the eutectic temp., the resistance decreases by 19 per cent. of that of the melt. There is no evidence of a two-step transformation, one for cementite and one for graphite. H. Shimank estimated the resistance of unannealed iron to be 2·614 ohms at 0° K., and for the ratio $R_r : R_0$ at 273·09°, 198·3°, and 20·4° K., the respective values 1·0000, 0·6148, 0·1088, and 0·0330. Similarly, for annealed iron, $R_0 = 3·342$ ohms, and the ratio $R_r : R_0$ at 273·09°, 197·8°, 80·6°, and 20·4° K. becomes respectively 1·0000, 0·6130, 0·1033, and 0·0280. J. T. MacGregor-Morris and R. P. Hunt, A. R. Meyer, and J. W. Donaldson studied the conductivity of iron.

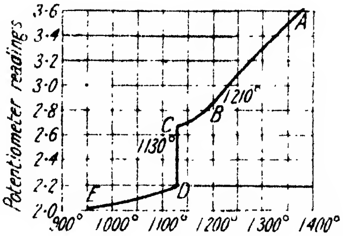

FIG. 259.—The Change of the Electrical Resistance of Cast Iron near the Eutectic Temperature.

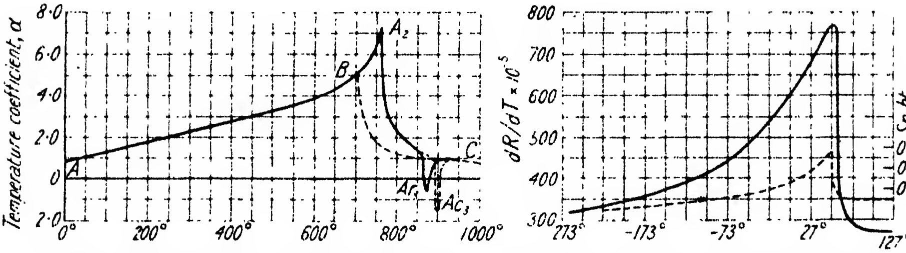
G. K. Burgess and I. N. Kellberg measured the variations in the electrical resistance of electrolytic iron with variations of temp., *i.e.* the temp. coeff. of the resistance, $a = (R_{100} - R_0)/100R_0$, between 0° and 950°, and found that the value of a increases at a gradually increasing rate until the neighbourhood of the first critical region (A_2) is reached—Fig. 260. This region is characterized by a point of inflexion on the curve at 757°. As the temp. is further increased, there is an abrupt fall in the value of a at about 894°, and the reverse change occurs at approximately the same temp. when the temp. is allowed to fall. This second critical region (A_3) extends over an interval of 25°. Whilst the change A_2 is reversible and does not appear to be associated with any alteration in crystalline structure, the change A_3 seems to be progressive and (thermoelectrically) non-reversible, and furthermore it is associated with a change in crystalline form. A. R. Meyer's results are represented by the dotted line, *ABC*, Fig. 260, where the transition temp. is 710°. K. Tamaru gave $32·7 \times 10^{-6}$ ohm for the sp. electrical resistance of austenite in a 0·5 per cent. carbon austenitic steel; and K. Honda gave $20·8 \times 10^{-6}$ for the resistance of β-martensite. W. Gerlach's values for the relation between the temp. coeff. of the resistance, dR/dT, are given in Fig. 261, and, for comparison, the dotted line represents the sp. ht.



FIGS. 260 and 261.—The Change in the Temperature Coefficient of the Electrical Resistance of Electrolytic Iron with Temperature.

W. Kohlrausch, and J. Hopkinson also observed that there is an abrupt change in the electrical resistance of iron at the critical temp. A. Goffey and F. C. Thompson, and F. C. Thompson and E. Whitehead observed discontinuities in the resistance of mild steel at approximately 60°, 120°, 170°, 260°, 320°, 360°, and occasionally at 90°, 200°, and 230°. These values vary according to the rate of heating. With high-carbon steels, there are well defined points at 50°, 90°, 120°, 160° (often a double point), 200° to 190°, 220°, 250°, 300°, and 350°. Electrolytic iron gave peaks at 70°, 120°, 170°, 230°, 290°, 310°, and 350° (usually a double peak). There are also indications of breaks at 200° and 300°—*vide supra*. P. Fournel observed singularities in the temperature-resistance curves for steels with :

Carbon . . .	0·08	0·11	0·22	0·37	1·05 per cent.
A_1	—	670°	695°	730° to 770°	730° to 750°
A_2	775°	780°	740°		
A_3	880°	890°	790°		

In addition to the observations of G. K. Burgess and I. N. Kellberg on the breaks in the electrical resistance of iron as the temp. passes through the critical points, discontinuities were also observed by W. Broniewsky, E. Hall, B. V. Hill, and O. Boudouard. A. von Hippel and O. Stierstadt studied the conductivity in the vicinity of the γ–β transition temp. K. Bornemann and K. Wagemann measured the conductivity of molten iron; F. Skaupy and O. Kantorowicz, and O. Jaamaa and Y. E. G. Leinberg, the resistance of finely-powdered iron; H. Kamura, of hydrogen-reduced iron; F. Sauerwald and S. Kubik, and F. Skaupy and O. Kantorowicz, the resistance of powdered iron under pressure; and H. B. Peacock, and J. Kramer and H. Zahn, the resistance of thin films.

According to C. Benedicks, if an electric current passes through a homogeneous metallic conductor, with originally a uniform temp. throughout, it generally exerts a transport of heat in its own direction, or else in the reverse direction, according to the nature of the material. If the transport of heat is positive as in the case of copper, and some kinds of carbon steel, the temp. decreases, in the direction of the current, but if the transport is negative, the temp. increases in the direction of the current.

L. Campredon observed that the conductivity of steel diminishes with increasing proportions of impurities, manganese being specially deleterious. H. le Chatelier concluded from his observations on the effect of additions of carbon that in annealed carbon steels, the progressive addition of cementite caused a linear increase in the resistance of iron corresponding with 7·0 microhms per cm. cube per 1 per cent. of cementite, and, by extrapolation, he concluded that the sp. resistance of cementite is 45·0 microhms, and that of ferrite, 9·5 microhms. E. Gumlich plotted the results of his own observations, and also those of J. Hopkinson, and H. le Chatelier, and concluded that the values for the electrical resistances lie on a straight line for proportions of carbon increasing up to 1 per cent. at the rate of 6 microhms per cm. cube. Above 1 per cent. of carbon, the slope of the curve is less steep. F. Stäblein said that the sp. resistance of the carbon steels is a linear function of the proportion of carbon, with a break at 0·9 per cent. E. Gumlich's later results for the resistance R, and the temp. coeff. α, for steels cooled slowly from 930°, and for the resistance R', and the temp. coeff. α', for steels quenched from 850°, give curves which have a break at about 0·9 or 1·0 per cent. of carbon. E. Gumlich gave for the resistance of purified iron, $R=0·0994$, and for alloys with p per cent. of carbon, $R=0·105+0·03p+0·02p^2$ for alloys slowly cooled from 930°, and $R=0·103+0·016p+0·236p^2$ for alloys quenched from 850°. The break in the curve for the hardened alloy is dependent on the quenching temp. With higher quenching temp., when the whole of the carbon as well as hypereutectoidal cementite is in solid soln., the resistance curve is said to be a straight line. P. Saldau found an average increase of 9·0 microhms per cm. cube for 1 per cent. of carbon; and he observed a small peak at the eutectoidal composition. His steels were heated up to and cooled down from 1000°, so that they do not represent normal annealed steels. K. Honda and T. Simidu's observations indicate an increase of about 4 or 5 microhms per 1 per cent. of carbon. The slope of E. D. Campbell's curves correspond with an increase of about 4·5 microhms per cm. cube for 1 per cent. of carbon. The variable results here indicated for annealed steels are possibly connected with different conditions of annealing. A. L. Norbury represented E. D. Campbell's values for carbon steels, water-quenched from 900° and 1100°, and showed that the resistances do not lie on a straight line, but rather on a curved line. This is also in agreement with P. Saldau's, and E. Gumlich's results for water-quenched steels. A. Michels, and E. L. Dupuy found that cold-work—*e.g.* drawing into wire—decreases the resistance, and L. Guillet and M. Ballay found that the percentage increase in the resistance of iron due to cold-work is 0·50. G. Tammann and M. Straumanis studied the effect of cold-work on the resistance. E. D. Campbell found that at 1100°, 1 per cent. of carbon increases the resistance of iron by about 34 microhms.

B. D. Enlund found the sp. electrical resistance, *R*, microhms, of annealed and quenched steels:

Carbon . .	1·56	1·22	0·88	0·83	0·58	0·35	0·21 per cent.
Annealed . .	25·2	20·3	19·1	17·8	16·7	17·0	17·8
Quenched . .	56·0	45·0	37·0	34·3	26·4	21·0	17·6

and the effect of annealing temp. is summarized in Fig. 262. This shows that in all cases there are two breaks, one between 110° and 120°, and another between 250° and 260°. The breaks correspond with the precipitation of cementite accompanied by an increased conductivity. The first break is assumed to be due to the transformation of martensite into austenite, and the second to the splitting of austenite into α-iron and cementite. The second bend with mild steels is quite distinct, showing that these steels are not free from γ-iron. The subject was studied by L. Grenet, A. Schulze, and G. Dillner and A. F. Enström; the effect of repeated heating and cooling on the resistance of iron, by H. Tomlinson; the resistance of plates, by G. Haufe; and the resistance of thin films, by J. C. Steinberg, and J. Kramer and H. Zahn. W. Geiss and J. A. M. van Liempt found that the variations in the electrical conductivity produced by cold-work cannot be adequately explained by changes in the atomic distances, but they assume that a kind of anistropy is induced at the surface of the crystallites.

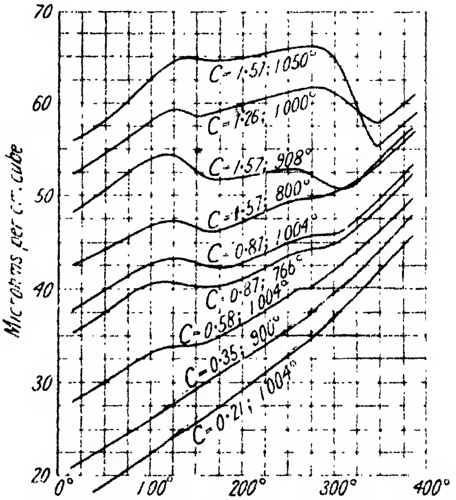


FIG. 262.—The Effect of the Annealing Temperature on the Resistance of Steels.

E. D. Campbell obtained the results indicated in Table XXXIX, for steels quenched from 892° and tempered at different temp. The calculated values for

TABLE XXXIX.—THE EFFECT OF HEAT-TREATMENT ON THE SPECIFIC RESISTANCE OF CARBON STEELS.

the annealed steels are made on the assumption that in the second and third cases, it is assumed that 0·07 per cent. of carbon remains in solid soln., and in all those containing more than 0·45 per cent. of carbon, 0·27 per cent. remains in solid soln.:

Carbon	0·04	0·35	0·41	0·57	0·76	0·945	1·05 per cent.
ΣC	0·076	0·461	0·521	0·678	0·901	1·063	1·174
R Obs.	11·10	17·63	18·46	21·41	30·95	36·82	40·07
R Calc.	9·63	19·96	21·56	25·78	31·75	36·09	39·06
R'' Obs.	10·66	14·38	14·45	14·78	17·26	17·23	17·50
R'' Calc.	9·63	12·45	12·45	17·72	18·61	18·00	18·16

The results are taken to mean that it is not the atomic concentration of the carbon which determines the effect of the solute on the sp. resistance. Equimolar concentrations of carbides in soln. exert an equal influence on the sp. resistance. A comparison of the values for the sp. resistances, *R*, of steels quenched from 907° and tempered at 105°, and the sp. resistance, *R′*, of steels annealed at 880° :

Carbon	0·04	0·35	0·41	0·57	0·76	0·945	1·05 per cent.
R 25°	10·90	16·83	17·89	19·87	25·75	27·31	29·19
R 95°	15·11	21·12	22·25	24·23	30·35	31·98	33·83
R' 25°	10·66	14·38	14·45	14·78	17·26	17·23	17·56
R' 95°	14·65	18·42	18·48	18·82	21·51	21·51	21·82

shows that the increase in the sp. resistance between 20° and 95° ranges in all cases between 0·057 and 0·067 per degree, and the deviation from the value with almost pure iron is very small. This is taken to mean that the increase in the sp. resistance with the rise of temp. is almost wholly due to the increase in the sp. resistance of the solvent, while that component of the total sp. resistance due to the solute in solid soln. is only slightly affected by the rise of temp.

The influence of the heat-treatment on steels was examined by C. Benedicks, O. Boudouard, H. le Chatelier, L. Campredon, H. A. Dickie, K. Honda, J. Hopkinson, W. H. Johnson, W. Köster and H. Tiemann, A. Martens and co-workers, E. Maurer, F. Osmond, W. Rohn, R. Schneider, T. Swinden, and G. Tammann and co-workers. V. Strouhal and C. Barus gave for the resistance, *R* microhms, and the temp. coeff., *a*, of steels :

		Annealed				
	Glass-hard	Light yellow (220°)	Yellow (250°)	Blue (300°)	Light blue (320°)	Soft
R	45·7	28·9	26·3	20·5	18·4	15·9
a	0·00161	0·00244	0·00280	0·00330	0·00360	0·00423

I. Iitaka studied the electric conductivity changes which accompany the cementite transformation. E. D. Campbell found the data of Table XXXIX for the sp. resistance, in microhms per cm. cube at 20°, of steels quenched from 892°, and tempered or annealed at the indicated temp. The result shows a close relationship between the concentration of the carbides in solid soln. and the sp. resistance. The divergence at 800° is attributed to the segregation of the carbides into relatively large masses, and although the precipitation would be nearly complete, the separated cementite consists of carbides saturated with iron in solid soln., and this causes an increase in the sp. resistance. H. le Chatelier, C. Benedicks, E. Maurer, E. D. Campbell, and A. McCance also showed that the electrical resistance of hypoeutectoidal steels increases with the temp. of quenching.

O. von Auwers and G. J. Sizoo measured the effect of *grain-size* on the sp. electrical resistance of iron, but obtained no appreciable difference. J. R. A. Mousson, and O. Chwolson found that the sp. resistance of drawn wire is smaller in the hard tempered state than that of the same wire in the soft state. P. Goerens observed that the change in the electrical conductivity of various steels induced by cold-working is too small to be detected ; and that the effect of the temp. of annealing is to produce a fall in the sp. conductivity from 12·25 to 11·90 corresponding with a 2·8 per cent. reduction in the conductivity in the neighbourhood of 520°. E. Maurer's observations on the percentage change in the resistance of austenite with variations in the annealing or tempering temp ; and the observations of J. H. Andrew and co-workers, and others are summarized in Table XXXIX. The effect of annealing was studied by I. P. Parkhurst ; and the effect of the duration of the period of heating before quenching, by A. M. Portevin. H. Kleine found that the electrical resistance of iron annealed in vacuo increases linearly if it be allowed to stand in air over a period of 5 days. The effect is due to the absorption of gases. Similarly, if the gassed metal is re-heated in vacuo, the resistance falls.

K. Honda and T. Simidu obtained for the sp. resistance, *R*, in 10^{-5} ohms per cm. cube at 30°, of iron with the following proportions of carbon, silicon and manganese, as forged, and as annealed at 900°, and quenched at 900° :

Carbon . . .	0·14	0·18	0·44	0·64	0·80	0·94	1·30	1·50	per cent.
[Mn + Si] . .	1·01	0·54	1·35	0·39	0·50	0·61	0·57	0·47	at. per cent.
R Forged . .	1·91	1·75	2·32	1·78	1·91	1·99	2·09	2·18	
R Annealed . .	1·91	1·75	2·14	1·77	1·92	1·99	2·18	2·18	
R Quenched . .	1·93	1·77	2·41	1·82	2·02	2·30	2·23	2·50	

J. H. Andrew and co-workers measured the sp. resistance of a number of steels quenched and tempered at different temp., and the results with carbon steels show that the sp. resistance of hypereutectoid steels is increased by raising the quenching temp., and that with hypoeutectoid steels, the sp. resistance is decreased by raising the quenching temp. E. D. Campbell, and P. Saldau reported that in hypoeutectoid steels, the raising of the quenching temp. increased the sp. resistance ; H. le Chatelier, C. Benedicks, and A. McCance, that this treatment made no change in the sp. resistance ; whilst J. H. Andrew and co-workers observed this treatment depressed the sp. resistance. The annealed carbon steels show a break at the eutectoid concentration, and beyond this percentage of carbon, the resistance increases less rapidly with the proportion of carbon. The amount of carbon dissolved in α-iron increases with the carbon-content up to 0·9 per cent. when further additions produce only free cementite. The sp. resistance of carbon steels, tempered for 6 hrs. at 240°, shows that some carbon steel remained in soln. in the tempered steels, although tempering was practically completed for that particular temp. To compare these results with those obtained by others, J. H. Andrew and co-workers recommended using the correction of G. K. Burgess and co-workers, E. Gumlich, and H. le Chatelier for silicon, where 1 per cent. silicon raises the resistance 13·5 microhms ; that of E. d'Amico, where 1 per cent. of phosphorus raises the resistance 11·0 microhms ; and that of W. F. Barrett and co-workers, G. Lang, and T. Matsushita, where 1 per cent. of manganese raises the resistance 5·5 microhms. C. Benedicks' corrections apply for carbon steels, but not for alloy steels. The resistance curves of the annealed steels are similar ; there is first a rapid increase and then a slow fall, or almost a constant value. In the curve for 1·6 per cent. carbon some austenite was retained after the quenching, and the other curves are typical of the tempering of martensitic steels. W. Fraenkel and E. Heymann measured the electrical resistance, *R*, of a steel containing 0·80 per cent. carbon, and 0·50 per cent. manganese, and quenched from 800°, at different stages of the annealing process. C. Barus, and L. C. Brant observed that glass-hard steel gradually softens at ordinary temp. when kept for prolonged periods. Thus, the curve, Fig. 263, represents the sp. resistance of two glass-hard, steel wires over a period of 30 years.

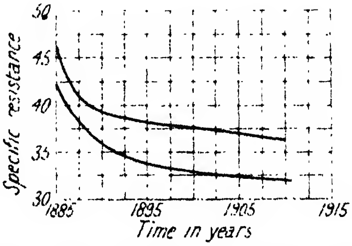

Fig. 263.—The Effect of Time on the Electrical Resistance of Hard Steel.

K. Takahasi observed minima in the changes in the electrical resistance of electrolytic iron, armco iron, and 0·1 and 0·3 per cent. carbon steels at different temperatures. The minimum for electrolytic iron is at 750° ; for armco iron, at 680° ; for 0·1 and 0·3 per cent. carbon steels, respectively, at 650° and 620°. The change of electrical resistance of a metal produced by cold-working has been attributed to the orientation of the minute crystals of which the metal consists. That is, by drawing, the minute crystals of the metal arrange themselves in a certain direction parallel to each other and also to that of the cold-drawing. The electrical resistance of the crystals is assumed to be greater in this direction than in all others, and hence the resistance of the metal increases in the direction of the cold-working. If, however, the metal is recrystallized by annealing, the orientation of the crystals has no longer a definite direction and the electrical resistance decreases. Against this view, K. Takahasi said that the anisotropic nature of the electric resistance of crystals belonging to the cubic system is not in agreement with observation. Besides, the change of resistance of a cold-worked metal by annealing has no intimate relation with the recrystallization of the metal. According to G. Tammann and co-workers, the change is not due to the internal stresses produced by cold-working because, in a metal severely cold-drawn, there is tension in the outer portion of it, and compression in the inner, and the equilibrium is maintained elastically. In this case, the change of resistance due to elastic tension and compression is equal in magnitude and opposite in sign, and these two effects cancel each other. It is not reasonable therefore to attribute the cause of the change of resistance to the internal stress. K. Takahasi bases his explanation on the fact that a severely cold-worked metal generally consists of a large number of minute groups of crystals, in each of which one portion undergoes a tension and the other portion a compression, these two balancing each other, so that the lattice expands in one portion and contracts in the other. Now, according to the ordinary law of atomic force, the expansion of the lattice is somewhat greater than the contraction for the same strength of tension and compression. Hence, the lattice expands as a whole, cold-working thus causing a diminution of density. Again, each atom of a metal consists of a nucleus and bound electrons revolving around it; the mutual distance of these atoms is very small, but comparable with the diameter of the orbit of outer electrons; hence, some of these electrons may stray off from the atom, to which they were originally bound, through the attraction of the nuclei of other atoms, and play the rôle of free electrons, thus conducting electricity through the metal. When the distance of these atoms is increased by cold-working, some of the free electrons may be caught again by an atom and the number of free electrons be diminished, an increase of electrical resistance being thus caused by cold-drawing. As the decrease of density caused by cold-drawing does not increase beyond a certain limit, the increase of resistance also cannot exceed a certain limit. Again, the electrical resistance is affected by the fibrous structure; as mentioned above, a metal which has undergone a severe cold-working has a fibrous structure; the crystals are broken up into small pieces which are elongated in the direction of the drawing. Hence, in this direction, the number of crystal boundaries is much less than that in the perpendicular direction, so that the specific resistance will be less in the direction of the drawing than in all other directions. As the degree of cold-drawing increases, the crystals become more and more elongated in the direction of the drawing, and thus the specific resistance in this direction always diminishes. Besides, insoluble impurities which have been segregated in a thin layer in the crystal boundaries and have prevented the flow of electricity, are broken up by cold-drawing and thus diminish the electrical resistance on the crystal boundaries. These two effects of the fibrous structure of metals are thus the cause of diminishing the electrical resistance in the severely cold-drawn metals. Hence, the cold-drawing produces, on one hand, an increase of resistance by internal strain, and, on the other hand, a decrease of it owing to the fibrous structure; as the result of these two opposite effects, the electrical resistance first increases and reaches a maximum, as the degree of cold-working increases, and afterwards begins to decrease. For C. Nusbaum and W. L. Cheney's observations on the effect of cooling an eutectoid carbon steel at different rates, *vide* Table XLI, magnetism.

H. Kleine observed that the resistance of iron decreased when the metal was tested under reduced press., and the phenomenon was traced to the effect of absorbed gases. T. Skutta studied the effect of high gas press. W. F. Barrett found that the conductivity of iron is diminished by alloying it with another metal, even though that metal be a much better conductor than iron. This reduction of conductivity is not related to the resistivity of the added metal; on the contrary, an alloy of very high sp. resistance can be produced by adding to iron an element of much lower sp. resistance than the iron itself; for instance, aluminium is more than three times a better conductor than iron, yet the addition of 5 per cent. of aluminium to iron makes the conductivity of the alloy five times worse than that of iron. The greatest reduction in conductivity in a given alloy is produced by the first increments of the added elements. A relationship appears to exist between the sp. ht. of the added element and the resistance of the alloy formed with the iron. Thus, the sp. resistance of an alloy of 5·5 per cent. of aluminium with iron is 70 microhms; the same amount of silicon with iron gives an alloy with a resistance of 65 microhms; of manganese with iron, 38 microhms; of nickel, 27 microhms; and of tungsten, 18 microhms. Now, the sp. ht. of these elements are: aluminium 0·212, silicon 0·183, manganese 0·122, nickel 1·109, and tungsten 0·035. Consequently, those elements having high sp. ht., and therefore small at. masses, produce the greatest increase in the electrical resistance of the corresponding alloy with iron.

H. le Chatelier observed that equi-atomic proportions of carbon and silicon in soln. raise the resistance of iron by the same amount. He showed that in A. Matthiessen's resistance curves for alloys, showing the effect of composition on the resistance, indicates that the constituents are mechanically admixed, but a drop in the curves corresponds with the formation of solid soln. W. F. Barrett and co-workers found that the effect produced on the resistance of iron by 1 per cent. of added element is inversely proportional to the at. wt. of the latter, and that the increase in sp. resistance follows the same order as the increase in sp. ht. C. Benedicks suggested that equivalent quantities of foreign elements dissolved in iron cause the same increase in resistance. The rule is based on the assumption that equi-atomic solutions in iron possess equal resistances; the subject was discussed by E. D. Campbell. If ΣC denotes the summated values of all the elements dissolved in the iron expressed in terms of carbon, and if 25·8 represents the increase in resistance caused by the presence of 1 per cent. of carbon, then, if 7·6 microhms per cm. cube represents the resistance of iron alone, the resistance of the alloy will be represented by *Benedicks' rule*: $R=7{\cdot}6+25{\cdot}8\Sigma C$. The carbon value is obtained by dividing the percentage proportion of the element, here represented by the chemical symbol in brackets, by its at. wt., and multiplying the result by 12, the at. wt. of carbon, *e.g.* $\Sigma C=[C]+0{\cdot}4200[Si]+0{\cdot}2184[Mn]+\ldots$ The rule was found to apply fairly closely for solid soln. containing C, Al, Si, P, Cr, Mn, Co, Ni, As, Mo, and W. C. Benedicks said that it is difficult to fix the upper limit of the validity of the rule. It applies to dil. soln. Probably ΣC will exceed 2 per cent., but not 3 per cent. He also observed that iron carbide or cementite does not appear to exert any influence on the resistance so long as it is isolated within the mass of the iron, but A. M. Portevin found that the structure has a considerable influence on the nature of the variations in resistance due to the addition of elements to iron—*vide infra*. Again, C. Benedicks' extrapolated value, 7·6 microhms per cm. cube, for the resistance of iron is much lower than the observed value about 10·0 microhms per cm. cube. C. Benedicks said that the difference can be explained by remembering that the higher value would be lowered to the extrapolation result by admitting the presence of only 0·004 per cent. of hydrogen in solid soln. A. Sieverts, however, heated iron wire in hydrogen between 20° and 920°, but could not detect any appreciable alteration in the electrical resistance. H. Jellinek found that the electrical resistance of iron shows an 8·9 per cent. increase when the press. of the hydrogen rises from 0 to 35 atm.; and in nitrogen, a decrease of 4·5 per cent. between 0 and 15 atm. press., and an increase of 13·3 per cent. between 15 and 20 atm. press. T. Sexl studied the effect of adsorbed gas on the resistance of iron. T. Skutta observed that the resistance of steel, in atm. of hydrogen and nitrogen, at press. up to 30 atm., is augmented, and that with hydrogen a stable soln. is formed. The extrapolation is based on the assumption that the resistance curve is a straight line, but this assumption is not quite correct. H. Masumoto's observations extrapolated for cementite, Fe_3C, gave $R=0{\cdot}0_314$ ohm per cm. cube; and F. Stäblein's observations, $0{\cdot}0_47$ ohm per cm. cube.

Other methods of calculating the electrical resistance of steels from the chemical composition, were discussed by P. Mahler, J. H. Partridge, F. Stäblein, M. A. Hunter and A. Jones, L. Guillet, E. D. Campbell and W. C. Dowd, C. H. Risdale, C. H. and N. D. Risdale, K. Honda and T. Simidu, and O. Boudouard. H. Masumoto gave $R=1{\cdot}044+0{\cdot}548[C]+1{\cdot}527[Si]+0{\cdot}718[Mn]+\ldots$ T. D. Yensen gave $R=9{\cdot}6+82{\cdot}5[C]+4{\cdot}5([C_1]-0{\cdot}02)$, where [C] denotes the excess of carbon under

0·02 per cent., and $[C_1]$, the excess of carbon over 0·02 per cent.; and E. D. Campbell and H. W. Mohr, $R=10{\cdot}44+3{\cdot}7[C]$ for [C] up to 1·1 per cent., and $R=14{\cdot}51+7{\cdot}8([C_1]-1{\cdot}1)$ for $[C_1]$ between 1·1 and 1·5 per cent. The results of a number of observations on the effect of additions of various elements on the electrical resistance of iron, compiled by A. L. Norbury, are given in Table XL, and the summary in Fig. 264 shows that equi-atomic proportions of the different elements in solid soln. in iron do not increase the electrical resistance to the amount required by C. Benedicks' rule. A factor dependent on the atomic properties of the particular elements in solution seems to determine the increase in the atomic resistance. E. D. Campbell pointed out that C. Benedicks' rule that equi-atomic concentrations in iron possess equal resistances, assumes that the elements other than iron are wholly in soln., and that each atom exerts an equal influence on the resistance. He compared the sp. resistances of steels hardened by quenching and when annealed, and added that in order that the elements may be in soln. as completely as possible, the sp. resistance under consideration must be that of steels in the hardened condition. Even then, however, there are such wide differences between the observed and calculated values that he said "the formula of C. Benedicks cannot be considered as being of any particular significance."

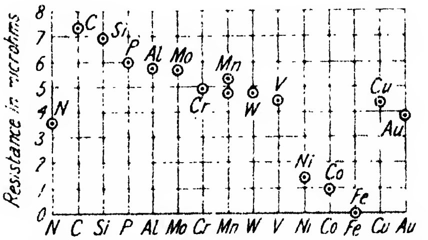

Fig. 264.—The Increase in the Specific Resistance of Iron by the Addition of 1 Gram-atom of Element in 100 Gram-atoms of Alloy.

K. Honda and T. Simidu, E. Grüneisen and E. Goens, and H. Masumoto compared the electrical and thermal conductivities from the point of view of G. Wiedemann and R. Franz's rule—*vide supra,* thermal conductivity. W. Broniewsky compared the sp. vol. and resistance of metals.

A. M. Portevin found that the electrical resistance of alloy steels varies with the nature of the added elements, and with the microstructure produced by quenching. As a result, the following types can be distinguished :

1. *Pearlitic steels.*—The resistance increases steadily with an increase in the percentage of the added element, and may be represented in terms of the latter factor, by a linear formula, or by a parabolic formula the coeff. of the squared term of which is small (aluminium steels). On quenching the steels, the resistance increases corresponding with the passage into solid soln. of the available carbon of the carbide. It was possible, in most instances, to verify the fact stated by C. Benedicks, that steels with about 0·8 per cent. of carbon in the normal state contain about 0·27 per cent. of their carbon in a state of solid soln. The presence of certain elements, such, for instance, as molybdenum, appears to modify the latter figure.

2. *Martensitic steels.*—The increase in the electrical resistance with that in the percentage of the special element is smaller than in the case of the pearlitic steels. The variation in the resistance on hardening is practically *nil* for the steels containing a low percentage of carbon, as may be very clearly seen with pearlitic steels containing the same percentage of carbon. For the martensitic steels with 0·8 per cent. of carbon there is an increased electrical resistance on hardening, the magnitude of which decreases in proportion as the percentage of the special element becomes higher. Not all the carbon of the martensitic steels is therefore in soln. This fact corresponds, likewise, with the hardening which occurs on quenching the martensitic steels; this is seen, in particular, with those steels which border closely on the pearlitic steels.

3. *Polyhedral steels.*—The polyhedral steels are distinguished by a rapid rise in the electrical resistance, with the rise in the percentage of the added element. On hardening they undergo no variation, or only a slight diminution. This diminution corresponds with the appearance of martensite, in lanceolate crystals, and occurs in steels which border closely upon the martensitic class.

4. *Double carbide steels.*—Two conditions may be distinguished : (*a*) The addition of the special element betrays itself by an increase in the amount of carbide (chromium and tungsten steels and vanadium steels with 0·8 per cent. of carbon and less than 5 per cent. of vanadium), while the electrical resistance remains practically constant or undergoes but slight increase. (*b*) With increasing proportions of the special element the amount of carbide varies but slightly (vanadium steels with low percentages of carbon and vanadium, and steels with 0·8 per cent. of carbon and over 7 per cent. of vanadium), and there is then seen a notable increase in the electrical

resistance which corresponds with the increased conc. of the solid soln. surrounding the carbide. The variation in the resistance on hardening depends both on the nature of the constitution which surrounds the carbide, and on the solvent capacity of this carbide. The pearlitic steels and those containing the carbide undergo an increase in their electrical resistance on hardening, corresponding with that of the ordinary pearlitic steels, to which has, at times, to be added that which results from the soln. of the carbide (vanadium steels). Steels with a martensitic basis display a smaller increase in electrical resistance on hardening than those of the preceding category.

Steels consisting mainly of a solid soln. do not, generally speaking, undergo any change on hardening. It is necessary in this connection to point out that the soln. of carbon on hardening depends on all the phases of the heat-treatment: temperature of heating; duration of heating; rate of cooling; and rate of traversing the critical point. It is not possible, therefore, definitely to pronounce upon the influence of this treatment on the electrical resistance, except after experiments in which these different factors had been varied. From what has been said it will be seen that C. Benedicks' law which expresses linearly the variation of the electrical resistance in terms of the percentages of the elements in solid soln. in the iron, can only be applied in the case of low percentages of the special elements. The limits of its applicability may, in the case of steels containing low carbon percentages (0·2 per cent.), be fixed approximately as follows: nickel steels less than 2·0 per cent.; chromium steels less than 1·0 per cent.; tungsten steels 7·0 per cent.; aluminium steels 1·0 per cent.; molybdenum steels 5·0 per cent.; vanadium steels 3·0 per cent.; titanium steels less than 0·5 per cent.; and boron steels less than 0·2 per cent. Below these amounts the increase in the electrical resistance for each per cent. of the element added agrees in a satisfactory manner with that calculated from C. Benedicks' formula, which thus appears to be chiefly a limiting formula to which an approach is made whenever the percentage of the added element decreases. It is the equation of the tangent of the commencement of the curve representing the electrical resistance in terms of the percentage of the special element. Observations were made by B. V. Hill.

O. Chwolson discovered a minimum in the resistance curve of steel when tempered below 350°, and C. Fromme observed a maximum in the sp. gr. curve in the same region. There is a rough sort of proportionality between the sp. gr. or sp. vol. and the resistance. Thus, with C. Fromme's data, for steel:

	Commercial soft	Glass-hard	Annealed			
			Yellow (250°)	Blue (300°)	Grey (350°)	Soft
Sp. gr. . .	1·00000	1·00772	1·00347	1·00217	0·99957	--
Resistance .	---	46	26	20	18	16

V. Strouhal and C. Barus studied the relation between *specific gravity*, and electrical resistance, and failed to find an immediate relation; and they also showed that the temp. coeff. of the electrical resistance decreases in proportion as the electrical resistance decreases, or as its hardness increases at a rate which diminishes in passing from soft to hard steel—*vide supra.*

N. S. Kurnakoff and S. F. Schemtschuschny showed that in solid soln. of the metals, there is a relation between the electrical resistance and the *hardness*, since these two properties usually vary in the same proportion. Comparing the hardness of alloy steels observed by L. Guillet with the resistance curves, A. M. Portevin observed that in their general characters, the curves present an air of family likeness, notably in the case of chromium steels, and tungsten steels containing 0·8 per cent. of carbon, and aluminium steels with 0·2 per cent. of carbon. Notable points of difference occur with the nickel steels. It is therefore inferred that these two physical properties—electrical resistance and hardness—are functions of a large number of variable factors, and that amongst those variable factors, there are certain common ones whose influence, when not masked by that of others, reveals itself by a correspondence in the appearance of the curves of variations in resistance and hardness.

P. W. Bridgman examined the effect of temp. and *pressure* on the electrical resistance of iron with less than 0·03 per cent. of impurity, and consisting entirely of ferrite. The results show that for press., p kgrms. per sq. cm., the press. coeff. are:

		0°	25°	50°	75°	100°
R		1·0000	1·1416	1·2918	1·4519	1·6206
Press. Coeff.	$p=0$	$-0{\cdot}0_5 2405$	$-0{\cdot}0_5 2420$	$-0{\cdot}0_5 2436$	$-0{\cdot}0_5 2451$	$-0{\cdot}0_5 2468$
	$p=1{\cdot}2000$	$-0{\cdot}0_5 2119$	$-0{\cdot}0_5 2150$	$-0{\cdot}0_5 2180$	$-0{\cdot}0_5 2209$	$-0{\cdot}0_5 2238$
	Averago	$-0{\cdot}0_5 2262$	$-0{\cdot}0_5 2285$	$-0{\cdot}0_5 2308$	$-0{\cdot}0_5 2330$	$-0{\cdot}0_5 2353$

These results correspond with an average temp. coeff. of 0·006206 between 0° and 100°; and for the average press. coeff., $-0{\cdot}0_5 246$. The value of the press. coeff. of the resistance of iron, $R^{-1}(dR/dp)$, is related to the change in the conductivity and compressibility, dv/dp, by the expression $R^{-1}(dR/dp)=K^{-1}(dK/dp)+\frac{1}{3}v(dv/dp)$, where K denotes the conductivity; v, the volume; and p, the press. U. Fischer gave for the press. coeff., $-10^{-7}dR/Rdp=21{\cdot}6$ at 273·1° K.; 23·7 at 198° K., and 34·4 at 81° K. P. W. Bridgman obtained for the average press. coeff. at 0°, −7·84°, and −182·9°, at press. up to 7000 kgrms. per sq. cm., $-0{\cdot}0_5 234$, $-0{\cdot}0_5 227$, and $-0{\cdot}0_5 234$. B. Beckman observed $-0{\cdot}0_5 2405$ for the press. coeff. E. D. Williamson found the ratio of the resistances at 1 and 12,000 kgrms. per sq. cm. press. to be 0·9729. A. T. Waterman, and A. Schulze discussed the conductivity as a function of press. in accord with the electron theory. The effect of cold-work on the electrical resistance was studied by P. Bardenheuer and H. Schmidt. A. Campbell measured the Joule heating effect of currents. G. R. Wait and co-workers observed that exposure to radio-frequencies had no effect on the resistance.

H. Rolnick, R. S. Bedi, J. Russner, and W. H. Johnson studied the effect of tensile stresses on the electrical resistance of iron. H. Tomlinson observed that the temporary increase in the electrical resistance of an iron wire under *tensile stresses* where the wire is stretched in the same direction as the current, is exactly proportional to the stretching force. The percentage increase in the resistance which occurs when a cube of the material is stretched by the same weight is greater with iron than with steel wire, and this increase is nearly the same for different specimens of the same material. The percentage increase in the resistance which occurs when the material is stretched to the same extent is greater with iron than with steel wire. There is in each case a residual increase over and above that which would follow from a mere increase in length or sectional area which is greater with iron than with steel. H. Tomlinson gave 2111×10^{-12} for the increase of resistance per unit produced by a stress of a gram per sq. cm.; 4·180 for the increase per unit of resistance which would be caused by a stress sufficient to double the length of the wire, and 2·618 for the increase per unit of sp. resistance which would be caused by a stress sufficient to double the length of the wire. Otherwise expressed, the percentage increase in the sp. resistance by a stretching force of one kilogram per sq. cm. is $0{\cdot}0_5 1080$ for steel, and $0{\cdot}0_5 1258$ for iron. S. Fukuta found for steels with 0·3 to 1·5 per cent. of carbon, the average $0{\cdot}0_6 1139$. In general, the increase in sp. resistance is proportional to the applied stress; and the increase in the sp. resistance decreases slightly with an increase in the proportion of carbon. T. Uêda found that the sp. electrical resistance of iron and carbon steel, when stretched, increases as the tensile stress increases, and makes a discontinuous change at the yield-point, and afterwards increases. The discontinuity is at first positive, and as the carbon-content increases, it becomes negative. The rate of change of the sp. resistance decreases as the carbon-content increases. R. S. Bedi, and J. B. Seth and C. Anand observed no decrease such as occurs with nickel wires in the early stages of the stretching. A. Campbell found no change in the electrical resistance of iron, and iron-nickel wires when subjected to tensile stresses up to the breaking-point. A. Campbell also found that the conductivity of soft iron remained practically constant under the influence of tensile stresses, indicating that up to the breaking-point the metal stretches out as if it were a liquid. W. Brown measured the effect of an electric current on the subsidence of the torsional oscillations of an iron wire.

P. W. Bridgman showed that the percentage change of electrical conductivity with loads of 2050 and 1025 kgrms. per sq. cm. are respectively $-0{\cdot}518$ and $-0{\cdot}257$ while the proportional changes of conductivity per kgrm. per sq. cm. are respectively $-2{\cdot}53\times10^{-6}$ and $-2{\cdot}51\times10^{-6}$; the proportional changes of sp. conductivity per kgrm. per sq. cm. are respectively $-1{\cdot}82\times10^{-6}$ and $-1{\cdot}80\times10^{-6}$. The value of $(1+2\sigma)/E$ is $0{\cdot}71\times10^{-6}$. He also found that with iron, the longitudinal fractional change of resistance per kgrm. per sq. cm. is $2{\cdot}13\times10^{-6}$ when the tension is parallel and also perpendicular to the direction of rolling, and when corrected for distortion, the value is $1{\cdot}42\times10$. The geometrical mean of longitudinal and transverse fractional change of resistance per kgrm. per sq. cm. is $0{\cdot}99\times10^{-6}$, or corrected for distortion, $0{\cdot}86\times10^{-6}$, when the tension is parallel to the direction of rolling; and when perpendicular to the direction of rolling, $1{\cdot}33\times10^{-4}$, or, when corrected for distortion, $1{\cdot}20\times10^{-6}$. The calculated fractional change of transverse resistance per kgrm. per sq. cm. is $0{\cdot}30\times10^{-6}$ when taken parallel, and $0{\cdot}78\times10^{-6}$ when taken perpendicular to the direction of rolling. R. S. Bedi found that the resistance of iron or steel, under a stretching load, decreases up to the elastic limit, and the resistance minimum coincides with the elastic limit. F. Credner observed that the decrease in the resistance of wires under tension when heated, reaches a minimum with iron at 600°—*vide* nickel. T. Ionescu discussed the Joule effect; W. G. Kannuluik, R. Kikuchi, the relation between the electrical and thermal conductivities—*vide supra*; and S. Procopiu, the relation between the electrical resistance, the sp. ht., and the temp. of a metal wire.

W. K. Mitiaeff observed an anomalous change in the resistance of iron wire at radio-frequencies, but G. R. Wait and co-workers would not verify this. H. M. Brown found that a magnetic field of 10,000 gausses increased the electrical conductivity 0·2 per cent. G. Barlow, W. F. Barrett, H. Bethe, L. Bloch, G. Borelius, H. Braune, W. Brown, M. Dumermuth, J. Dorfman and co-workers, N. H. Frank, W. Gerlach and E. Englert, W. Gerlach and K. Schneiderhan, K. Ghosh, T. Gnesolto, A. Gray and E. T. Jones, P. Kapitza, G. Mahoux, J. A. Mathews, M. Medici, E. Merritt, A. Perrier, H. Sachse, K. Schneiderhan, O. Stierstadt, and H. Tomlinson studied the change of the electrical conductivity in strong magnetic fields *vide infra*. O. Stierstadt studied the change in the electrical conductivity of iron in a longitudinal magnetic field. H. H. Potter measured the effect of magnetization on the change of resistance and some results are summarized in Fig. 265. The temperatures are expressed in terms of the Curie temperature 1050° K. The dotted lines refer to the transverse and the continuous lines to the longitudinal effect. Near the Curie point, the value $\delta R/R$ changes less rapidly than the first power of H, but with rising temp. the curves gradually change in shape until, above the Curie point, the value of $\delta R/R$ varies as H^2. H. Walker, and R. Schenck made observations on the subject. O. Stierstadt observed that some of the anomalies observed with small fields are due to errors, mainly incomplete demagnetization. A. G. S. Gwyer, A. T. Waterman, K. Höjendahl, and K. F. Herzfeld discussed the theory of the conductivity of metals. A. Eucken defined a metal in terms of its electrical conductivity, which term is dependent on

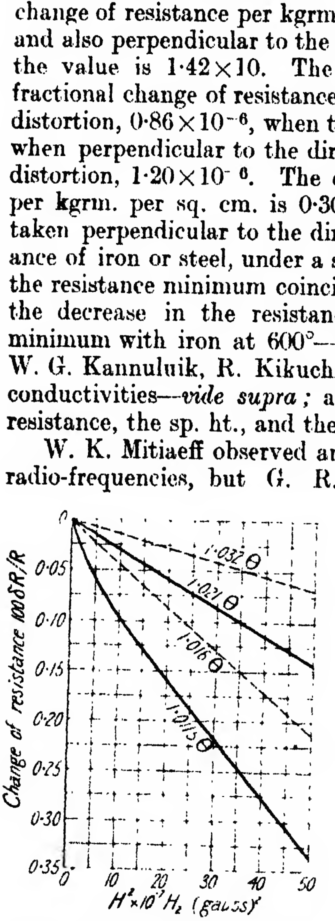

FIG. 265.—The Effect of Magnetization on the Resistance.

the presence of free electrons. Only a certain number of elements have these free electrons.

W. Ostwald[2] calculated for the **heat of ionization** of $Fe^{\cdot\cdot}$ from the metal, Fe, in dil. aq. soln., +93 kilojoule, when the heat of ionization of $H^{\cdot}$ from H_2 is zero; and for the formation of $Fe^{\cdot\cdot\cdot}$ from $Fe^{\cdot\cdot}$, +39 kilojoules. J. D. Bernal and R. H. Fowler calculated for the **ionization energy** of $Fe^{\cdot\cdot}$, 561 Cals. per gram-ion, and of $Fe^{\cdot\cdot\cdot}$, 1346 Cals. The **transport number** of $Fe^{\cdot\cdot}$-ions at 18° was found by K. Szalagyi to be 50; A. Heydweiller gave 45·2; G. von Hevesy, 48; and A. Stepniczka-Marinkovic, 46. For $Fe^{\cdot\cdot\cdot}$-ions, A. Heydweiller gave 61·2 at 18°; G. von Hevesy, 45; and K. Hopfgartner, 43.

E. Dubois[3] studied the **Volta effect** in water-vapour. M. Andauer attributed the potential difference between iron and air, of the order of 0·15 volt, to the formation of a conducting film of gas over the entire surface of the metal. M. Forro and E. Patai found the contact potential of iron and sodium to be 1·4 volts. S. J. French and L. Kahlenberg studied the gas-metal electrode of iron with oxygen, hydrogen, or nitrogen. J. Galibourg measured the contact potential of steels of various kinds against mercury at temp. between 20° and 320°. He found the results dependent on the composition of the metal, but were only slightly affected by the degree of tempering. He said that the steels can thus be classified without analyzing them. G. Mönch gave − 0·35 volt for the contact potential of iron and copper; G. N. Glasoe, 0·21 volt for gas-free iron and nickel; and F. Polednik gave 1·99 volts for the contact potential of iron and quartz, and 1·15 volt for iron and glass. W. Ende, and R. F. Hanstock studied the effect of cold-work on the contact potentials of metals. J. B. Seth and co-workers studied the e.m.f. developed by a rapidly rotating steel disc against aluminium magnesium, zinc, tin, cobalt, cadmium, lead, manganese, bismuth, nickel, platinum, antimony, arsenic, gold, tellurium, copper, and silver, and the values increase from —730 millivolt to 123 millivolts in the order stated. E. Perucca, O. Scarpa, A. Lafay, and H. F. Richards studied the subject. R. D. Kleeman and W. Fredrickson studied the electric charges of colloidal particles of iron in distilled water. R. T. Dufford studied the **photovoltaic effect** with iron in Grignard's soln.; and P. E. Shaw and co-workers, the **triboelectric effect**.

When iron dissolves in dil. hydrochloric acid, it forms a soln. of bivalent iron, ferrous chloride, and assuming that the salt, under these conditions, is ionized, the reaction is represented $Fe+2H^{\cdot}=Fe^{\cdot\cdot}+H_2$. Salts of univalent iron are unknown —*vide infra*. A unit charge is equivalent to $C=96,540$ coulombs, so that when iron passes into a bivalent charge ion, $Fe^{\cdot\cdot}$, it acquires a charge of 2×96,540 coulombs; and when bivalent iron passes into a tervalent ion, $Fe^{\cdot\cdot\cdot}$, it acquires a charge of 3×96,540 coulombs. From this point of view, iron, and the bivalent and tervalent charged ions, can almost be regarded as allotropic modifications of one substance. The electrical energy or work, W, involved in the reversible transformation $Fe\rightleftharpoons Fe^{\cdot\cdot}$ is the product of the quantity of electricity, C, and the pressure E, so that the work $W=2CE$ volt-coulombs. E can be determined by dipping iron in a soln. of a ferrous salt, and measuring the difference of potential of this combination against another electrode taken as zero. Observations show that the difference of potential, E, depends on the conc., $[Fe^{\cdot\cdot}]$, of the soln. such that $E=E_0+0{\cdot}02885 \log [Fe^{\cdot\cdot}]$ volt, where E_0 represents the value of E when the conc. $[Fe^{\cdot\cdot}]=1$. The **electrode potential** of iron in a soln. of a ferrous salt of conc. $[Fe^{\cdot\cdot}]=1$ is called the normal potential. Since E and E_0 represent differences of potential, their respective values depend on the electrode which is taken as zero. As shown by R. Abegg and co-workers, if the normal calomel electrode, Hg : HgCl : N-KCl be taken as zero, the potential is symbolized E_0; if the dropping electrode be zero, E is symbolized E_0; and if the normal hydrogen electrode be zero, E is symbolized E_H. Under these conditions $E_H=E_0-0{\cdot}277$; $E_c=E_0-0{\cdot}56$, so that $E_H=E_c+0{\cdot}283$.

R. Schenck and co-workers calculated from the equilibrium measurements of E. Baur and A. Glässner, and A. B. Lamb's observations on the heat of formation of ferrous oxide, that the **normal potential: $Fe \rightarrow Fe^{\cdot\cdot}$** is $E_H = -0{\cdot}47$ volt for iron in contact with a molar soln. of a ferrous salt. K. Jellinek and H. Gordon think this value is too strongly positive. W. H. Hampton gave −0·4413 volt; C. Drucker, −0·44 volt; and R. Abegg and co-workers considered −0·43 volt to be the best representative value for iron in contact with a normal soln. of a ferrous salt at 18°. This gives for the e.m.f. of the transformation $Fe \rightarrow Fe^{\cdot\cdot}$,

$$E_H = -0{\cdot}43 + \frac{0{\cdot}058}{2}\log[\mathrm{Fe}^{\cdot\cdot}] \text{ volt} \quad . \; . \; . \; . \; . \; . \; . \quad (1)$$

For a normal soln. of ferrous chloride, B. Neumann gave −0·361 volt, and for a $2N$-soln., E. Petersen gave −0·337 volt. F. Förster found for the electrode potential of iron in a soln. with N-$FeCl_2$ and N-NH_4Cl, at the beginning, −0·492 volt at 20°, and −0·420 volt at 75°; and after an hour's time, respectively −0·463 and −0·420 volt. Numerous observations have been made with iron against soln. of ferrous sulphate. B. Neumann obtained −0·367 volt for the electrode potential of iron against N-$FeSO_4$; M. Mugdan, −0·34 volt for $0{\cdot}1N$-$FeSO_4$; E. Petersen, −0·337 volt for $2N$-$FeSO_4$. W. Muthmann and F. Fraunberger found that iron deposited electrolytically on iron or platinum gives $E_H = -0{\cdot}66$ volt. This value agrees with that obtained by F. W. Küster; and G. Coffetti and F. Förster showed that the high value applies not to iron, but rather to iron charged with hydrogen; if an allowance be made for this, the value for iron in N-$FeSO_4$ is −0·46 volt. High results for electrolytic iron were also obtained by C. E. Fawsitt. S. Glasstone gave for the cathode potential of iron in N-$FeSO_4$ at 15° for current densities of D amp. $\times 10^{-4}$ per sq. cm.:

D	$0{\cdot}02N$-H_2SO_4	$p_H = 2{\cdot}8$	$p_H = 4{\cdot}0$	$p_H = 5{\cdot}0$
0·14	−0·46	−0·47	−0·47	−0·47
4·2	−0·46	−0·49	−0·49	−0·53
8·4	−0·46	−0·52	−0·50	−0·58
20·0	−0·48	−0·57	−0·56	−0·60
40·0	−0·53	−0·68	−0·68	−0·68
80·0	−0·68	−0·70	−0·69	−0·70
100·0	−0·70	−0·78	−0·71	−0·71

The overvoltages are discussed below.

O. Bauer observed with electrolytic iron in a 1 per cent. soln. of sodium chloride a potential of −0·363 volt at the start; −0·479 volt in 1 hr.; −0·739 volt in 24 hrs.; and −0·755 volt in 120 hrs. For cast iron, the potential at the start was −0·628 volt; −0·740 volt after 2 hrs.; and −0·765, and −0·762 volt after 24 and 120 hrs. respectively. For mild steel, with 0·036 per cent. carbon, −0·575 volt at the start; −0·688 volt after 5 hrs.; and −0·755 volt after 120 hrs. For 0·86 per cent. carbon steel, −0·528 volt at the start; −0·626 volt after 1 hr.; −0·700 volt after 5 hrs.; and −0·744 volt after 120 hrs.

For an acidified soln. of N-$FeSO_4$, F. Haber and F. Goldschmidt gave −0·453, for cast or wrought iron. C. E. Fawsitt found that the proportion of carbon in iron had very little influence on the electrode potential; thus, with

Carbon	0	0·18	0·23	0·40	0·9 per cent.
E_H	−0·356	−0·352	−0·352	−0·351	−0·350 volt

T. W. Richards and G. E. Behr gave −0·72 to −0·74 volt; W. H. Hampton, −0·71 to −0·78 volt; K. Iwase and K. Miyazaki, −0·66 to 0·669 volt; and S. Sato, −0·68 volt. Observations on the electrode potential of iron in soln. of ferrous sulphate were also made by A. Finkelstein, T. W. and W. T. Richards, H. Endo and S. Kanazawa, K. Murata, E. Heyn and O. Bauer, E. Grave, B. Strauss, W. J. Sweeney, N. T. M. Wilsmore, S. Labendzinsky, and W. H. Walker and C. Dill. According to F. Förster, the effect of time on the electrode potential of iron in N-$FeSO_4$ containing 0·5 per cent. of boric acid is as follows:

Time		0	5	45	60	120 minutes
E_H	0°	−0·515	−0·479	—	−0·460	−0·460 volt
	20°	−0·480	−0·474	−0·460	−0·460	−0·460 „

C. A. Lobry de Bruyn also noted that with $0{\cdot}1N$-$FeSO_4$ in an atm. of hydrogen, the potential originally at —0·422 volt rises, when the soln. is exposed to air, and attains —0·387 volt in 24 hrs. G. Grube and H. Gmelin gave for a soln. of $0{\cdot}0242M$-Na_2FeO_2 in 40 per cent. sodium hydroxide, $E_H=-0{\cdot}855$ volt. A. Finkelstein gave —0·10 volt for iron against N-K_4FeCy_6; and W. van Wüllen-Scholten calculated from the solubility product of ferrous hydroxide, —0·569 volt for the electrode potential of iron against ferrous hydroxide. V. Nejedly gave for the e.m.f., $E=1{\cdot}320$ volt, and for the temp. coeff., $dE/d\theta=-0{\cdot}0011$, for iron and a soln. of $0{\cdot}001N$-$FeCl_2$ and $0{\cdot}01N$-KCl. According to W. H. Hampton, the potential of different varieties of iron against a $0{\cdot}1M$-soln. of ferrous chloride were for iron amalgam, 0·8090 volt; for finely-divided iron reduced from ferric oxide, 0·8088 volt. T. Mashimo observed that with iron electrodes in $0{\cdot}5M$-$FeCl_3$, and one electrode subjected to mechanical agitation and a magnetic field, the potential at the disturbed electrode was positive, and the other one, negative.

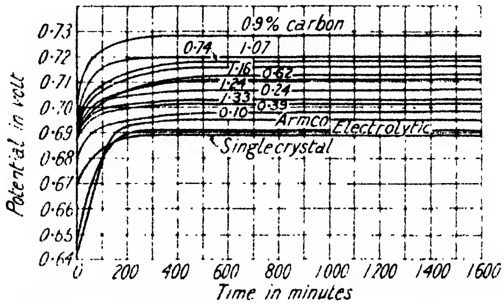

FIG. 266.—The Electrode Potentials of Iron and Steel.

H. Endo and S. Kanazawa measured the electrode potential of iron and steel with varying proportions of carbon, and the results are summarized in Fig. 266. The electrolyte was N-$FeSO_4$ against a normal calomel electrode. The electrolytic iron was re-melted. Forged iron gives the largest potential, cast iron comes next, and annealed iron gives the smallest potential. The effect of a roughened surface is greater than that of the carbon in steels. Thus, with electrolytic iron having the surface polished, with electrolytic iron unpolished, and with electrolytic iron heated for 15 hrs. at 250° to 300° in order to remove hydrogen and then polished:

	Electrolytic iron (polished)				Electrolytic iron (not polished)				Electrolytic iron (dehydrogenized and polished)			
Time .	2	62	222	3007	2	58	142	3143	5	79	372	3105
E.m.f.	0·647	0·705	0·734	0·738	0·656	0·740	0·755	0·750	0·696	0·729	0·732	0·733

The results with annealed and with fine globularized steel having 0·9 per cent. of carbon show that the annealed steel is at first a little more electropositive than the fine globularized steel, but it soon becomes electronegative, reaches a maximum, and then decreases to an asymptotic value 0·016 volt. With coarse globularized steel, the potential has an opposite sign to that of the fine globularized specimen. G. N. Glasoe studied the contact potential of iron and nickel.

The **normal potentials $Fe\rightarrow Fe^{\cdot\cdot\cdot}$** for iron in soln. of ferric salts, cannot be measured directly, because iron reduces soln. of ferric salts to the ferrous state. Applying R. Luther's study of the oxidation of iron in stages, K. Jellinek and H. Gordon, R. Abegg and co-workers, F. Auerbach, and C. Drucker found that the resultant of the operations $Fe\rightleftharpoons Fe^{\cdot\cdot}$ and $Fe^{\cdot\cdot}\rightleftharpoons Fe^{\cdot\cdot\cdot}$ is $Fe\rightleftharpoons Fe^{\cdot\cdot\cdot}$; so that the work, W, will be $W_{Fe\rightleftharpoons Fe^{\cdot\cdot}}+W_{Fe^{\cdot\cdot}\rightleftharpoons Fe^{\cdot\cdot\cdot}}$. If C denotes unit charge, $2CE_{Fe\rightleftharpoons Fe^{\cdot\cdot}}+CE_{Fe^{\cdot\cdot}\rightleftharpoons Fe^{\cdot\cdot\cdot}}=3CE_{Fe\rightleftharpoons Fe^{\cdot\cdot\cdot}}$, or $E_{Fe\rightleftharpoons Fe^{\cdot\cdot\cdot}}=\frac{1}{3}(2E_{Fe\rightleftharpoons Fe^{\cdot\cdot}}+E_{Fe^{\cdot\cdot}\rightleftharpoons Fe^{\cdot\cdot\cdot}})$. Again, for the reaction $Fe\rightleftharpoons Fe^{\cdot\cdot\cdot}$, $E=E_0+\frac{1}{3}0{\cdot}058\log[Fe^{\cdot\cdot\cdot}]$, on the assumption that the concentrations $[Fe^{\cdot\cdot}]$ and $[Fe^{\cdot\cdot\cdot}]$ are the same. By substituting the value of E for $Fe\rightleftharpoons Fe^{\cdot\cdot}$ and $Fe^{\cdot\cdot}\rightleftharpoons Fe^{\cdot\cdot\cdot}$, where $[Fe^{\cdot\cdot}]$ is the same, then, for $Fe\rightleftharpoons Fe^{\cdot\cdot\cdot}$ $E_0=\frac{1}{3}\{2(-0{\cdot}43)+0{\cdot}75\}=-0{\cdot}037$, that is, —0·04 nearly. G. Grube and H. Gmelin obtained $E_H=-0{\cdot}09$ volt. C. E. Fawsitt obtained values ranging from —0·128 to —0·234 volt for the electrode potential of different varieties of iron in N-$FeCl_3$; and A. Finkelstein, $E_H=-0{\cdot}09$ volt for iron in N-K_3FeCy_6. W. van Wüllen-Scholten calculated

$-0{\cdot}220$ volt for electrode potential of iron against ferric hydroxide from the solubility product of hydrated ferric oxide.

R. Peters studied the **normal potential : $Fe^{\cdot\cdot}\rightleftharpoons Fe^{\cdot\cdot\cdot}$,** where $E=E_0+0{\cdot}0577 \log [Fe^{\cdot\cdot\cdot}]/[Fe^{\cdot\cdot}]$, where $[Fe^{\cdot\cdot\cdot}]$ and $[Fe^{\cdot\cdot}]$ represent the respective ionic concentrations. The value of E_0 here works out to be $E_0=0{\cdot}0577 \log K$, where K is the equilibrium constant. By working with a normal mercury electrode, $Hg : HgCl . N\text{-}KCl : FeCl_2 . FeCl_3 : Pt$, where there is the reaction $Hg+Fe^{\cdot\cdot}+Cl'\rightleftharpoons Fe^{\cdot\cdot}+HgCl$. The current ceases when the free energy of the reaction : $Hg+Cl'\rightleftharpoons HgCl$ is equal to that of the reaction : $Fe^{\cdot\cdot}\rightleftharpoons Fe^{\cdot\cdot\cdot}$. For equilibrium, $[Fe^{\cdot\cdot}][HgCl]/[Hg][Fe^{\cdot\cdot\cdot}][Cl']$, or $K=[Fe^{\cdot\cdot}]/[Fe^{\cdot\cdot\cdot}]$ since the concentrations of the solids, and $[Cl']$ can be regarded as constant. Consequently, for the reaction $Fe^{\cdot\cdot}\rightleftharpoons Fe^{\cdot\cdot\cdot}$, $E=0{\cdot}0577 \log K+0{\cdot}058 \log [Fe^{\cdot\cdot\cdot}]/[Fe^{\cdot\cdot}]$. When $K=[Fe^{\cdot\cdot}]/[Fe^{\cdot\cdot\cdot}]$, E is zero, R. Peters measured E_c for soln. containing different proportions of ferrous and ferric salts, at 17°, and obtained :

$Fe^{\cdot\cdot}$.	0·5	1·0	10	20	40	60	80	99·5
$Fe^{\cdot\cdot\cdot}$.	99·5	99·0	90	80	60	40	20	0·5
E . .	0·296	0·312	0·375	0·391	0·419	0·436	0·462	0·545
E_0 . .	0·428	0·427	0·430	0·426	0·429	0·426	0·427	0·413

The best representative value of E_0 is 0·427 obtained from $E_0=E_c-0{\cdot}0577 \log [Fe^{\cdot\cdot\cdot}]/[Fe^{\cdot\cdot}]$, and since $E_0=0{\cdot}577 \log K$, $\log K=7{\cdot}45$, or $K=10^{7\cdot45}$. By the addition of potassium chloride, the value of K was diminished, the mean value obtained being $10^{7\cdot15}$. In neutral solutions, the potential was found to vary considerably with dilution, but this was not the case in acid soln. or in soln. containing potassium chloride. Solutions in a normal soln. of sodium nitrate gave values almost identical with those in pure water, so that ferric chloride and ferric nitrate are equally dissociated. In the case of mixtures of ferric and ferrous sulphates, the value of K was found to be $10^{6\cdot6}$, so that at equal concentrations ferric sulphate gives fewer ferric ions than the chloride. The addition of fluorine ions in all cases raises the reduction potential, and this effect was further examined. The conductivity of mixtures of iron salts with sodium fluoride is less than the sum of conductivities of the constituents, the difference being greatest with ferric compounds, in which case also it increases with dilution. The ferric salts, therefore, probably form complex compounds with the sodium fluoride, a view further supported by f.p. determinations. By the addition of sodium fluoride to the mixed iron salts the e.m.f. falls greatly ; thus, in the case of a mixture of $0{\cdot}1N$ ferrous and ferric salts the addition of an equal vol. of $0{\cdot}3N$-soln. of sodium fluoride caused the e.m.f. to become negative, or decreased the conc. of the ferric ions to 10^{-75} of its former amount. A white salt is also precipitated by the fluoride, and the composition was found to be $Na_3FeF_6\frac{1}{2}H_2O$. This was proved to be a complex salt in which the iron is present in the anion, as by electrolysis the percentage of iron increased at the anode and decreased at the cathode. It is probable that the reduction of the e.m.f. by addition of sodium fluoride is due to the formation, not only of the slightly dissociated ferric fluoride, but also of this salt. Confirmatory results were obtained by C. Fredenhagen ; he also found for the calomel electrode $E_0=0{\cdot}987$, or with the hydrogen electrode, in agreement with R. Peters, 0·710 volt. G. Grube found that with (i) a soln. of 250 c.c. of $0{\cdot}5M\text{-}K_3FeCy_6$ with 750 c.c. of $0{\cdot}5M\text{-}K_4FeCy_6$, and (ii) a soln. of 750 c.c. of the former and 250 c.c. of the latter :

	(i)			(ii)		
C . .	0	0·002	0·01	0·1	0·5	2·0
E_H . .	0·456	0·436	0·463	0·523	0·531	0·555 volt

W. Maitland obtained for the equilibrium constant, $K=10^{7\cdot8}$; and calculated for E_0, for the hydrogen electrode, 0·743 volt. R. Abegg and J. Neustadt gave 0·066 volt for E_0 in the reaction $Fe^{\cdot\cdot}\rightleftharpoons Fe^{\cdot\cdot\cdot}$ in pyridine soln. Observations were also made by C. Drucker, F. Auerbach, E. Müller and J. Janitzki, S. R. Carter and T. J. Glover, S. R. Carter and F. H. Clews, S. Popoff and co-workers, L. Michaelis and E. Friedheim, L. Michaelis and C. V. Smythe, K. Masaki and T. Ikkatai, T. J. Glover, and K. Jellinek and H. Gordon. R. Abegg and co-workers gave for the best representative value, with the hydrogen electrode, $E_0=0\cdot75$ volt, so that for the reaction $Fe^{\cdots}\rightleftharpoons Fe^{\cdot\cdot}$ at 18°:

$$E_H=0\cdot75+0\cdot058\log[Fe^{\cdots}]/[Fe^{\cdot\cdot}]\text{ volt} \quad . \quad . \quad . \quad . \quad . \qquad (2)$$

R. Peters gave 0·296 volt for the e.m.f. of the cell Pt : $0\cdot0005N$-$FeCl_3.0\cdot0995N$-$FeCl_2$, $0\cdot1N$-HCl, $1\cdot0N$-KCl, Hg_2Cl_2 : Hg, at 17°; 0·522 volt at 17° for Pt : $0\cdot098N$-$FeCl_3$, $0\cdot002N$-$FeCl_2$, $0\cdot1N$-HCl, $1\cdot0N$-KCl, Hg_2Cl_2 : Hg; 0·429 volt at 17° for Pt : $0\cdot045N$-$Fe_2(SO_4)_3$, $0\cdot01N$-$FeSO_4$, $0\cdot1N$-H_2SO_4, $1\cdot0N$-KCl, Hg_2Cl_2 : Hg; 0·331 volt at 17° for Pt : $0\cdot005N$-$Fe_2(SO_4)_3$, $0\cdot09N$-$FeSO_4$, $0\cdot1N$-H_2SO_4, $1\cdot0N$-KCl, Hg_2Cl_2 : Hg. H. Schäfer gave 0·295 volt at 25° for Pt : $0\cdot01N$-$(NH_4)_2Fe(SO_4)_2$, $1\cdot0N$-$(NH_4)_2SO_4$, $1\cdot0N$-KCl, Hg_2Cl_2 : Hg; and 0·364 volt when $0\cdot09N$-$(NH_4)_2Fe(SO_4)_2$ is used. A. A. Noyes and B. F. Brann gave for Pt : xN-$Fe(NO_3)_3$, yN-$Fe(NO_3)_2$, $0\cdot05N$-HNO_3, 3·5 or $1\cdot75N$-KCl, $1\cdot0N$-KCl, Hg_2Cl_2 : Hg, at 25°, 0·04486 volt when $x=0\cdot05$ and $y=0\cdot05$; 0·4528 volt when $x=0\cdot0125$ and $y=0\cdot0125$; 0·4726 volt when $x=0\cdot0739$ and $y=0\cdot0293$; and 0·4643 volt when $x=0\cdot0112$ and $y=0\cdot0089$. C. Fredenhagen gave 0·133 volt at 17° for Pt : $0\cdot01N$-K_3FeCy_6, $0\cdot09N$-K_4FeCy_6, $1\cdot0N$-KCl, Hg_2Cl_2 : Hg; and 0·241 volt for Pt : $0\cdot09N$-K_3FeCy_6, $0\cdot01N$-K_4FeCy_6, $1\cdot0N$-KCl, Hg_2Cl_2 : Hg. For Pt : $0\cdot0245N$-K_3FeCy_6, $0\cdot00054N$-Na_4FeCy_6, $0\cdot1N$-KCl, Hg_2Cl_2 : Hg. K. Schaum and R. von der Linde gave −0·170 volt at 25° and −0·143 volt at 50°; and for Pt : $0\cdot00025N$-K_3FeCy_6, $0\cdot0270N$-Na_4FeCy_6, $0\cdot1N$-KCl, Hg_2Cl_2 : Hg, −0·039 volt at 25°, and −0·078 volt at 50°. E. Liebreich discussed the polarization of the cells Fe : Zn, Pb : Zn, and C : Fe, Hg : Fe.

S. Popoff and co-workers measured the oxidation-reduction potential with the ferric-ferrous electrode, $Pt.H_2 \mid HCl \mid HCl, FeCl_2.FeCl_3 \mid Pt$, with different concentrations of acid, and obtained the results shown in Fig. 267. The normal value is −0·7473 to −0·7476 volt. G. Grube represented the variation of the potential of the anode with current density by Fig. 268, and comparing the result with platinum, in neutral soln., it shows how very strong the polarization is with the iron anode which forms a surface film of oxide. Observations were made by W. J. Müller and co-workers, J. Hinnüber, and S. R. Carter and F. H. Clews. N. Isgarischeff and A. Turkovskaja studied the effect of various salts on the oxidation-reduction potentials of the $Fe^{\cdots}-Fe^{\cdot\cdot}$-system, and found that the e.m.f., E_H, is increased by the addition of cadmium chloride, and is diminished by the addition of various other chlorides in the following order: action of $LiCl<MgCl_2<CaCl_2<BaCl_2<NaCl<KCl<NH_4Cl$; zinc chloride lowers E_H at concentrations below normal and raises E_H at higher concentrations, whilst the action of the remaining chlorides increases with their concentration. Nitrates raise the E_H value proportionately to their concentration in the order: action of $NH_4NO_3<KNO_3<NaNO_3<Sr(NO_3)_2<Ca(NO_3)_2<LiNO_3<Mg(NO_3)_2<Cd(NO_3)_2$. The addition of sodium bromide

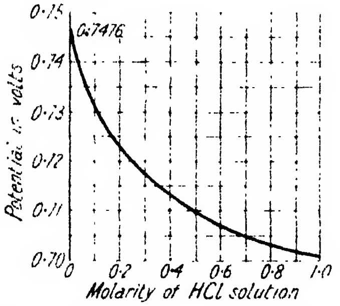

FIG. 267.—The Effect of Acid on the Oxidation-Reduction Potential of the Ferrous-Ferric Electrode.

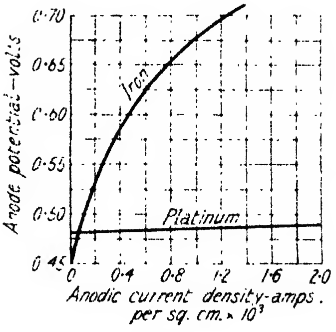

FIG. 268.—The Effect of Current Density on the Anode Potential of Iron.

raises E_H more than does sodium nitrate, and sodium sulphate depresses E_H to a greater extent than does sodium chloride. The above effects cannot be attributed to variations in p_H consequent on the addition of these salts, or to the formation of complex double salts with iron chlorides. S. Bodforss found that the potential of iron is a linear function of the H$^{\cdot}$-ion concentration of the soln. K. Murata, E. Liebreich, and J. Glover studied the subject. W. van Wüllen-Scholten found the potential of iron to ferrous hydroxide is —0·569 volt, and to ferric hydroxide, —0·220 volt, but in the presence of oxygen, a solid soln. of the two hydroxides occurs as a single phase where the ratio $Fe^{\cdot\cdot\cdot}/Fe^{\cdot\cdot}$ in the phase is dependent on the oxygen conc. of the soln.

K. Zang measured the oxidation of ferrous chloride soln., after the lapse of different intervals of time: $4Fe^{\cdot\cdot}+O_2+2H_2O\rightleftharpoons 4Fe^{\cdot\cdot\cdot}+4(OH)^1$, or $Fe^{\cdot\cdot}\rightleftharpoons Fe^{\cdot\cdot\cdot}+\ominus$. This represents the first phase of the reaction, and K. Zang assumed that in the second phase, the oxygen reacts with the electrons, and with this hypothesis deduced the equation $dx/dt=k_0(a-x)/x$. Let a denote the original conc. of the soln., and x the conc. of the ferric salt at the time t, then $k_1t=\log\{(a-x_0)/(a-x)\}$ represents the value of k_1 for a unimolecular reaction; let k_2 denote the constant for a bimolecular reaction; and k_0 the constant for the reaction whose speed is $dx/dt=k_0(a-x)/x$. The following is a selection from the observed results:

t	Potential	$x\times10^3$	$k_1\times10^4$	$k_2\times10^2$	$k_0\times10^6$
0	254·2	0·23	—	—	—
2	300·0	0·47	13·8	1·90	—
20·0	335·3	2·6	13·9	1·61	1·5
67·5	352·8	5·4	9·1	1·06	2·6
118·0	362·3	7·6	7·5	0·92	3·7
193·0	369·8	9·4	5·8	0·69	2·7
312·5	377·0	12·7	4·9	0·60	3·2
481·5	383·8	16·2	4·4	0·54	3·5

After a period of induction, the constancy of k_0 is taken to mean that the original hypothesis is confirmed.

According to C. Benedicks and R. Sundberg, the potential, E_H, of a metal in a soln. entirely devoid of oxygen—the hydrogen potential—and the potential, E_0, of a metal in a soln. containing oxygen—the oxygen potential—then, for quenched carbon steels, the H-potential is reduced irregularly from —0·745 volt down to —0·64 volt as the proportion of carbon increases, while the O-potential rises and also shows irregularities. For unquenched steels, the value for the H-potential falls as the proportion of carbon rises to 0·9 per cent., and then rises as the proportion of carbon increases still more. For steels with up to 0·9 per cent. of carbon, c, the value of $E_H=-0{\cdot}708+0{\cdot}010c$ volt. The O-potential rises from 0·311 volt as the carbon increases, and the results, though irregular, act like those with the H-potential but in the converse way.

For the **normal potential : Fe→Fe$^{\cdot\cdot\cdot\cdot\cdot\cdot}$**, G. Grube and H. Gmelin obtained $E_H=-0{\cdot}13$ volt; and with iron against 0·1M-Na_2FeO_4 in 40 per cent. sodium hydroxide, at 25°, the results were not constant, because the ferrate is reduced to ferrite in contact with iron.

Measurements of the electrode potential of iron against distilled *water*, and sea-water were made by T. Andrews, K. Arndt, F. Haber, F. Haber and P. Krassa, K. Hasegawa and S. Hori, E. Heyn and O. Bauer, A. de Méritens, W. Muthmann and F. Fraunberger, and F. H. Rhodes and E. B. Johnson. The electrode potential of iron against soln. of *ammonium hydroxide* was measured by A. Finkelstein, and M. Mugdan; against soln. of *sodium hydroxide*, by G. Grube and H. Gmelin, F. Haber and F. Goldschmidt, E. Heyn and O. Bauer, P. Krassa, M. Mugdan, and W. Pick; against soln. of *potassium hydroxide*, by J. Billiter, O. Faust, F. Förster and V. Herold, C. Fredenhagen, E. Grave, G. Grube and H. Gmelin, P. Krassa, M. Mugdan, W. Muthmann and F. Fraunberger, W. Pick, E. P. Schoch and C. P. Randolph, and J. Woost; and against a soln. of *calcium hydroxide*, by F. Haber and F. Goldschmidt, and E. Heyn and O. Bauer.

The electrode potential of iron in *hydrochloric acid* was measured by M. Centnerszwer and M. Straumanis, A. Thiel and K. Keller, and W. Muthmann and F. Fraunberger; of iron in a soln. of *potassium chloride*, by T. P. Hoar and U. R. Evans, and F. Vles and A. Ugo; and of iron in *sulphuric acid*, by T. Andrews, H. G. Byers and C. W. Thing, H. G. Byers and S. C. Langdon, M. Centnerszwer and M. Straumanis, C. Fredenhagen, E. Grave, W. J. Müller and O. Löwy, M. Mugdan, and A. Thiel and K. Keller. C. G. Fink and C. M. Decroly found the electrode potential of electrolytic iron in sulphuric acid of the percentage composition

H_2SO_4 .	0·45	2·40	5·14	9·92	17·54	32·03	54·69 per cent.
E . .	−0·941	−0·916	−0·928	−0·905	−0·872	−0·827	−0·715 volt

A. L. McAulay and G. L. White's results for the effect of the $H^{\cdot}$-ion concentration, represented by p_H, on the electrode potential of iron in air-free, 0·2*N*-KCl, are summarized in Fig. 269. The curve with a 0·2*M*-phosphate soln. is dotted in Fig. 269. H. G. Byers and S. C. Langdon, J. P. Hoar and U. R. Evans, and W. J. Müller and K. Konopicky measured the electrode potential of iron against sulphuric acid in the presence of hydrogen, and also oxygen; E. Grave, likewise against sulphuric acid in the presence of ozone, and also of hydrogen dioxide. C. Fredenhagen, W. J. Müller, and W. Muthmann and F. Fraunberger measured the electrode potential of iron against *nitric acid*—the passive state; E. Heyn and O. Bauer, against *arsenious acid*; E. Heyn and O. Bauer, W. Muthmann and F. Fraunberger, and G. C. Schmidt, against *dichromic acid*; and M. Mugdan, against *acetic acid*. Measurements of the potential are also discussed in connection with the passivity of iron.

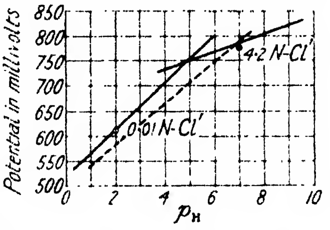

FIG. 269.—Equilibrium Potentials of Iron with Solutions of Different $H^{\cdot}$-ion Concentration.

J. H. Andrew and co-workers measured the electrode potentials of steels against a soln. of ferric chloride and a normal calomel electrode with the idea of finding the effect of heat-treatment, and the state of the carbon in the alloys. The results are indicated in Figs. 270 and 271. The electrode potential of quenched steels—with

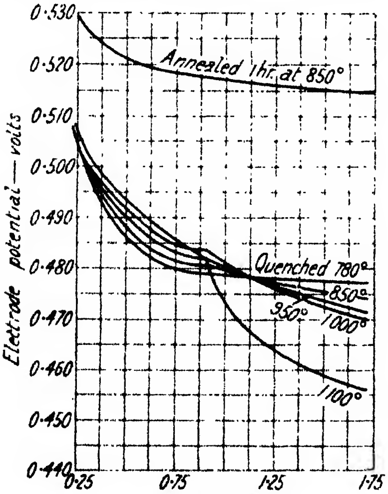

FIG. 270.—The Electrode Potentials of Carbon Steels Quenched at Different Temperatures.

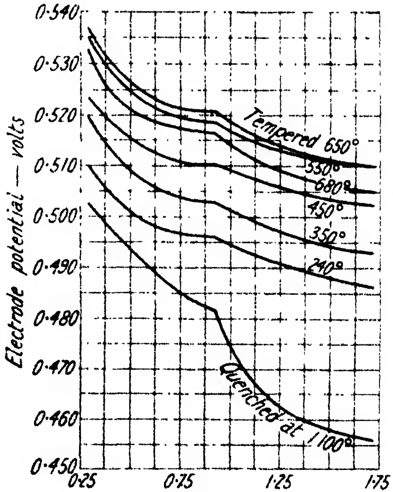

FIG. 271.—The Electrode Potentials of Carbon Steels Tempered at Different Temperatures.

α-iron—decreases as the proportion of carbon increases, so that the iron is rendered less active by dissolved carbon. The potential of hypoeutectoid steels is increased by raising the quenching temp., so that with an increase in the quenching temp., the least concentrated area of the solid soln. becomes less concentrated in carbon. J. H. Andrew and R. Hay found that carbide segregation occurs on soaking at a temp. above the Ac$_3$-arrest. The potential of hypereutectoid steels is lowered by an increase in the quenching temp. There is a marked deviation of the curve for hypereutectoid steels quenched at 1100° from that obtained for the same steel quenched at 1000°. Steels with over 1·2 per cent. of carbon, and quenched at 1100°, contain austenite, but since austenite is less active than martensite this does not explain the deviation of the curve at 1100°. The curves probably mean that the martensite obtained by quenching high-carbon steels from 1100° is much more concentrated than that obtained by quenching at 1000°. This may be due (i) to the cementite line being more curved than is generally assumed, so that the solubility of carbon in γ-iron at 1100° is much greater than it is at 1000°—this is not in accord with measurements of the electrical resistance; or (ii) that so long as particles of cementite in hypereutectoid steels remain undissolved before quenching, they may act as nuclei and cause a partial precipitation of the carbide even with rapid cooling.

The curves, Fig. 271, show that the electrode potential increases progressively with the raising of tempering temp., showing that the proportion of carbon in soln. is reduced by tempering. After tempering at any temp. up to, say, 450°, an appreciable amount of carbon remains in soln., and this proportion is reduced by raising the tempering temp. On heating quenched steels to a given temp., tempering proceeds until a limiting value is attained, after which it either stops or proceeds very slowly. A similar conclusion was inferred from measurements of the electrical resistance. The potential curve obtained after tempering at 680° lies below that obtained at 650°, indicating that carbon dissolves in α-iron below the Ac$_1$-arrest. C. F. Brush and R. A. Hadfield, and others have investigated the evolution of heat by a quenched steel at room temp.; and the effect of ageing on the potential of steel immediately after quenching, and after remaining at room temp. for different periods of time is indicated in Fig. 272. The potential decreases with time; this may be due to the relief of the strains caused by quenching. The electrode potentials at 18° of carbon steels quenched at 1100° and at 780°, and chromium steels at 1100°, did not change appreciably before and after immersion in liquid air. This indicates that austenite, unlike martensite, is not affected by liquid air. W. H. Walker and C. Dill discussed the electrode potential and the structure of iron.

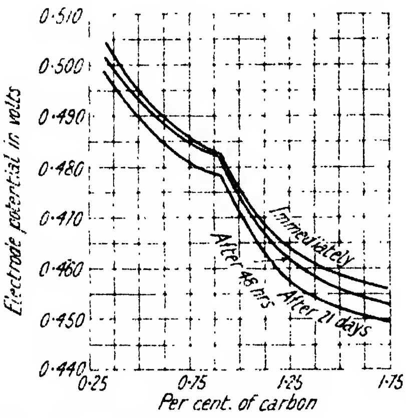

FIG. 272.—The Effect of Time on the Electrode Potential of Carbon Steels Quenched at 1100°.

M. Faraday studied the **electrochemical series,** and found that iron in nitric, hydrochloric, or sulphuric acid is negative towards bismuth, copper, and antimony, and positive towards tin, lead, cadmium, and zinc; in soln. of potassium hydroxide, iron is negative towards copper, silver, and nickel, and positive towards bismuth, lead, antimony, cadmium, tin, and zinc; and in yellow and colourless soln. of potassium sulphide, iron is positive towards many metals. According to J. C. Poggendorff, and S. B. Christy, iron in soln. of potassium cyanide is negative towards palladium, silver, carbon, and platinum, and positive towards nickel, bismuth, tin, antimony, copper, lead, cadmium, and zinc. S. B. Christy found that in distilled water, iron is positive towards zinc, and lead, and negative towards copper, silver, mercury, and gold. R. Abegg and co-workers gave for the electrochemical series —Li, K, Na, Mg, Zn, **Fe**, Cd, Co, Ni, Pb, Sn, H, Cu, Ag, Hg, Au+ ; F. Streintz gave for soln. of the metal in nitrate soln., —Mg, Zn, Cd, Sn, Al(Pb), Fe, Co, Bi, Ni, Cu, and Ag+ ; and in chloride soln., —Mg, Zn, Al, Cd, Fe, Sn, Bi, Co, Sb, and Cu+. C. B. Gates, and G. Gore studied the place of iron in the electrochemical series in molten salts, and in non-aqueous solvents ; and A. S. Russell found for iron in mercury, —Zn, Cd, Tl, Pb, Co, Mn, Fe, Bi, Co, Hg, Ni, and Pt+. T. Andrews studied the electrochemical series with different forms of iron and steel in sea-water, and in salt soln. ; whilst A. Schleicher found that the order with iron is + passive wrought iron, rusted cast iron, rusted wrought iron, wrought iron, passive cast iron, cast iron — ; and for steels, + nickel steel (25 : 75), nickel steel (5 : 95), chrome steel, tungsten steel, and cast steel (0·1 per cent. carbon). G. N. Glasoe gave 0·20 volt for the contact potential of nickel and iron.

The electrode potential of iron in *hydrofluoric acid* was examined by C. Bedel, and A. Travers and J. Aubert ; in an aq. soln. of *sodium fluoride*, by M. Mugdan ; in pyridine soln. of *lithium chloride*, by H. Eggert ; in acetone soln. of lithium chloride, by U. Sborgi and P. Marchetti ; in aq. soln. of *sodium chloride*, by T. Andrews, E. Heyn and O. Bauer, R. Lorenz, A. L. McAulay and F. P. Bowen, M. Mugdan, E. Petersen, and W. van Wüllen-Scholten ; *ammonium chloride*, by E. Heyn and O. Bauer ; in aq. soln. of *potassium chloride*, by K. Arndt, U. R. Evans, E. Heyn and O. Bauer, M. Mugdan, W. Muthmann and F. Fraunberger, G. C. Schmidt, W. H. Walker and co-workers ; in aq. soln. of different acidities, by F. Vles and A. Ugo ; in methyl alcohol soln. of potassium chloride, by H. Eggert ; in aq. soln. of *potassium bromide*, by M. Mugdan ; *potassium iodide*, by M. Mugdan, and G. C. Schmidt ; *potassium chlorate*, by M. Mugdan, E. Heyn and O. Bauer, and E. P. Schoch and C. P. Randolph ; *perchloric acid*, by A. Travers and J. Aubert ; *potassium perchlorate*, by M. Mugdan, and E. P. Schoch and C. P. Randolph ; *potassium bromate*, E. Heyn and O. Bauer, and E. P. Schoch and C. P. Randolph ; *potassium iodate*, by E. Heyn and O. Bauer, and E. P. Schoch and C. P. Randolph ; *calcium, barium, and magnesium chlorides*, by E. Heyn and O. Bauer ; in *sodium hydroxide*, by C. Bedel ; *stannous chloride* and hydrochloric acid, by A. Thiel and K. Keller ; *ammonium hydrosulphide*, by A. Finkelstein ; *sodium hydrosulphide*, by R. Zuppinger ; *sodium sulphate*, by H. G. Byers and C. W. Thing, and E. Heyn and O. Bauer ; *sulphuric acid*, by W. Wolff, A. Travers and J. Aubert, and C. Bedel ; *potassium sulphate*, by U. R. Evans, E. Heyn and O. Bauer, J. F. G. Hicks, A. L. McAulay and S. H. Bastow, M. Mugdan, and E. P. Schoch and C. P. Randolph ; and soln. of potassium sulphate mixed with sulphuric acid, potassium hydroxide, potassium fluoride, or potassium dichromate, by E. P. Schoch and C. P. Randolph ; *ammonium, magnesium and manganese sulphates*, by E. Heyn and O. Bauer ; acetone soln. of *silver nitrate*, by U. Sborgi and P. Marchetti ; ethyl alcohol soln. of *ammonium and calcium nitrates*, by U. Sborgi and G. Cappon ; *stannous sulphate* and sulphuric acid, by A. Thiel and K. Keller ; *sodium nitrate*, by E. Heyn and O. Bauer ; *potassium nitrate*, by M. Mugdan ; potassium nitrate with nitric acid or potassium hydroxide, by E. P. Schoch and C. P. Randolph ; *ammonium nitrate*, by E. Heyn and O. Bauer ; *silver nitrate*, by O. Kohlschütter and co-workers ; *ammonium, and sodium hydrophosphates*, by E. Heyn and O. Bauer ; *phosphoric acid*, by A. Travers and J. Aubert ; *sodium carbonate, and hydrocarbonate*, by F. Haber and F. Goldschmidt, and E. Heyn and O. Bauer ; *potassium carbonate*, and *calcium hydrocarbonate*, by E. Heyn and O. Bauer ; *sodium acetate*, by E. Heyn and O. Bauer, and M. Mugdan ; *ammonium acetate*, by E. Heyn and O. Bauer ; *potassium cyanide*, by A. Brochet and J. Petit, F. C. Frary and R. E. Porter, S. B. Christy, A. Finkelstein, C. B. Gates, E. Heyn and O. Bauer, W. Muthmann and F. Fraunberger, and A. van Oettingen ; *potassium thiocyanate*, by W. Muthmann and F. Fraunberger ; *sodium tetraborate*, by E. Heyn and O. Bauer ; *potassium chromate*, by E. Heyn and O. Bauer, and E. P. Schoch and C. P. Randolph ; *potassium dichromate*, by H. G. Byers and C. W. Thing, E. Heyn and O. Bauer, M. Mugdan, and E. P. Schoch and C. P. Randolph ; and *potassium permanganate*, by E. Heyn and O. Bauer, and M. Mugdan.

The **electromotive force** of a large variety of single, double, or more cells has been determined.

Single liquid cells.—In cells with one electrolyte and iron : Fe | solution | metal, C. Barus studied cells with water and steel annealed at different temp. R. B. Clifton observed that copper is positive and zinc negative with *water* as electrolyte. N. R. Dhar, that tin is positive ; C. A. Lobry de Bruyn, that aluminium is negative ; and F. Tödt, that platinum is positive. A. de la Rive observed that tin is positive and copper negative with a soln. of *ammonia* as electrolyte, and combinations with silver, platinum, copper, and tin were studied by J. C. Poggendorff ; F. F. Runge, and E. Branly found that with *potassium hydroxide* soln. zinc is negative, and J. C. Poggendorff studied the combinations with copper, silver, zinc, cadmium, mercury, tin antimony, or platinum. P. Bechtereff found that carbon with a 20 per cent. soln. of *sodium hydroxide* gives $E=0{\cdot}9$ volt at 95°; F. Tödt examined cells with sodium hydroxide soln. and platinum; and F. Jirza, with silver; J. C. Poggendorff also studied cells with *hydrochloric acid* and copper, silver, zinc, cadmium, mercury, tin, antimony, or platinum; C. L. Speyers, combinations with hydrochloric acid and mercury. M. Centnerszwer and M. Straumanis found that with hydrochloric acid of concentration 0·5, 0·25, and 0·1 eq. per litre against platinum at 25°, E was respectively 0·101, 0·116, and 0·152 volt. M. Centnerszwer found aluminium is negative in $0{\cdot}5N$-HCl. M. Centnerszwer and M. Straumanis found with a $0{\cdot}1N$-soln. of *hydrobromic acid* and platinum, $E=0{\cdot}109$ volt at 25°. K. W. G. Kastner studied combinations with a soln. of *sodium chloride* with zinc as the negative pole, and observations were also made by J. C. Poggendorff with the same soln. and copper, silver, zinc, cadmium, mercury, antimony or platinum; F. Tödt studied cells with $0{\cdot}01N$-NaCl and zinc. U. R. Evans studied a cell with $0{\cdot}5N$-NaCl and aerated and non-aerated electrodes. E. J. Micheli found copper is positive in a soln. of sodium chloride; R. Lorenz, that copper oxide is positive under similar conditions; and E. Liebreich measured the effect of coating the iron with red-lead, ferric oxide, zinc-white, white-lead, or varnish. W. van Wüllen-Scholten measured the e.m.f. of cells with rough and smooth iron in soln. of sodium chloride. N. R. Dhar found tin is positive with a soln. of *potassium chloride*, and C. A. Lobry de Bruyn, that aluminium is negative. N. R. Dhar studied the e.m.f. of iron against soln. of potassium chloride. E. Liebreich and co-workers found that with $0{\cdot}1N$-KCl at 20°, and ferric oxide, $E=0{\cdot}09$ volt, with zinc oxide, 0·150 volt, with lead carbonate, 0·095 volt, and with red-lead, 0·075 volt. U. R. Evans studied a cell with $0{\cdot}1N$-KCl and steel electrodes one of which was aerated. N. Vlacovich found that zinc is negative with a soln. of *ammonium chloride*. J. C. Poggendorff studied the combinations with a hydrochloric or sulphuric acid, or an aq. soln. of *potassium iodide*, or of *potassium bromide* and copper, silver, zinc, cadmium, mercury, tin, antimony, or platinum. M. Randall and M. Frandsen found that the cell Fe, $Fe(OH)_2$ against $0{\cdot}05M$-soln. of *barium hydroxide*, and HgO, Hg, had an e.m.f. of 0·973 volt at 25° with highly purified iron. E. L. Nichols and W. S. Franklin found that platinum is negative in a soln. of *ferrous chloride*; W. H. Hampton studied the cell with iron against $0{\cdot}1M$-$FeCl_2$ and HgCl, Hg, and gave 0·4413 for the electrode potential of iron. The cell was studied by M. Randall and M. Frandsen. E. Petersen found that the cell with carbon and $2N$-soln. of *ferric chloride* gives 0·90 volt; W. Spring, that with conc. ferric chloride, carbon or platinum is positive—the cell with carbon was also studied by A. A. Beadle, F. W. Küster, H. Pauling, and E. Petersen. E. Petersen found that zinc is negative with $2N$-$FeCl_2$ with 20 per cent. of sodium chloride, and $E=0{\cdot}537$ volt. W. H. Hampton obtained $E=0{\cdot}8088$ volt with a cell having $0{\cdot}2N$-$FeCl_2$ and a calomel electrode. Zinc is negative with a soln. of *zinc chloride*. E. L. Nichols and W. S. Franklin found that platinum is positive with a dil. hydrochloric acid soln. of potassium chlorate; M. J. Roberts, J. C. Poggendorff, and R. B. Clifton found that with dil. *sulphuric acid*, zinc is negative; M. J. Roberts, and C. Hockin and H. A. Taylor, that zinc amalgam is negative; E. Branly, that copper, platinum, and carbon are positive; P. Casamajor, iron-amalgam is negative. R. B. Clifton found that zinc is negative, and copper and mercury are positive with dil. sulphuric acid. J. C. Poggendorff studied cells with sulphuric acid and an electrode of copper, silver, zinc, cadmium, mercury, zinc amalgam, tin, antimony, or platinum; C. L. Speyers studied cells with sulphuric acid and mercury; and S. P. Thompson, sulphuric acid with an electrode of copper at different temp. A. L. McAulay and S. H. Bastow found that cells with $0{\cdot}5N$-soln. of *potassium sulphate* and a calomel electrode, had E between 0·75 and 0·80 volt. H. L. Heathcote found that iron is negative against passive iron in sulphuric acid (1 : 6); M. Centnerszwer and M. Straumanis gave for platinum against sulphuric acid of concentration C eq. per litre, at 25°:

C-H_2SO_4 . . .	1	0·5	0·25	0·1	0·05
E	0·161	0·163	0·171	0·169	0·171 volt.

A cell with $0{\cdot}5N$-H_2SO_4 and copper had $E=0{\cdot}024$ volt, and with silver, 0·060 volt. W. D. Bancroft studied cells with N- and $2N$-H_2SO_4 and iron electrodes one or both of which was treated with air, hydrogen, nitrogen, or coal gas. M. Centnerszwer examined cells with $0{\cdot}5N$- and $2N$-H_2SO_4 and aluminium. P. Goerens found that with cold-worked iron annealed at 520°, $0{\cdot}1N$-$FeSO_4$, and iron annealed at 520°, the voltage is practically zero. W. Broniewsky found that for soft steel, N-$FeSO_4$, and steel with

	Carbon	0·24	0·44	0·79	5·12 per cent.
E	Steel	0·014	0·017	0	0·016 volt
	Steel tempered . . .	0·021	0·027	0·014	0·038 ,,

C. A. Lobry de Bruyn studied cells with a calomel electrode having an electrolyte with a mixture of *ferrous and ferric sulphates*, against soft and hard steels. H. Wolff found that zinc is negative with a soln. of *zinc sulphate*; C. Hockin and H. A. Taylor, that zinc amalgam is negative with a soln. of zinc sulphate; J. C. Poggendorff, and R. T. Lattey and M. W. Perrin studied cells with a sulphuric acid soln. of zinc sulphate and copper, silver, tin, or platinum; and C. Barus and V. Strouhal studied cells with a soln. of zinc sulphate and steel annealed at different temp. G. Tammann and W. Wiederholt studied cells with N-$ZnSO_4$ and copper, silver, gold, zinc, tin, or lead; T. W. and W. T. Richards, ferrous sulphate of concentration C eq. per litre, and a normal calomel electrode at 25°:

C	1·02	0·366	0·327	0·039
E	0·741	0·753	0·759	0·778 volt
C-$FeSO_4$	0·365	0·393	0·366	0·390
C-H_2SO_4	0·001	0·100	0·25	0·50
E	0·753	0·724	0·669	0·634 volt
C-$FeSO_4$	0·329	0·329	0·327	—
C-$Fe_2(SO_4)_3$ . . .	0·003	0·017	0·088	—
E	0·719	0·687	0·630	— volt

F. F. Runge found that with *nitric acid*, mercury is positive; and the same cell was studied by C. L. Speyers. J. C. Poggendorff found that zinc is negative, and he also studied cells with nitric acid and copper, silver, zinc, cadmium, tin, antimony, and platinum; E. L. Nichols and W. S. Franklin showed that carbon is positive with nitric acid; and W. Hittorf, that platinum is negative. C. F. Schönbein studied a cell with dil. nitric acid and lead dioxide. M. Faraday showed that with conc. nitric acid, silver and copper are negative, but with dil. acid, positive; C. A. Lobry de Bruyn, that aluminium is negative with a soln. of *potassium nitrate*; and W. Wolff, that zinc is negative with a soln. of *zinc nitrate*. J. C. Poggendorff studied cells with a soln. of *sodium carbonate*, and copper, silver, zinc, cadmium, mercury, antimony, or platinum; and F. Tödt, cells with sodium carbonate soln. and platinum. S. P. Thompson found that with a soln. of *potassium cyanide*, carbon is positive, and J. C. Poggendorff studied cells with the same soln., and copper, silver, zinc, cadmium, mercury, tin, antimony, or platinum. C. L. Speyers studied cells with *acetic acid* and mercury. M. Dauvé found copper positive in a cell with a soln. of *copper acetate*. J. C. Poggendorff studied cells with *sodium tetraborate* and sulphuric acid and copper, silver, tin, or platinum; E. L. Nichols and W. S. Franklin, W. Kistiakowsky, and A. Naccari and M. Bellati, with *chromic acid* and a carbon positive electrode; and P. Bechtereff, cells with 20 per cent. soda-lye and *potassium permanganate* with a carbon negative electrode, and E. L. Nichols and W. S. Franklin, permanganate with platinum as positive electrode.

Double liquid cells.—M. Faraday observed that iron in a dil. soln. of *potassium hydroxide* is negative against iron in a conc. soln. of the alkali; J. C. Poggendorff, and J. P. Joule, that iron in potash-lye is negative against platinum in nitric acid; J. P. Joule, that iron in potash-lye is negative against platinum in nitric sulphuric acid and lead dioxide, or against copper in sulphuric acid; C. Fredenhagen gave 0·248 volt for iron in N-KOH against N-KCl, Hg_2Cl_2, and mercury. W. Hittorf found that iron in a soln. of *sodium hydroxide* is negative against platinum in chromic acid; and with iron in 0·1N-NaOH + 0·1N-KOH, M. Mugdan found the e.m.f. to be 0·303 to 0·403 volt, and with iron in 0·1N-NaOH against 0·1N-KCl Hg_2Cl_2, and mercury, F. Haber and F. Goldschmidt obtained an e.m.f. of 0·7 to 1·1 volt. W. Hittorf found that iron in a N-soln. of *ammonia* is negative against mercury in N-KCl with mercurous chloride, and with 0·1N-NH_4OH, M. Mugdan found that the e.m.f. is 0·103 volt; F. Haber and F. Goldschmidt found that iron in a soln. of *calcium hydroxide* against 0·1N-KCl, Hg_2Cl_2, and mercury, had an e.m.f. of 0·4 to 0·8 volt; and O. Faust, that iron in 20 per cent. potash-lye against zinc amalgam in 20 per cent. potash-lye containing 2 per cent. of zinc hydroxide had an e.m.f. of 0·446 volt. M. Mugdan found that with iron in a 0·1N-soln. of *sodium fluoride* against N-KCl, Hg_2Cl_2, and mercury the e.m.f. is 0·553 to 0·583 volt. M. Faraday found that iron in dil. *hydrochloric acid* is negative against iron and conc. hydrochloric acid; E. L. Nichols and W. S. Franklin, with platinum as positive electrode in a hydrochloric acid soln. of potassium chlorate; and with platinum as positive electrode in a soln. of ferrous chloride. J. Strachan found that iron in hydrochloric acid against carbon in a hydrochloric acid soln. of lead tetrachloride has an e.m.f. of 0·83 volt. L. Ponci, and J. Thomsen found that iron in a soln. of *ferrous chloride* is negative against carbon in a soln. of ferric chloride; S. Czapsky, negative against mercury in mercurous chloride; C. R. A. Wright and C. Thompson, negative against silver in silver chloride, and positive against amalgamated zinc in zinc chloride, or cadmium in cadmium chloride. R. Abegg and S. Labendzinsky found for iron in a mixed soln. of ferrous and potassium chlorides against N-KCl, Hg_2Cl_2, and mercury:

$FeCl_2$	1·0	1·0	0·1	0·1 eq. per litre
KCl	0	1·0	0	1·0 „
E	0·760	0·762	0·780	0·792 volt

A. F. W. von Escher, that iron in a soln. of *ferric chloride* is positive against zinc amalgam in sulphuric acid; T. Erhard, that iron in a soln. of ferric chloride is negative against indium in a soln. of indium trichloride; and T. W. Richards and G. E. Behr, that iron in a soln. of ferric chloride is negative against 0·1N-KCl, Hg_2Cl_2, and mercury; a similar cell was examined by C. A. Lobry de Bruyn; L. Kahlenberg, iron in 0·3N-$FeCl_3$ against mercury as positive electrode in N-KCl and mercurous chloride. A. Finkelstein found that iron is negative in a 0·01*N*-soln. of ferrous and ferric chlorides and 0·02*N*-HCl against *N*-KCl, Hg_2Cl_2 and mercury, and the e.m.ff. of the cell with the following percentage proportions of ferric chloride were:

$FeCl_3$.	0	10	20	40	60	80	100 per cent.
E . .	0·546	0·534	0·530	0·519	0·532	0·518	0·509 volt

C. R. A. Wright and C. Thompson found that iron in a soln. of *ferrous bromide* is positive against amalgamated zinc in zinc bromide, or cadmium in cadmium bromide. J. P. Joule found that iron in a soln. of *sodium chloride* is negative against platinum in nitric acid, or copper in copper sulphate; M. Mugdan gave 0·603 to 0·703 volt for the e.m.f. of a cell with iron in a 0·1*N*-soln. of *potassium chloride* with 0·1*N*-NaCl against *N*-KCl, Hg_2Cl_2, and mercury. W. H. Walker and co-workers studied the e.m.f. of the cell Fe : KCl : Pt : KCl : Fe. M. Mugdan found that against *N*-KCl, Hg_2Cl_2, and mercury, iron in a 0·1*N*-soln. of *potassium bromide* is 0·523 to 0·643 volt; with a 0·1*N*-soln. of potassium iodide, 0·473 to 0·553 volt; with a 0·1*N*-soln. of *potassium chlorate*, 0·203 to −0·353 volt; and with a 0·1*N*-soln. of *potassium perchlorate*, 0·703 volt. J. Strachan found that iron in a soln. of *ammonium chloride* against carbon in a hydrochloric acid soln. of lead tetrachloride has an e.m.f. of 0·95 volt; and if the ammonium chloride be replaced by *zinc chloride*, an e.m.f. of 0·73 volt.

M. Faraday observed that iron in dil. *sulphuric acid* is negative against iron in the conc. acid; J. P. Joule, that iron in dil. sulphuric acid is negative against platinum in nitric acid, copper in copper sulphate, or platinized silver in dil. sulphuric acid; E. L. Nichols and W. S. Franklin, with platinum as positive electrode in a dil. hydrochloric acid soln. of potassium chlorate; and with carbon as positive electrode in nitric acid; M. Mugdan, that with iron in 0·1*N*-H_2SO_4 against *N*-KCl, Hg_2Cl_2, and mercury, the e.m.f. is 0·553 to 0·603 volt—C. Fredenhagen gave 0·625 volt. R. Zuppinger studied the cell with iron in *sodium hydrosulphide* with zinc as negative electrode in a soln. of zinc sulphate; and A. Finkelstein, a cell with iron in a *N*-soln. of *ammonium sulphide* against mercury as positive electrode in *N*-KCl with mercurous chloride. F. Braun, and C. R. A. Wright and C. Thompson found that iron in a soln. of *ferrous sulphate* is positive against zinc in zinc sulphate or cadmium in cadmium sulphate; J. J. Coleman, C. R. A. Wright and C. Thompson, and F. Förster, negative against copper in copper sulphate; C. R. A. Wright and C. Thompson, iron in ferrous sulphate soln. is negative against silver in silver sulphate or lead in lead sulphate. H. W. Töpffer studied cells with iron in a soln. of ferrous sulphate with and without ammonium oxalate or sulphate against cobalt as positive electrode in a soln. of cobalt sulphate with or without ammonium oxalate or sulphate, and with nickel as positive electrode with a soln. of nickel sulphate with or without ammonium sulphate or oxalate; A. Finkelstein, iron as negative electrode in *N*-$FeSO_4$ against mercury in *N*-KCl with mercurous chloride, and M. Mugdan found with 0·1*N*-$FeSO_4$ the e.m.f. is 0·623 to 0·703 volt; H. Euler, iron in a soln. of ferrous sulphate against iron in a soln. of ferrous sulphate and sodium thiosulphate has an e.m.f. of 0·01 to 0·02 volt. T. W. Richards and G. E. Behr studied the e.m.f. of cells with iron, and of iron charged with hydrogen in *N*-$FeSO_4$ against 0·1*N*-KCl, Hg_2Cl_2, and mercury. A. H. Bucherer studied the case of iron in a sat. soln. of *ammonium ferrous sulphate* with a few drops of a soln. of ferric sulphate against iron as positive electrode in 1·5*N*-$Fe_2(SO_4)_3$ and a few drops of a soln. of ammonium ferrous sulphate. J. P. Joule found that iron in a soln. of *sodium sulphate* is negative against platinum in nitric acid, or copper in copper sulphate. W. Hittorf found that iron in a soln. of sodium sulphate is negative against platinum in a soln. of chromic acid; M. Berthelot, iron in a soln. of H_2SO_4+NaOH against iron in soda-lye has an e.m.f. of 0·295 volt; iron in a soln. of $NaOH+Na_2SO_4$ against iron in soda-lye, 0·185 volt; and in $Na_2SO_4+H_2SO_4$, 0·12 volt. M. Mugdan found that the e.m.f. of iron in a 0·1*N*-soln. of *potassium sulphate* against *N*-KCl, Hg_2Cl_2, and mercury, is 0·603 to 0·703 volt. E. Heyn and O. Bauer, and F. Förster found that a cell with iron in *N*-$FeSO_4$ against *N*-KCl, Hg_2Cl_2, and mercury, has an e.m.f. of 0·68 volt at 17·5°. R. Abegg and S. Labendzinsky found for iron in a mixed soln. of ferrous and sodium sulphates against *N*-KCl, Hg_2Cl_2, and mercury:

$FeSO_4$.	1·0	1·0	0·1	0·1	0·1	0·01	0·01	0·01 eq. per litre
Na_2SO_4 .	0	1·0	0	0·1	1·0	0	0·01	1·0 ,,
E . .	0·762	0·774	0·785	0·787	0·803	0·795	0·799	0·827 volt

C. A. Lobry de Bruyn found the e.m.f. of cells with passive iron in a 0·1*N*-soln. of mixed ferrous and ferric sulphates against *N*-KCl, Hg_2Cl_2, and mercury, to be:

$FeSO_4$ . . .	67·5	48·5	36·0	29·0	1·0 per cent.
E	0·335	0·357	0·370	0·380	0·460 volt

W. Broniewsky found that cells with steel in *N*-$FeSO_4$ against carbon in manganese dioxide had an e.m.f. of:

Steel . .	0·06	0·24	0·44	0·79	1·12 per cent. carbon
E . . .	1·112	1·099	1·097	1·110	1·091 volt

L. Kahlenberg found the e.m.f. of a cell with iron in 0·375*N*-$FeCl_3$ in ethyl alcohol against iron in 0·3N-$\mathrm{FeCl_3}$ in aq. soln. to be 0·273 volt; iron in a soln. of 1·4508 grms. of ferric chloride in 77·6 c.c. of nitrobenzene against iron in 0·375N-$\mathrm{FeCl_3}$ in ethyl alcohol $E=0{\cdot}909$ volt.

T. Hawkins studied the case of iron (positive) and *nitric acid* against sulphuric acid and zinc or iron; M. Faraday, iron (negative) and dil. nitric acid against iron and conc. nitric acid; J. P. Joule, that passive iron in nitric acid is positive against amalgamated zinc in potash-lye; and H. Buff that iron (passive, or superficially coated with oxide) is positive against zinc in sulphuric acid, or iron in sulphuric acid; F. Petruschefsky, that iron in nitric acid is positive against zinc amalgam in sulphuric acid; F. J. Micheli, that iron in fuming nitric acid is positive against copper in dil. sulphuric acid. W. Hittorf found that iron in a soln. of *sodium nitrate* is negative against platinum in nitric acid; M. Mugdan found that the e.m.f. of a cell with iron in a soln. of *potassium nitrate* against mercury in N-KCl and mercurous chloride falls rapidly to zero; and with 0·1N-$\mathrm{KNO_3}$, the e.m.f. is 0·443 to 0·583 volt.

W. Hittorf found that iron in a soln. of *potassium cyanide* is positive against platinum in chromic acid; S. B. Christy gave for soln. with 1, 0·1, and 0·001 eq. of KCy per litre against N-KCl, $\mathrm{Hg_2Cl_2}$, and mercury, $E=0{\cdot}116$, 0·046, and 0·046 volt respectively; M. Mugdan gave for a cell with iron in 0·1N-KCy against a similar electrode, $E=0{\cdot}103$ to 0·263 volt; A. Finkelstein, that iron in N-KCy is positive against mercury in N-KCl and mercurous chloride, and that iron is negative in a N-soln. of *potassium ferrocyanide or ferricyanide* against mercury in N-KCl and mercurous chloride; and analogous cells were studied by E. Heyn and O. Bauer. M. Mugdan obtained $E=0{\cdot}543$ to 0·603 volt for a cell with iron in a 0·1N-soln. of *acetic acid* against N-KCl, $\mathrm{Hg_2Cl_2}$, and mercury, and for iron in a 0·1N-soln. of *sodium acetate*, 0·103 to −0·303 volt. W. Hittorf found that iron is negative in a soln. of sodium acetate against platinum in chromic acid. W. Hittorf found that iron is negative in a soln. of *potassium dichromate* against platinum in chromic acid; M. Mugdan gave $E=0{\cdot}157$ volt for iron in 0·1N-potassium dichromate against N-KCl, $\mathrm{Hg_2Cl_2}$, and mercury; and 0·577 volt for iron in a 0·1N-soln. of *potassium permanganate* against a similar electrode. P. Bechtereff also studied cells with iron in 20 per cent. soda-lye with potassium permanganate against iron in soda-lye.

Double liquid cells with an intermediate inert liquid.—N. R. Dhar examined cells with iron in distilled *water* against 0·1N-KCl, $\mathrm{Hg_2Cl_2}$, and mercury, with 0·1N-KCl as intermediary and similar cells with iron in a 0·1N-soln. of *potassium chloride*; N. R. Dhar and G. Urbain studied similar cells with iron in a 0·1N-soln. of *ferric fluoride*. B. Rane studied cells with iron in a N-soln. of hydrochloric acid, in the presence of different proportions of brucine against N-KCl, $\mathrm{Hg_2Cl_2}$, and mercury, with a sat. soln. of potassium chloride as intermediary. F. Streintz found that iron in a soln. of *ferrous chloride* is negative against copper in copper chloride with water as intermediary; and positive against zinc in zinc chloride with water as intermediary: F. Braun found that iron in ferrous chloride is negative against silver in silver chloride with hydrochloric acid as intermediary; B. Neumann, that iron in N-$\mathrm{FeCl_2}$ is negative against N-KCl, $\mathrm{Hg_2Cl_2}$, and mercury, with a N-soln. of an indifferent electrolyte as intermediary; and similarly with a N-soln. of *ferric chloride*. N. R. Dhar and G. Urbain examined cells with iron in 0·1N-$\mathrm{FeCl_3}$, or in a 0·1N-soln. of *ammonium ferric chloride*, against 0·1N-KCl, $\mathrm{Hg_2Cl_2}$, and mercury, with 0·1N-KCl as intermediary. F. Braun found that iron in a soln. of *ferrous sulphate*, is positive against cadmium in cadmium sulphate with and without nitric acid as intermediary; iron is negative in a soln. of ferrous sulphate against copper in copper sulphate, or platinum in hydrochloroplatinic acid, with sulphuric acid as intermediary, and also against silver in silver nitrate, or lead in lead acetate, with nitric acid as intermediary; B. Neumann, that iron is negative in N-$\mathrm{FeSO_4}$ against N-KCl, $\mathrm{Hg_2Cl_2}$, and mercury, with a N-soln. of an indifferent electrolyte. F. Haber and F. Goldschmidt found that cast or wrought iron in acidified N-$\mathrm{FeSO_4}$ is negative against 0·1N-KCl, $\mathrm{Hg_2Cl_2}$, and mercury, with a 1 per cent. soln. of potassium nitrate as intermediary. P. Krassa, W. Kistiakowsky, and N. R. Dhar and G. Urbain examined similar cells with a sat. soln. of potassium chloride as intermediary. F. Förster, and M. de Broglie examined similar cells with different varieties of iron; and B. Rane found that in these cells the e.m.f. is lowered by the addition of increasing proportions of brucine. N. R. Dhar and G. Urbain studied cells with iron in a 0·1N-soln. of *ammonium ferrous sulphate* against 0·1N-KCl, $\mathrm{Kg_2Cl_2}$, and mercury, with a soln. of potassium chloride as intermediary; S. Bodforss, a similar cell with N-KCl, $\mathrm{Hg_2Cl_2}$, and mercury; and K. Iwase and K. Miyazaki, cells with iron in ammonium ferrous sulphate against

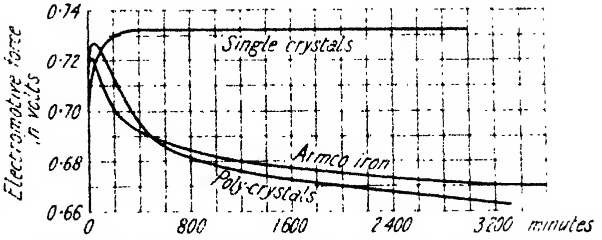

FIG. 273.—The Effect of Time on the Electromotive Force of Iron.

0·1N-KCl, Hg_2Cl_2, and mercury, with N-KCl as intermediary. The initial maximum, and end values of the e.m.f. were respectively with armco iron, 0·716, 0·722, and 0·669 volt, with polycrystals of iron, 0·718, 0·726, and 0·661 volt, and with single crystals of iron, 0·704, and 0·728 volt. The results are plotted in Fig. 273. N. R. Dhar examined cells with iron in a 0·1N-soln. of *potassium nitrate* against 0·1N-KCl, Hg_2Cl_2, and mercury, with 0·1N-KCl as intermediary. F. Streintz found that iron in a soln. of *ferric nitrate* is negative against copper in copper nitrate with water as intermediary; and positive against zinc in zinc sulphate with water as intermediary. G. Grube examined cells with iron in a mixture of *potassium ferrocyanide* and *potassium ferricyanide* with different proportions of potassium hydroxide against N-KCl, Hg_2Cl_2, and mercury, with a sat. soln. of potassium chloride as intermediary. N. R. Dhar and G. Urbain also examined similar cells with 0·1N-K_4FeCy_6, or 0·1N-K_3FeCy_6 against 0·1N-KCl, Hg_2Cl_2, and mercury, with a soln. of potassium chloride as intermediary; likewise also cells with iron in a 0·1N-soln. of *sodium nitroprusside*, or *potassium ferric oxalate*, or *ammonium ferric citrate* in place of the ferrocyanide.

Cells with fused oxides or salts as electrolytes.—W. W. Jacques constructed a cell with molten *sodium hydroxide* as electrolyte, an iron anode, and carbon cathode. The cell was studied by F. Haber and L. Bruner, A. C. Bradley, R. Lorenz, R. Lorenz and F. Kaufler, and P. Bechtereff. P. Bechtereff observed that the e.m.f. is a function of the temp., such that:

	337°	413°	456°	518°	551°	624°
E.m.f. .	0·623	0·683	0·728	0·784	0·804	0·830 volt

and the temp. coeff. between 400° and 580° is 0·00097 volt per degree. With a cell with passive iron as anode, fused sodium hydroxide, against 0·1N-KCl, Hg_2Cl_2, and mercury:

	337°	367°	418°	440°	552°	647°
E.m.f. .	0·288	0·308	0·363	0·378	0·478	0·583 volt

where the temp. coeff. between 400° and 580° is 0·00089 volt per degree. With active iron as anode:

	445°	501°	536°	564°	606°	618°
E.m.f. .	1·535	1·56	1·575	1·58	1·60	1·61 volt

E. Bauer found the e.m.f. of cells with molten sodium hydroxide, active iron as anode, and silver as cathode to be near 1·19 at 350° to 385°; and with passive iron as cathode, and active iron as anode, 1·19 volt at 350°. The e.m.f. of a cell with iron, molten sodium hydroxide and sodium was 2·16 to 2·26 volt at 380°. P. Bechtereff gave for a cell with carbon as cathode, passive iron as anode, molten sodium hydroxide and selenium as electrolyte, E=0·06 volt, with molten sodium hydroxide and tellurium as electrolyte, E is very small, using molten sodium hydroxide with 3 per cent. sodium chlorate, the e.m.f. was 0·65 volt at 395°; A. C. Bradley studied a cell with iron against carbon in molten sodium hydroxide and manganese dioxide and for a cell with passive iron, molten *lithium hydroxide* and potassium permanganate against carbon, the e.m.f. was 0·773 volt at 508°, and 0·822 volt at 616°. C. Liebenoff and L. Strasser found the e.m.f. of a cell with iron, molten *potassium hydroxide*, and carbon as cathode, to be $0·815+0·00105(\theta-500°)$ volt, and a cell with iron as cathode, molten potassium hydroxide, and N-KCl, Hg_2Cl_2, and mercury as anode, E=0·38 volt at 500°. R. von Hasslinger found that a cell with iron as cathode, platinum as anode, and molten *lithium or potassium chloride* as electrolyte:

	Lithium chloride				Potassium chloride			
	350°	800°	1000°	1100°	850°	950°	1200°	1500°
E .	0·68	1·07	0·88	0·77	0·54	0·75	0·81	0·85 volt

P. Bechtereff found for a cell with iron as anode, carbon as cathode, and molten *sodium and potassium carbonate* as electrolyte, E=0·32 volt at 1100°, and at higher temp. as the electrolyte begins to boil, the e.m.f. drops to zero. G. Gore studied a similar cell with a molten mixture of sodium carbonate, calcium oxide, and silica as electrolyte; C. P. Shrewsbury and co-workers, with molten *potassium nitrate* as electrolyte; G. Gore, with molten *lead chromate* as electrolyte; and P. Bechtereff, with molten *cryolite* and 10 per cent. alumina as electrolyte.

Cells with an iron electrode in the vapour of salts in flames.—These were studied by R. von Hasslinger. Iron is positive against platinum with 2N- and 4N-soln. of *lithium chloride* (E=0·37 and 0·43 volt), and positive against nickel with 2N-LiCl (E=0·11 volt):

	LiCl in flame			LiCl vapour in platinum tube	
	1550°	1400°	1000°	800°	500°
E	0·37	0·30	0·14	0·16	0·24 volt

Iron is positive against platinum with 2N- and 4N-soln. of *ammonium chloride* (E=0·29 and 0·33 volt), and against nickel with 2N-NH_4Cl (E=0·05 volt), and similarly with 2N-soln. of *ammonium bromide and iodide* (E=0·54 or 0·74 volt) against platinum. Iron is negative against platinum with $4N$-soln. of *sodium chloride* (E=0·16 volt), and $2N$-soln. of *potassium chloride, bromide, or iodide* (E=0·32, 0·37, and 0·26 volt). H. J. Bliksl ager studied the electrochemistry of iron electrodes in fused alkali chlorides. R. von Hasslinger observed that iron is positive against nickel with $4N$-*calcium chloride* (E=0·16 volt), and against platinum with $4N$- and $8N$-CaCl_2 (E=0·41 and 0·51 volt) with $4N$-soln. of *strontium chloride* (E=0·59 volt); with $2N$-soln. of *barium chloride* (E=0·30 volt); with $4N$-soln. of *ammonium sulphate* (E=0·43 volt); with a $2M$-soln. of *lithium salicylate* (E=0·10 volt); and with a $2M$-soln. of *aniline chloride* (E=0·28 volt).

S. J. French and L. Kahlenberg showed that the potential of iron in an electrolyte depends on the nature of the electrolyte and on the surrounding gas; W. Muthmann and F. Fraunberger, that the potential of the iron electrode is very sensitive to the presence of air; and J. Stapenhorst, that the longer the time iron is exposed to air, the more does the potential approach that of the noble metals. If two electrodes of iron dip in a soln. so that they are separated by a diaphragm, and if air be allowed to play about one electrode, the aerated electrode becomes the cathode and the other the anode. These aerated currents were studied by U. R. Evans, and F. Tödt. Observations were also made by T. W. Richards and G. E. Behr, by R. Kremann and H. Breymesser, and by W. Rathert. G. C. Schmidt observed that the presence of nitrogen has no perceptible effect on the electrode potential, but the potential is lowered by hydrogen and increased by oxygen, thus:

	Hydrogen				Oxygen	
Time . .	1	45	71	89	155	217 mins.
E_H . .	−0·535	−0·689	−0·721	−0·744	−0·730	−0·518 volt

T. Andrews observed that when opposite poles of two electrically connected magnets of approximately equal strength are immersed in various soln., the north pole becomes positive to the south pole. When the soln. were applied to the upper ends of the magnets, the north pole was still positive, but the e.m.f. was slightly less than before. In both cases the south pole becomes momentarily positive at the commencement of the experiment—*vide* passivity of iron for the effect of magnetism on the dissolution of iron in nitric acid. He also found that when couples consisting of magnetized and non-magnetized bars, simultaneously, were exposed to the action of a soln. of potassium chlorate with nitric acid or hydrochloric acid, also nitric, hydrochloric, and concentrated sulphuric acids, the magneto-chemical effects were very small. The magnetized rod was the positive element in every instance, except when dil. hydrochloric acid and conc. sulphuric acid were employed, when the electro-negative effect is possibly due to the presence of nascent hydrogen. D. Hurmuzescu observed that magnetized iron is always electropositive to non-magnetized iron; and that the e.m.f. depends on the strength of the magnetic field.

W. Muthmann and F. Fraunberger, and T. W. Richards and G. E. Behr agree that the presence of carbon has very little influence on the electrode potential of iron—*vide supra.* C. E. Fawsitt showed that the electrolytic soln. press. is raised by roughening the surface of the metal; and polishing the metal was found by W. Muthmann and F. Fraunberger, J. Stapenhorst, G. C. Schmidt, A. Speidel, H. Eggert, G. Tammann and C. Wilson, and H. Endo and S. Kanazawa—*vide supra*—to make the metal baser towards N-FeSO_4. According to T. W. Richards and G. E. Behr, the potential of iron towards soln. of its salts is not perceptibly influenced by raising the press. on the electrode to 350,000 kgrms. per sq. cm.; and likewise also an iron wire, 0·08 cm. in diameter, which had been subjected to a tension of 61 kgrms., suffered no perceptible change. T. Andrews, C. Hambuchen, and W. H. Walker and C. Dill also found that the effect of press. and torsion is very small; T. W. Richards and G. E. Behr, that iron reduced at a low temp. is baser than when the metal is reduced at a high temp., and E. Heyn and O. Bauer found that over-heated iron is nobler than it is when not over-heated. Hard, cold-drawn steel, low in carbon, in feebly acidified $0{\cdot}1N$-FeSO_4, is 0·040 volt nobler than the same metal in the annealed state; and P. Goerens found that the difference decreases as the annealing temp. is raised. H. Endo and S. Kanazawa found the effect of a slight strain on the potential of iron is masked by other influences, but with single crystals a strained electrode is more electropositive than is the case with an unstrained specimen. T. Andrews found that metal strained by tension, torsion, or flexion is electronegative to the unstrained metal, so that the strained metal, *per se*, is less liable to corrosion than the unstrained metal. I. Lifschitz and M. Reggiani studied the Becquerel effect—**10.** 58, 4.—with iron. T. F. Russell estimated that the cold-working of iron whereby 4·6 per cent. is converted into the vitreous phase, causes an increase of potential energy equivalent to 2·27 cals. per gram, or $9·49\times10^7$ ergs, on the assumption that the sp. ht. of crystalline and vitreous iron are the same. This means that the e.m.f. generated when cold-worked steel is one electrode and unworked steel the other, will be 0·000275 volt, or $0·000275\times10^8$ ergs—*vide supra*, cold-working. G. Tammann and C. Wilson found that hard iron is baser than soft metal; G. Tammann, that the rate of deposition of radium-F is greater for the hard metal than for the soft metal; and the rate of dissolution of iron in acids is augmented by cold-working.

According to R. Ruer, the cell Fe (passive) : HNO_3 (sp. gr. 1·4) : H_2SO_4 (66 per cent.) : Zn has an e.m.f. of 1·62 volts; and if an alternating current be applied, the e.m.f. rises to 1·95 volts, and if the alternating current be raised to 3 amp., no other change occurs. The original potential is restored by removing the applied alternating current. The cell Fe (passive) : H_2SO_4 (10 per cent.) : H_2SO_4 (66 per cent.) : Zn has the iron passivated by a direct current of 0·5 amp., and the cell gives an e.m.f. of 2·85 volt, and by the simultaneous application of an alternating current of 1 ampère, the iron is activated, and the e.m.f. falls to 0·67 volt. J. C. Ghosh found that an alternating current does not change the potential of iron in the cells Fe : $ZnSO_4$: Hg, Fe : $ZnSO_4$: Pt, and Fe : $CdSO_4$: Hg. P. Vaillant observed that an alternating current acting on the cell +Fe (small electrode) : NaCl; Fe (large electrode), makes the small electrode positive and the large electrode negative, and increasing the strength of the current makes the e.m.f. pass from a positive to a negative value. A. J. Allmand and R. H. D. Barklie compared the corrosion of iron by direct and alternating currents. The *moto-electric effect*, that is, the current produced in a short-circuited cell, consisting of two similar electrodes, in the same electrolyte, by the movement of one of them was discussed by A. H. Bucherer, W. Kistiakowsky, H. C. Regnart, and W. J. Müller and K. Konopicky. S. Procopiu measured the e.m.f. of a moving electrode of iron in water, $0·2N$-H_2SO_4, and $0·2N$-HNO_3, and found respectively 0·052, 0·062, and 0·072 volt. According to E. Bouty, if one of two electrodes in a ferrous or ferric salt soln. be heated, an e.m.f. is developed—0·000002 volt per degree with the former, and 0·00156 volt per degree with the latter—which is smaller with the ferrous than with the ferric salt soln. C. E. Mendenhall and L. R. Ingersoll found that small globules of iron in Nernst's glower move against the current.

When two similar electrodes are placed in a salt soln., and one electrode is placed in a magnetic field, an e.m.f. is developed. A. H. Bucherer, W. Rathert, and T. W. and W. T. Richards attributed the phenomenon to changes produced in the concentration of the electrolyte. T. Gross showed that with conc. soln. of ferric chloride or nitrate, or an acidified soln. of ferrous chloride or sulphate, an e.m.f. is developed if magnetized and non-magnetized iron electrodes are employed, and the e.m.f. and direction of the current re the same whether the north or the south pole of the magnetized rod of iron dips in the soln. E. L. Nichols and W. S. Franklin showed that if both electrodes be magnetized, one more intensely than the other, a current flows from the more strongly magnetized, electrode to the other electrode. Observations were also made by G. O. Squier. T. Andrews found that the direction of the current is different with different soln. The magnetized pole is positive with soln. of cupric sulphate, nitrate, acetate, chloride or bromide, nickel chloride, ferrous sulphate or chloride, mixtures of nitric acid with ferric chloride alone or mixed with potassium dichromate with or without ferric chloride, mixtures of potassium chlorate with nitric or hydrochloric acid, aqua regia, a mixture of a soln. of potassium bromide and bromine; the current flows from the non-magnetized to the magnetized electrode, and with sulphuric or hydrochloric acid, the current flows in the reverse direction. D. Hurmuzescu said that with oxalic acid, the magnetized electrode is positive. A. H. Bucherer found that with magnetized and non-magnetized iron electrodes the e.m.f. at 18° with $18N$-$Fe_2(SO_4)_3$ was 0·068 volt; with $1{\cdot}5N$-$FeCl_3$, 0·005 volt; with $5N$-HNO_3, 0·028 volt; with N-$KClO_3$ and $2N$-HNO_3, 0·002 volt; with $0{\cdot}2N$-H_2SO_4, 0·0008 to 0·001 volt; and $0{\cdot}2N$-$CuSO_4$, 0·014 volt. T. Gross observed a current of short duration first flowing from the non-magnetized to the magnetized electrode; H. A. Rowland and L. Bell called this the primary current, and A. H. Bucherer thought it was due to the shaking of the electrode. E. L. Nichols and W. S. Franklin found that the e.m.f. of the cell Fe (magnetized) : $(K_2Cr_2O_7+H_2SO_4)$: Pt increases with increasing field strength, *H* gauss :

H .	2,000	3,600	7,770	8,400	12,750	16,300	19,700
E.m.f.	0·0008	0·0045	0·0386	0·0424	0·0487	0·0510	0·0680 volt

Observations were also made by D. Hurmuzescu, and P. Janet, and E. Staicu. E. Staicu also showed that the e.m.f. is greater, the smaller the concentration of the iron salt soln. used as electrolyte; thus, with field strengths of 4700 and 5750 gauss, the e.m.ff. developed with 9·88 grms. of $FeCl_3$ per 100 c.c. of water are respectively 0·0276 and 0·0302 volt, and with a soln. of 0·988 grm. per 100 c.c. of water, respectively 0·03609 and 0·04059 volt. T. W. and W. T. Richards found that with the application of a magnetic field for 20 secs., the e.m.f. of the cell −Fe : $1{\cdot}02N$-$FeSO_4$: N-KCl, Hg_2Cl_2 : Hg+ falls about 0·001 volt; and if the iron is charged with hydrogen, the fall of the e.m.f. is greater, and is nearly proportional to the intensity of the magnetic field. The phenomenon was discussed by A. H. Bucherer, P. Duhem, D. Hurmuzescu, W. Rathert, and T. W. and W. T. Richards. C. Maurain discussed the magnetic properties of iron in the act of deposition; and O. M. Corbino, the polarization of colloidal iron in a magnetic field.

From W. Nernst's formula, $E=-(RT/n)\log(P/p)$, where p is the osmotic press. of the metal ions, and P is the **solution pressure**—1. 16, 3—if E is zero, $p=P$. For a concentration $[Fe^{\cdot\cdot}]=1$, and if the osmotic press. $p=22$ atm., and $E=0{\cdot}153$ volt, then $0{\cdot}153=\frac{1}{2}\times0{\cdot}059\log(P/22)$ for $Fe=Fe^{\cdot\cdot}$, or, at 18° the soln. press. is $3{\cdot}3\times10^6$ atm.; and similarly for $Fe\rightleftharpoons Fe^{\cdot\cdot\cdot}$, at 18°, the soln. press. is about 1·4 atm. Metallic iron thus behaves as if it were an alloy of ferrous and ferric iron with soln. press. in the ratio $1:10^{-6}$. The soln. press. can also be regarded as a measure of the tendency of the two ions to give up their charges. This tendency is very much greater with ferric than it is with ferrous ions. It can also be regarded as representing a tendency of the ferrous ions to acquire an additional charge. R. Abegg and G. Bodländer discussed the affinity of these ions for electric charges, and observed that the **electroaffinity** of ferrous ions is far greater than that of ferric ions; and K. Schaum said that of the two forms of ions, ferrous ions are the stronger.

The work involved in the production of the different stages of oxidation of iron can be calculated from the preceding formulæ. In an electrolytic cell, both ferrous and ferric ions can lose their charges at the cathode, or the ferric ions can be reduced to ferrous ions; and at the anode, $Fe^{\cdot\cdot}$-ions can be oxidized to $Fe^{\cdot\cdot\cdot}$-ions, or with an anode of iron, iron can produce $Fe^{\cdot\cdot}$-ions, or $Fe^{\cdot\cdot\cdot}$-ions. In order that these changes may occur, the electrode must not only be charged with a definite quantity of electricity, but it must be also charged to a minimum potential. If an iron wire dips into a soln. of ferrous ions of unit concentration, the electrode $E_H=-0{\cdot}43$ volt when the system is in a state of equilibrium; but if the wire is polarized by a positive potential, it follows from $E_H=-0{\cdot}43+\frac{1}{2}\times0{\cdot}058\log[Fe^{\cdot\cdot}]$ volt, that this corresponds with a higher conc. of the $Fe^{\cdot\cdot}$-ions for equilibrium, and accordingly $Fe^{\cdot\cdot}$-ions pass into soln.; and conversely, if the iron receives an additional negative potential, $Fe^{\cdot\cdot}$-ions will be discharged to form metallic iron. Consequently, if iron is to be deposited from a soln. of a ferrous salt, the potential of the cathode must exceed that value below which iron passes into soln. This subject was discussed by F. Förster, and H. Lee. Remembering also that the potential for the change $Fe \rightleftharpoons Fe^{\cdot\cdot}$ is $-0{\cdot}43$ volt, and for $Fe \rightleftharpoons Fe^{\cdot\cdot\cdot}$, $-0{\cdot}04$ volt, it follows that ferric ions have a greater tendency than ferric ions to form iron. Hence, in a mixture of ferric and ferrous ions it might, at first sight, be assumed that on electrolysis, the first change to occur will be $Fe^{\cdot\cdot\cdot} \rightarrow Fe$. Actually, it is easier to reduce ferric to ferrous salt: $Fe^{\cdot\cdot\cdot} \rightarrow Fe^{\cdot\cdot}$, because less work is required for the "distribution" of the positive charges. When the process has continued long enough, and the ratio $[Fe^{\cdot\cdot\cdot}]:[Fe^{\cdot\cdot}]$ corresponds with $0{\cdot}75+0{\cdot}058 \log [Fe^{\cdot\cdot\cdot}]/[Fe^{\cdot\cdot}]=-0{\cdot}04+\frac{1}{3}0{\cdot}058 \log [Fe^{\cdot\cdot\cdot}]$, the work required for both changes is the same. This condition is satisfied when nearly all the ferric ions have been converted into ferrous ions. When the cathodic reaction $Fe^{\cdot\cdot\cdot} \rightarrow Fe^{\cdot\cdot}$ is about completed, and the ratio $[Fe^{\cdot\cdot\cdot}]:[Fe^{\cdot\cdot}]$ is favourable for the discharge of the $Fe^{\cdot\cdot}$-ions, it is necessary to raise the cathode potential in order to keep the process continuous, and it thereby attains a value which also favours the direct reduction of the ferric ions to the metal. Hence, all three reactions—$Fe^{\cdot\cdot\cdot} \rightarrow Fe^{\cdot\cdot}$, $Fe^{\cdot\cdot} \rightarrow Fe$, and $Fe^{\cdot\cdot\cdot} \rightarrow Fe$—can take place simultaneously; but since the concentration of the $Fe^{\cdot\cdot\cdot}$-ions is very small, the work done at the cathode is virtually all expended in reducing the ferrous ions to the metal. Consequently, in the electrolytic deposition of iron it is best to work with a soln. of a ferrous salt. V. Kohlschütter and H. Stäger studied the anode reactions; and A. P. Rollet, the electrode reactions of iron in sulphuric acid, and alkali-lye under the influence of an alternating current, and noted that the electrodes are alternately covered with oxide and with powdery metal.

According to R. S. Lillie and S. E. Pond, an electric current corresponding with a potential of 10 volts flowing across a caoutchouc membrane of thickness 40μ interposed between two electrolyte soln., one of which is a mixture of ferrous chloride and potassium thiocyanate, causes oxidation of ferrous to ferric iron at the surface of the membrane facing the cathode.

According to E. J. Mills, when iron is deposited electrolytically on the bulb of a thermometer, a pressure, which has been called *electrostriction* is exerted, so that the bulb of the thermometer contracts. The phenomenon was studied by E. Bouty, who found that when first deposited, the film of metal may have a higher temp. than the electrolyte, and as the metal cools, it will contract and exert a pressure. In some cases there is a cooling effect, so that the metal immediately after deposition is heated, and expands. This subject was discussed by V. Kohlschütter and E. Vuilleumier, V. Kohlschütter and A. Nägeli, V. Kohlschütter, G. G. Stoney, R. H. D. Barklie and H. J. Davies, and H. Stäger—*vide* nickel.

The minimum cathode potential for the electrodeposition of iron is not the same with different soln. In the presence of other metal ions, the result depends on the conc. of the $Fe^{\cdot\cdot}$-ions, and on that of the $H^{\cdot}$-ions. Complex salts may be formed in the soln. which, when neutral, produce so small a proportion of ferrous ions that there is no electrodeposition. Thus the iron may not necessarily be cathodically precipitated from normal acidic molar soln. of ferrous chloride. The electrode potentials of the reactions $Fe^{\cdot\cdot} \rightarrow Fe$ and $2H^{\cdot} \rightarrow H_2$ are, respectively, $-0{\cdot}43$ and $0{\cdot}0$ volt. So little work is required for the separation of gaseous hydrogen that it is given off at once from the cathode, the conc. of the $H^{\cdot}$-ions is not much impoverished, and with high current densities it is scarcely possible to make the cathode potential as negative as is required for the deposition of iron: $Fe^{\cdot\cdot} \rightarrow Fe_2$. From the relation $-0{\cdot}43+\frac{1}{2}\times 0{\cdot}058 \log [Fe^{\cdot\cdot}]=0{\cdot}0+\frac{1}{2}\times 0{\cdot}048 \log [H^{\cdot}]^2$, it follows that when the same work is involved in the separation of iron and hydrogen from molar soln., $[H^{\cdot}]=3{\cdot}8\times 10^{-8}$. H. F. Haworth discussed the resistance of soln. of ferric chloride with an alternating current. S. Glasstone found the deposition potential of iron from normal soln. to be:

	15°	36°	55°	70°	90°
Potential . .	−0·68	−0·55	−0·49	−0·46	−0·46
Overvoltage . .	0·22	0·09	0·03	*nil*	*nil*

The reversible potential of iron in N-soln. of a ferrous salt is probably -0·46, as found by W. H. Hampton, so that at temp. of about 70° iron may be deposited almost reversibly.

The **hydrogen overvoltage** of iron was discussed by J. N. Pring and J. R. Curzon, and C. W. Bennett and J. G. Thompson. As with most metals, electrolytic hydrogen does not develop with the potential of $H^{\cdot}=H_2$. because there is an overvoltage effect, which W. A. Caspari found to be $E_H=-0·08$ volt for smooth iron in a soln. of sodium hydroxide. If the overvoltage effect is independent of the electrolyte and the current density, the above relation becomes $0·43+\frac{1}{2}\times0·058 \log [Fe^{\cdot\cdot}]=0·0+\frac{1}{2}\times0·058 \log [H^{\cdot}]^2-0·08$, so that the same work is required for the separation of iron and hydrogen from a molar soln. of ferrous chloride with a $H^{\cdot}$-ion concentration of $0·9\times10^{-7}$. This is nearly the same as for a neutral soln. which approximates to $0·74\times10^{-7}$, and this means that hydrogen is also given off when a neutral soln. of ferrous chloride is electrolyzed. A. Coehn and K. Dannenberg gave $E_H=-0·03$ volt for the overvoltage of hydrogen in N-KOH. H. G. Möller obtained −0·23 volt; G. Carrara, −0·21 volt; M. Centnerszwer and M. Straumanis gave −0·28 volt at 20°; E. Newbery, −0·30; and A. Thiel and W. Hammerschmidt, −0·17. F. Förster, and O. Mustad studied the effect of the $H^{\cdot}$-ion concentration in hydrochloric and sulphuric acid soln., and of additions of ammonium chloride, sodium hydrocarbonate, and boric acid. A. Thiel and E. Breuning gave for iron etched with sulphuric acid at 25°, and in

	N-KOH	N-NaOH	1·3N-LiOH	N-KH_2PO_4	5N-$KC_2H_3O_2$	5N-$NaC_2H_3O_2$
Overvoltage .	0·075	0·087	0·056	0·121	0·176	0·127

The two alkali acetate soln. were mixed with 2N-acetic acid. E. Newbery obtained the cathodic overvoltages E_H milliamps. in N-H_2SO_4, and N-NaOH at 15° with a current density D:

	D . . .	2	6	10	50	100	400	1000	2000
E_H	N-H_2SO_4 .	0·24	0·26	0·26	0·27	0·27	0·28	0·27	0·26
	N-NaOH .	0·28	0·32	0·33	0·34	0·35	0·35	0·34	0·34
	N-$FeSO_4$.	0·30	0·30	0·30	0·32	0·34	0·33		
	N-$FeCl_2$.	0·35	0·34	0·34	0·36	0·36	0·41		

The cathodic overvoltages in N-H_2SO_4 of iron of a high degree of purity; steel with 0·5 per cent. of carbon; and chrome steel with 10 per cent. of chromium, were:

Current density .	2	6	10	50	100	1000	2000
Iron . . .	0·27	0·27	0·27	0·29	0·30	0·29	0·27
Steel . . .	0·26	0·28	0·28	0·28	0·27	0·25	0·23
Chrome steel .	0·26	0·27	0·28	0·28	0·29	0·30	0·29

U. C. Tainton found that a high current density increases the hydrogen overvoltage of the iron cathode. A. L. McAulay and co-workers found that when there is no sensible concentration of the ions of an iron electrode in a soln., and when the electrode is not covered by an oxide film, its potential is determined by the $H^{\cdot}$-ion concentration if its hydrogen overvoltage is positive to the deposition potential which it would have in a soln. of the order of 0·001N of its own ions. When this is not the case, the potential is controlled by the concentration of the anions, probably acting through a film of electrolyte in contact with the metal and with a concentration of the iron-ions of the order 0·0001N. G. R. Hood and F. C. Krauskopf studied the hydrogen overvoltage in connection with the efficiency of the electrolyte reduction of aq. soln. of potassium chlorate.

M. Knobel and co-workers found for 2N-H_2SO_4 at 25°:

D . . .	0	1	5	10	100	200	500	1500
E_H . . .	0·2026	0·4036	0·5024	0·5571	0·8184	0·9854	1·2561	1·2908

M. Centnerszwer and M. Straumanis found that with a current density of 0·075 amp. per sq. cm., the overvoltage is independent of the current density. Observations on the overvoltage, and the iron cathode were also made by S. Glasstone,

N. Koboseff and N. I. Nebrassoff, H. L. Lochte, H. L. Lochte and R. E. Paul, E. Newbery, and M. Bodenstein. S. Glasstone found that when an alternating current of 0·10 max. amp. is superposed on a direct current of 0·12 amp., the overvoltage in N-NaOH is 0·64 to 0·66 volt, and in N-H_2SO_4, 0·67 to 0·71 volt. The overvoltage may be augmented in the presence of some organic substances. A. Sieverts and P. Lueg observed that the overvoltage of iron in acid is very little affected by the presence of α-naphthaquinone; the ether-soluble, basic constituent of crude anthracene increases the overvoltage. No connection was observed between the retardation of the rate of dissolution in acid, and the overvoltage, but it is assumed that the " poison " is adsorbed on the metal surface, and reduces the amount of metal accessible to the acid. L. G. Knowlton found the overvoltage in $2N$-H_2SO_4 sat. with aniline is 0·05 volt higher than with the acid alone; E. L. Chappell and co-workers observed the overvoltage with different kinds of iron in N-H_2SO_4 is augmented by the addition of quinoline ethiodide—*vide* Figs. 275 and 276, corrosion; and J. C. Warner found that the addition of gelatin raises the overvoltage. U. Sborgi and G. Cappon, and G. Carrara found that in an alcoholic soln. of N-KOH the overvoltage is 0·23 volt, and with a methyl alcohol soln., 0·26 volt at 19° to 20°.

According to A. Coehn and Y. Osaka, an iron wire dipping in N-KOH gives a current-voltage curve corresponding with an **oxygen overvoltage** of 0·24 volt. E. Newbery found that with a current density, D, in N-H_2SO_4 and N-NaOH, at 15°, the oxygen or anodic overvoltages are :

	D . .	2	6	10	50	100	400	1000	2000
E_H	N-H_2SO_4 .	0·75	0·76	0·75	0·74	0·73	0·70	0·67	0·63
	N-NaOH .	0·44	0·48	0·49	0·51	0·51	0·52	0·52	0·51
	N-$FeSO_4$.	0·02	0·06	0·06	0·08	0·09	1·85*	..	..
	N-$FeCl_2$.	0·05	0·07	0·08	0·10	0·10	0·11	..	..

The asterisk means that the metal became passive. Observations were also made by S. Glasstone, and F. Meunier. If a direct current of 0·12 amp. has superposed an alternating current of 0·07 to 0·10 amp., the oxygen overvoltage in N-NaOH is 0·52 to 0·54 volt, and in N-H_2SO_4, 0·62 to 0·74 volt. L. W. Haase found that the oxygen depolarization current varies with the illumination of the system iron-platinum with water or a dil. soln. of potassium chloride. U. Sborgi and G. Cappon found that the anodic behaviour in ethyl alcohol soln. of ammonium and calcium nitrates show that it is passive at all temp. and current densities employed. R. A. Dengg and H. J. Donker measured, with inconclusive results, the polarization of different types of iron and steel in $0{\cdot}1N$-KCl and $0{\cdot}1M$-K_2CO_3. W. M. Thornton and J. A. Harle, and K. Georgi studied the anodic corrosion of iron; and A. J. Allmand and R. H. D. Barklie, the effect of alternating currents on the electrolytic corrosion of iron. J. W. Shipley and C. F. Goodeve found that in the electrolysis of a soln. of sodium hydroxide with iron electrodes and an alternating current the critical density of 3·8 amp. per sq. cm. must be exceeded before gas is evolved; with steel electrodes, the critical density is 4·5 amp. per sq. cm. A. P. Rollet studied the anodic behaviour of iron in acidic or alkaline soln.; and R. T. Dufford, the photovoltaic effect with cells containing an ethereal soln. of Grignard's reagent and iron.

A. Günther-Schulze studied the **electrolytic valve action** of iron in fuming sulphuric acid. With an anodic current density of 0·003 amp. per sq. cm., and 60 per cent. sulphuric acid, the valve action appears, and with 75 per cent. sulphuric acid the valve action gradually changes into passivity; and with higher concentrations, the valve action is stable. Alternating currents are rectified by the iron under these conditions. A layer of oxide is formed. The rectification in 89 per cent. sulphuric acid at 0° is equal to that with aluminium. W. Winter observed that the rectification occurs in dil. soln. of sulphuric acid, and potassium hydroxide; it is only slight in hydrochloric acid, and does not occur in nitric acid. One per cent. sulphuric acid was found by W. Holtz to exert a small valve action.

According to A. Günther-Schulze, with polarizing iron anodes and a constant current, and with sulphuric acid of less conc. than 50 per cent. the iron is only rendered passive, but above 60 per cent. and a current of 3 milliamp. per sq. cm., valve action occurs before the metal becomes passive. The electrolytic valve action below 75 per cent. concentration of acid is unstable and slowly changes to passivity, but at higher concentrations is stable. The maximum potential varies according to the concentration of the acid between 40 and 70 volts. Below the maximum potential the residual current which flows through the cell is very small. Iron, both in conc. and in fuming sulphuric acid, has, like aluminium, the property of partially transforming an alternating current into a direct current. The electrostatic capacity of the active layer formed on iron is of the same order of thickness, and depends on the water-content of the sulphuric acid in the same way as does that on aluminium. I. Lifschitz and M. Reggiani found the valve action is reduced by illumination.

F. Marx described an **iron accumulator** with two iron negative electrodes, and an intermediate porous carbon block as positive electrode; the electrolyte is a hydrochloric acid soln. of ferric chloride, which is reduced by the discharge and oxidized by the charge. The Akkumulatoren Werke tried the cell with an iron electrode, alkali-lye, or a soln. of sodium carbonate, potassium dichromate, or phosphoric acid, and an electrode of ferric oxide; and A. P. T. Tully, iron in a soln. of ammonium chloride, and carbon in nitric acid or bromine water. C. R. Hardy studied the screening effect of ferrous hydroxide on the iron anode.

Several measurements have been made of the **decomposition voltage** of ferrous salt soln. The current-potential curves of these soln. show a break corresponding with the decomposition voltage. The cathode potential does not show such a break, because hydrogen is evolved simultaneously with the iron. The minimum voltages required for the separation of iron from ferrous salt soln. were found by F. W. Küster to be:

$FeSO_4$ . . .	1·0N-	0·5N-	0·1N-	0·05N-
H_2SO_4 0·1N- . .	0·753	0·743	0·733	0·873 volt
H_2SO_4 0·01N- . .	0·693	0·663	0·736	0·733 ,,
H_2SO_4 0·001N- . .	0·673	0·653	0·678	0·663 ,,

and for 0·1N-$FeSO_4$ with 0·01N-H_2SO_4 the values for foil and wire cathodes are respectively 0·683 and 0·747 volt, and with no acid, 0·648 and 0·673 volt. Hence, iron is deposited on the foil before it is deposited on the wire. G. Coffetti and F. Förster tried the effect of gradually increasing the current density—ampères per sq. cm.—at the cathode in the electrolysis of N-$FeSO_4$, time constant. The voltage, E_H, at which iron and hydrogen are simultaneously formed, and the current yield are as follow:

Current density . .	0·00113	0·00227	0·00455	0·0091	0·0182
Acidity	0·0025N-	0·005N-	0·0075N-	0·01N-	0·02N-
E_H	0·70	0·71	0·73	0·75	0·79
Current yield . . .	20	31	38	—	56

F. Förster found the effect of temp. and current density, $D10^{-4}$ amp. per sq. cm., to be:

D . . .	182	91	45	22	11	5	
E_H 20° . .	−0·72	−0·70	−0·685	−0·67	—		volt
E_H 50° . .	0·62	0·61	−0·59	−0·58	−0·57	−0·56	,,
E_H 75° . .	0·57	0·55	−0·545	−0·54	—		,,
E_H 95° . .	—	−0·52	−0·51	−0·51	—		,,

S. Glasstone found that with a copper cathode and N-$FeSO_4$ the decomposition potential is:

	15°	36°	55°	70°	90°
E . .	−0·68	−0·55	−0·49	−0·46	−0·46 volt

and W. A. Noyes, with neutral N-$FeCl_2$:

	20°	50°	102°	122°	182°
E_H	−0·66	−0·45	−0·14	−0·18	−0·23 volt

Observations were also made by G. Coffetti and F. Förster, W. A. Noyes, C. Marie and N. Thon, F. Meunier, and A. Smits and A. H. W. Aten. E. Müller and J. Janitzki studied the effect of rubbing on the potential in soln. of acids, bases, and neutral salts; E. S. Hedges, the periodic electrodeposition of iron from soln. of potassium ferrous cyanide; V. Sihvonen and G. Kerkkänen, the effect of a magnetic field on the electrolytic potential; and U. Sborgi, on the anodic behaviour of iron.

A. F. W. von Escher found that in the electrolysis of a soln. of zinc and ferrous sulphates in equal proportions, the alloys deposited at 18°, and at 90° with small current densities consist principally of zinc; an excess of iron in the deposit under these conditions can be obtained only when the proportion of ferrous sulphate is preponderating. In Fig. 274 the results with a soln. containing $0{\cdot}01N\text{-}H_2SO_4$ and $Fe^{\cdot\cdot}:Zn=9:1{\cdot}5$, at 90°. The transition from high to low proportions of iron occurs at low current densities. The transition to deposits with a high proportion of zinc occurs at the higher current densities. The current efficiency is below 90 per cent. at low current densities, and above that value at high current densities. When the ratio of Fe : Zn is 9 : 0·63, the transition occurs at a current density of 0·035 or 0·040 amp. per sq. cm.; with the ratio 9 : 1, at 0·022 amp. per sq. cm.; and at 9 : 1·5, at about 0·020 amp. per sq. cm. S. Glasstone studied this subject; W. H. Creutzfeldt, the deposition of iron from soln. of copper and iron salts; and J. Prajzler, the simultaneous deposition of iron and other metals related to iron.

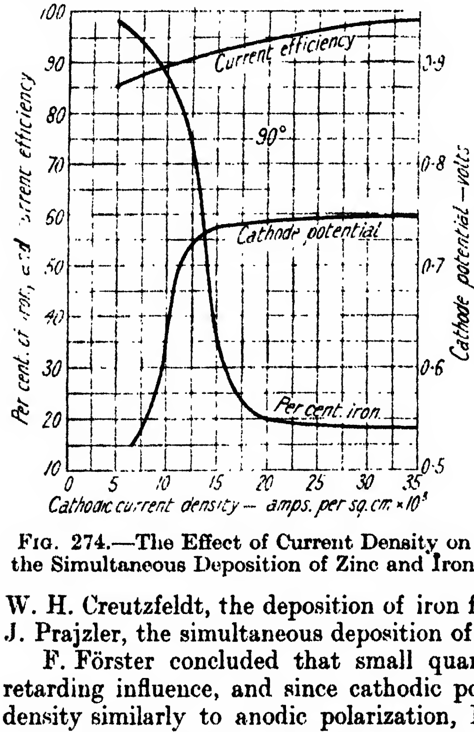

FIG. 274.—The Effect of Current Density on the Simultaneous Deposition of Zinc and Iron.

F. Förster concluded that small quantities of zinc, like hydrogen, exert a retarding influence, and since cathodic polarization varies here with the current density similarly to anodic polarization, F. Förster speaks of *cathodic polarization*—*vide infra*, passivity. The phenomenon was discussed by G. Grube, and A. Smits.

The **polarization** of iron electrodes was studied by M. le Blanc, F. Förster, E. Vogel, E. Liebreich, A. Smits and A. H. W. Aten, and C. M. Gordon and F. E. Clark. G. Grube observed that whilst anodes of nickel, cobalt, copper, gold, and platinum do not become polarized when ferrocyanide in alkaline soln. is electrolytically oxidized, anodes of iron, nickel copper, cobalt, lead, and silver become polarized in a neutral soln. of potassium ferrocyanide and ferricyanide, and anodes of iron, lead, silver, and zinc become polarized also in alkaline soln. of these substances. In all these cases there is evidence of the formation of a surface film of oxide, and it must be assumed that in these cases the oxidation of the ferrocyanide is effected by the intermediate formation of peroxides. Since at electrodes of gold and platinum in neutral and alkaline soln., at electrodes of nickel, cobalt, and copper only in alkaline soln., of potassium ferrocyanide and ferricyanide oxidation of the former salt takes place at the same potential and with the same velocity, it is improbable that the passivity of these metals is due to a layer of oxide; it is probably due to the effect of the oxygen charge of the electrode in retarding the liberation of cations from the metal. It is shown that an electrode immersed in alkaline ferrocyanide-ferricyanide soln. becomes more fully charged with oxygen than in neutral soln., and this explains the greater passivity in alkaline soln. In the case of iron, the oxygen charge does not completely hinder the liberations of $Fe^{\cdot\cdot}$-ions from the metal, and therefore there is the possibility of the formation of a surface film of oxide on the anode.

W. J. Müller observed that iron dissolves anodically at all current densities without measurable polarization; and that the current-voltage curves of iron anodes show that the passive state is preceded by the formation of a film of a basic salt or hydroxide of iron which causes a local increase of current density, and the high current density inaugurates the passive state. According to E. Liebreich, during cathodic polarization, the charged hydrogen first formed at the cathode is absorbed either by the metal or by the solution, leaving a film of solution containing an excess of hydroxyl ions which react with the metal to form basic salts or hydroxide; as the polarization increases, the increasing quantities of hydrogen produced reduce these salts again to metal, after which the hydrogen is evolved in bubbles.

F. Förster, and H. Lee found that the yield is increased by raising the temp. M. M. Tichwinsky, also, found that 0·3 volt more is required for the separation of iron from a soln. of ferrous sulphate in darkness than in light. C. Benedicks and R. Sundberg found that the potential of a carbon steel is affected by light provided that some ferric ions are present. A photo-cell was constructed by means of two strips of stainless steel, since, when immersed in a soln. of ferrous sulphate, light increases the value of the electrode potential, making the steel slightly more basic.

A. Finkelstein measured the current-voltage curves at the anode for soln. of ferrous salts, and the results are shown in Fig. 275; and for soln. of ferric chloride at the cathode, in Fig. 276. The breaks in the curves with 0·1*N*-, 0·01*N*-, and 0·001*N*-$FeCl_3$ occur respectively at E_H=0·82, 0·79, and 0·75 volt. The soln. were all 0·1*N*- with respect to hydrochloric acid. The current, *C*, is expressed in arbitrary units. A. Finkelstein said that the break occurs at the cathode when the iron itself separates in the ferric state; and this very quickly is reduced to ferrous iron, which then dissolves in the ferrous salt soln.—*vide infra*, passive iron. A. Finkelstein also determined the e.m.f. of iron electrodes against various soln., and observed that the addition of potassium cyanide to the soln. greatly lowers the e.m.f.; and in soln. of mixed ferrous and ferric salts, the e.m.f. decreases as the ferrous salt is replaced by ferric salt. C. Fredenhagen discussed whether at the electrode during the electrolysis of ferrous or ferric salt soln. (i) a direct change $Fe^{\cdot\cdot}+(\epsilon)\rightleftharpoons Fe^{\cdot\cdot\cdot}$ occurs, as supposed by A. Finkelstein, or (ii) whether the action involves the secondary changes $H^{\cdot}+(\epsilon)=H$, or $2OH'+2(\epsilon)=H_2O+O$, and subsequently $2H+2Fe^{\cdot\cdot\cdot}=2Fe^{\cdot\cdot}+2H^{\cdot}$, or $O+Fe^{\cdot\cdot}+H_2O=Fe^{\cdot\cdot}+2OH'$. According to R. Abegg and J. Neustadt, the potential of ferrous and ferric salts dissolved in

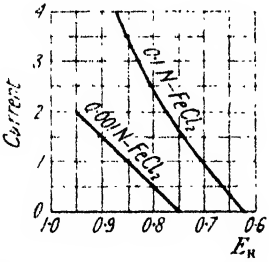

FIG. 275.—Current-Voltage Curves for Ferrous Chloride Solutions at the Anode.

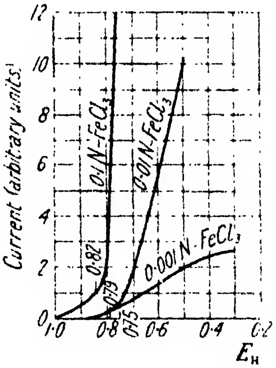

FIG. 276.—Current-Voltage Curves for Ferric Chloride Solutions at the Cathode.

pyridine is constant, showing that the change is direct $Fe^{\cdot\cdot}+(\epsilon)-Fe^{\cdot\cdot\cdot}$. In the first case, the speed of the electrical change depends on the diffusion of the iron salts to the electrodes, and in the second case, on the speed of the chemical reactions as well. The speed of the chemical reactions are very great, so that the speed of the electrical change depends only on the rate of diffusion. Z. Karaoglanoff observed that the rate of reduction of a ferric salt by electrolysis depends on the rate at which ferric ions can be changed into ferrous ions at the electrode, and on the rate at which ferric ions can diffuse into the layer of soln. in contact with the electrode. In a soln. which is not stirred, convection also occurs; owing to the changes of composition and density in the soln. near the electrode, convection currents are produced which tend to keep up the concentration of the ferric ions at the electrode. The same considerations hold good for the oxidation of a soln. of a ferrous salt. The time t during which a current C must flow in order to diminish the concentration of ferric or ferrous ions at the electrode to such a value that hydrogen (or oxygen) is evolved in a soln. of concentration c, is given by $C\sqrt{t}=kc$, where k is a constant which is proportional to the square root of the diffusion coefficient of the salt. This formula is shown to hold good for ferrous and ferric salts so long as the current is not too small. For very small currents, convection at the electrode suffices to maintain the concentration of the ferrous ions above the limit at which gas is evolved. The potential of the electrode during the period in which the concentration of the iron salt is diminishing is also measured, and the curves obtained are found to have the general form required by the assumptions that the loss of ferric ions at the electrode is being replaced by diffusion, and that the relation between the potential of the electrode and the concentration of the soln. is given by R. Peters' formula: $E_H=RT\log\{x/(1-x)\}+E_0$, where x denotes the fractional part of the iron which is present as ferrous salt. T. Graham's experiments show that ferrous and ferric ions diffuse at about the same speed.

In the electrolysis of iron salts, the acidification of the soln. lowers the yield, and unfavourably influences the nature of the deposit. Neutral soln. give the best results; but, as shown by G. Coffetti and F. Förster, and A. Ryss and A. Bogomolny, with the discharge of $H^{\cdot}$-ions at the cathode, there is a tendency to form some ferrous hydroxide which oxidizes easily, and is apt to spoil the deposit. It is therefore advisable to add to the electrolyte some substance which hinders the precipitation of the hydroxide, and forms complex iron-ions. A. Classen, B. Neumann, and E. F. Smith recommended forming complex citrates, tartrates, or oxalates for the electrodeposition of iron for analytical purposes, but ordinary chemical processes are usually more convenient for the determination of iron. F. Braun discussed the **electrostenolysis** of iron—*vide* cobalt.

According to A. Skrabal, two kinds of iron are produced by electrolysis. Type-*A* is white, compact, and very hard, and it is obtained by electrolyzing a soln. of a ferrous salt with an iron anode, and small current density; while type-*B* is greyer in colour, less compact, and softer than type-*A*; it is produced when a platinum anode with a large current density is employed, and a soln. of a complex ferrous salt. By varying the conditions between these two extremes, intermediate types may be formed. By electrolyzing a soln. of ferrous ammonium sulphate with a platinum cathode, an anode of electrolytic iron, and an e.m.f. of about 0·4 volt, the deposit is silvery white and sometimes crystalline. It dissolves slowly in warm, dil. sulphuric acid, and rusts in moist air. Sometimes specimens are obtained which are scarcely attacked by acids or halogens. Type-*A* is always hard, and it usually scratches glass; it is also brittle, but it loses these qualities when it is heated to redness. When the iron is exposed to air, it slowly loses occluded hydrogen, and more rapidly when it is immersed in hot water. This loss of hydrogen does not diminish its hardness and brittleness. A. Skrabal thinks that iron of type-*A* is γ-iron, and it is therefore unstable at ordinary temp. When heated, it changes into stable α-iron which is soft. It cannot be hardened by heating and sudden quenching, owing to the high temp. at which γ-iron changes into β-iron. The presence of large quantities of hydrogen is attributed to the greater solvent action of γ-iron, which is known to dissolve carbon much more readily than α-iron. H. Lee, F. Haber, and others have studied the hydrogen content of electrolytic iron—*vide infra*, action of hydrogen. W. J. Müller and K. Konopicky discussed the residual current; and A. M. Hasebrink, the electrolysis of a soln. of potassium nitrate with iron electrodes.

About 1820, T. J. Seebeck[4] first observed that heat could be transformed into electrical energy—the so-called **thermoelectric force**—without the intervention of a liquid, and he arranged a number of metals and alloys in the order of their thermoelectric effects; he also noted that changes in the order occurred as the temp. was gradually raised, but J. Cumming had also observed that when wires of copper, gold, etc., were gradually heated in contact with iron, the current generated rose to a maximum, fell off, and was reversed at a red-heat. F. T. Trouton observed that a thermoelectric current is produced in iron and steel by a *moving source* of heat, for if an iron or steel wire be heated to redness at any one point of its length, and the source of heat, such as a Bunsen flame, be moved along, an electric current is set up in the direction in which the flame travels. By means of clockwork the flame can be caused to move continuously, and a continuous circuit obtained. There are, however, no signs of e.m.f. in the circuit until the recalescent point is passed; then re-glow takes place behind the moving flame and the cooling effect in front. This thermal difference is thought to be an effect of the resultant e.m.f., for it ceases when the flame ceases to move, and is absent in those metals where recalescence does not occur. Hot iron is thermoelectrically negative to cold iron, but at the critical point a large increase in the e.m.f. is suddenly developed. H. Tomlinson has shown that iron at a bright red-heat in contact with iron at the temp. of the air develops an e.m.f. of about one-twentieth of a volt, or upwards of twice that between a bismuth and antimony couple with a temp. difference of 100° between their junctions. E. D. Campbell and B. A. Soule compared the thermoelectric force of the two ends of a cooling bar of iron. The thermoelectric force of metals was studied by J. Galibourg, S. W. T. Smith and co-workers, P. Nicolau, and R. Cazaud; G. Tammann, G. Tammann and G. Bandel, A. Egal, and E. D. Campbell and W. C. Dowd studied the effect of heat-treatment, etc., on the thermoelectric force of these metals against iron.

The thermoelectric force of a couple made of annealed and unannealed iron showed a sharp maximum at 490° and a minimum at 790°. The e.m.f. of iron against *platinum* at 100° when the cold joint is at 0°, was found by W. Jäger and H. Diesselhorst to be 1·45 millivolt, where the positive sign means that the current flows through the cold junction to the platinum; J. Dewar and J. A. Fleming gave 1·91 millivolt; G. K. Burgess and H. Scott, 1·88 millivolt; and E. Wagner, 1·77 millivolt. A. Goetz gave for $E\times10^{-6}$ volt per degree, with purified iron against platinum:

	650°	700°	750°	800°	850°	900°	910°
$E=$	12·0	14·5	17·0	18·5	19·0	19·5	10·5

	950°	1000°	1100°	1200°	1300°	1400°	1405°	1450°
$E=$	11·0	12·5	15	18	19·5	23	26	27

G. K. Burgess and H. Scott's results for the thermoelectric force of a platinum-iron couple with iron of 99·968 per cent. purity, are shown in Fig. 277. They say: the A_3-transformation in iron is indicated by a marked discontinuity, Ac_3 being always above Ar_3. The arrests are located at approximately the same temp. by the thermal, crystallographic, magnetic, electrical resistance, dilatational and thermoelectric methods, namely, Ar_3 just below 900°, and Ac_3 slightly above 910° C. These physical discontinuities are apparently all a measure of the same transformation. At the A_2-arrest, the thermoelectric force-temp. curve has a break, or change in direction; and the other physical properties, except the crystallographic change, which has not been detected at A_2, appear to undergo abrupt but slight modification—except for the magnetic change, which is relatively enormous here. It is considered that the A_2- and A_3-transformations are essentially different in kind, but nevertheless both have a distinct physical existence; or, in other words, A_2 and A_3 are critical points that may be said to delimit α-, β-, and γ-iron. There appears to be no break or discontinuity in the thermoelectric properties of iron between 0° and 768°; the actual shape of the curve for the thermoelectric force is, of course, contributed to by both the iron and the platinum. At about 880°, in the β-range, there appears to be a slight discontinuity in the thermoelectric properties of iron. The subject was also studied by J. F. T. Berliner, and J. Galibourg. J. Thiele studied the effect of ageing on the result. W. Broniewsky observed a critical point at 1020° with a thermocouple of platinum and electrolytic iron. G. Belloc obtained the results summarized in Fig. 278 for steels containing different proportions of carbon against platinum. The minimum at 380° has not been explained. He said that his observations show that β-iron forms solid soln. with α-iron between 730° and 750°, and with γ-iron between 950° and 1020°. Some other explanation than this is probably needed. M. von Laue and G. Siljeholm observed an abnormal effect near the A_3-arrest. Observations were also made by O. Chwolson, J. R. A. Mousson, H. G. Magnus, and W. Thomson (Lord Kelvin), who found that hard-tempered steel is the negative to soft steel. For couples of magnetized and non-magnetized iron, *vide infra*. The differentials of the platinum-platinum rhodium couple, and of the platinum-electrolytic iron couple with temp. were measured by W. Schneider, and the curve for the platinum-iron couple, plotted in Fig. 280, shows a change of direction at A_2, and sharp breaks at A_3 and A_4. Some hysteresis is shown at the A_3-arrest.

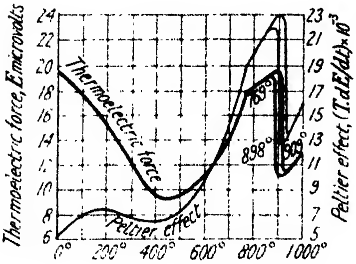

FIG. 277.—The Thermoelectric Force and Peltier Effect with the Platinum-Iron Couple.

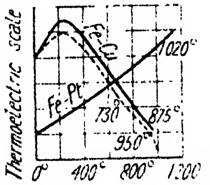

FIG. 278. — Thermoelectric Force of the Iron-Platinum and Iron-Copper Couples.

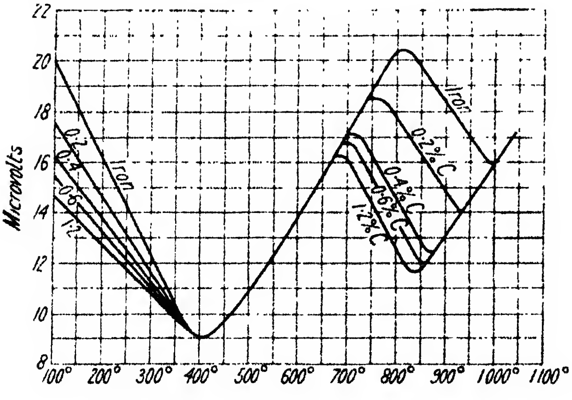

FIG. 279.—The Thermoelectric Force of Platinum against Iron-Carbon Alloys.

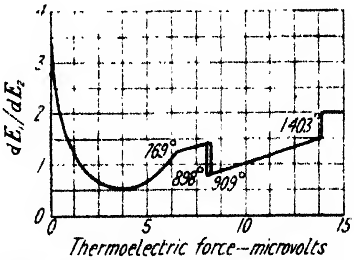

FIG. 280. — The Thermoelectric Force of the Iron-Platinum Couple against a Platinum-Platinum Rhodium Couple.

W. H. Keesom and co-workers measured the thermoelectric force of iron against a gold-silver alloy between −256° and 20°. C. Dannecker measured the e.m.f. of iron against *constantan* and found for the e.m.f. in millivolts:

	−185°	−80°	0°	100°	300°	500°	700°	900°
E.m.f. .	−7·0	−3·4.	0	+5·1	+15·1	+25·7	+36·2	+47·9

F. Hoffmann and A. Schulze obtained values between 0·1 and 1·0 millivolt larger. R. von Dallwitz-Wegner studied the subject. W. Rohn, E. P. Harrison, and L. Holborn and co-workers obtained for iron against *nickel*:

	−185°	0°	100°	300°	500°	700°	900°	1100°
E.m.f. .	−5·08	0	+3·13	+9·2	+11·8	+14·9	+19·5	+23·7

J. P. Joule found that ordinary cast iron is thermoelectrically negative towards *copper*. H. K. Onnes and G. Holst gave for iron against copper at −192°, −250°, −268·74°, and −269·80°, respectively −1·293, −1·319, −1·309, and −1·309 millivolts. E. L. Dupuy and A. M. Portevin found the thermal e.m.f. of various steels against copper, in millivolts, when the steel contained up to 0·05 per cent. of silicon; up to 0·09 Mn; up to 0·025 P; 0·022 S; and 0·011 As:

Carbon . .		0	0·07	0·24	0·44	0·79	1·12	1·58 per cent.
Annealed	−80°	12·20	18·71	10·90	9·50	7·90	5·90	6·61
	100° .	8·70	8·55	7·65	6·20	5·40	4·10	4·15
Hardened	−80°	—	12·35	9·81	5·10	0·92	−5·15	−6·40
	100° .	—	8·73	6·93	3·46	−1·32	−5·70	−15·80

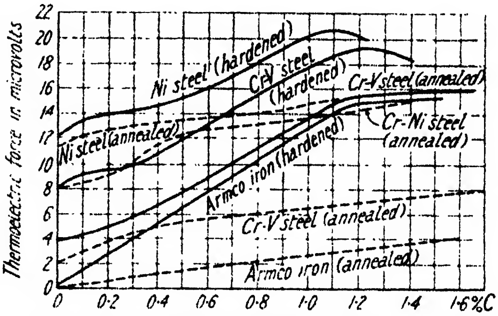

FIG. 281.—The Thermoelectric Force of Iron and Some Alloys.

For these percentages of carbon, *c*, for annealed steels, the e.m.f. in millivolts per degree between −78° and 0° is $E=5\cdot6c+12\cdot2$, and between 0° and 100°, $E=4\cdot6c+8\cdot7$; and for hardened steels between −78° and 0°, $E=-16\cdot7c+13\cdot5$, and between 0° and 100°, $E=-13\cdot9c+9\cdot9$. The decrease in the e.m.f. with increasing carbon is more rapid with hardened than with annealed steels, owing to the passage of carbon into solid soln. in the quenched steels. For the effect with alloy steels, *vide* the respective alloys. E. Dubois found that the thermoelectric effect against copper becomes electronegative after the metal has been heated and subsequently cooled. R. Nübel studied the effect with iron and hydrogenized iron. E. D. Campbell and B. A. Soule examined the thermoelectric force of electrolytic iron against quenched carbon, silicon, nickel and manganese steels at 950°. The effects of tempering alloy steels at about 110° were greater than with the carbon steels. E. D. Campbell and H. W. Mohr obtained the results summarized in Fig. 281, for the thermoelectric force in microvolts per degree, with alloys hardened by quenching at 950°, and then annealed at 800°. W. H. Ross, and C. W. Heaps discussed the thermoelectric force of transversely and longitudinally magnetized iron.

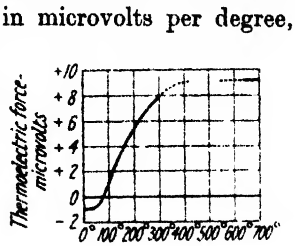

FIG. 282.—The Effect of the Annealing Temperature on the Thermoelectric Force of Steel against Silver.

W. Broniewsky observed a critical point at 730° with a thermocouple of copper and electrolytic iron—dotted line, Fig. 281. This temp. is probably a low reading for the 769° of W. Schneider. There was also a break at 950°. E. P. Harrison's results for the iron-copper couple, continuous line, Fig. 278, showed a break at 859°, which is near the A_3-arrest. Observations on the subject were made by F. E. Bash. V. Strouhal and C. Barus gave the results shown in Fig. 282 for the thermoelectric force of *silver* against hardened steel, and the same steel annealed at different temp. P. G. Tait found that the thermoelectric force of iron against *lead* is 16·2 microvolts at 20°, and 14·74 at 50°; the thermoelectric power, $dE/d\theta = 17 \cdot 15 - 0 \cdot 04828$, and the neutral point, is 356°. Observations were also made by A. Matthiessen, and E. Becquerel. P. G. Tait also noticed that the thermoelectric force of iron alters suddenly in a remarkable way at a red-heat. P. Nicolau examined the thermoelectric force of iron against mercury. G. Borelius observed a number of critical points in the thermoelectric force of the couple of iron and tungsten—*vide supra*, the allotropes of iron.

H. F. Newall, and F. T. Trouton observed that the change which occurs when iron or steel passes through a red-heat can be shown by the thermoelectric current generated when a short portion of wire is made red-hot by the flame of a lamp, if the flame is moved slowly, the direction of the current depends on the direction in which the flame travels. W. F. Barrett called the phenomenon *thermoelectric hysteresis*. H. le Chatelier, and O. Boudouard attempted to apply the phenomenon to the study of allotropic changes; C. Benedicks devised an apparatus for locally heating a wire by a small electric furnace through which the wire travels with a uniform speed. No discontinuity in the thermoelectric effect corresponding with the A_2-arrest was observed; but there is a marked discontinuity corresponding with the A_3-arrest. For magnetized and non-magnetized wires, *vide infra*. C. R. Darling and R. H. Rinaldi found with a couple of iron and an alloy of tin with 60 per cent. of bismuth shows a re-inversion, for with the cold junction at 0°, the e.m.f. is zero when the hot junction is at 0°, 100°, or 350°; during the first interval it is negative with a maximum of 0·5 mvolt, for the second interval, positive with a maximum at 0·13 mvolt; and it becomes increasingly negative above 350°.

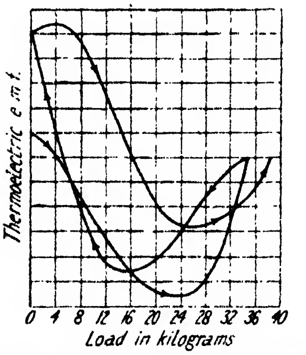

FIG. 283.—The Effect of Load on the Thermoelectric Properties of Iron.

According to A. Goetz, when a thermocouple of iron is so arranged that one of the wires is heated through the transition temp., there is a big decrease in the thermoelectric power as iron passes from the α- to the β-state, and a big increase as the iron passes from the γ- to the δ-state. Iron with the body-centred lattice structure is positive with respect to iron with the face-centred structure. E. Cohn, and J. A. Ewing found that there is much hysteresis of the thermoelectric properties of iron with respect to stress. The effect of a load on the thermoelectric properties of iron, and the hysteresis are illustrated by Fig. 283. The subject was also studied by W. Thomson (Lord Kelvin), C. A. P. Turner, H. G. Magnus, G. W. von Tunzelmann, and R. Overbeck. S. W. J. Smith and co-workers, and L. J. Neuman studied the thermoelectric force between annealed and strain-hardened specimens of iron; O. Tesche, between α- and γ-iron; H. Broili, and J. Kousmine, between magnetized and non-magnetized iron; and M. Maclean found for a thermocouple of drawn and undrawn wires of annealed steel an e.m.f. of 0·1028 microvolt per degree difference of temp. With iron wires one unstretched and the other stretched, the thermoelectric current passes from the unstretched to the stretched wire, and

Total load	250	500	750	1000	1250	1500	1750	2000 grams
Temporary elongation	-	-	0·023	0·03	0·06	0·19	0·39	--
Permanent elongation	-	-	-	0·02	0·027	0·08	0·23	3·41
Microvolt per degree	0·000912	0·006216	0·006216	0·07192	0·09485	0·09430	0·08696	0·07576

For O. L. Kowalke's observations on the thermoelectric force of the cobalt-iron thermocouple, *vide infra*, cobalt; and for couples of iron with aluminium-nickel, and copper-nickel alloys, *vide infra,* nickel alloys. A. Smits and J. Spuyman studied the iron and tin thermocouple. P. W. Bridgman found the thermoelectric effect, E volts, of iron against *lead* at atm. press. to be $E=(16{\cdot}18\theta-0{\cdot}0089\theta^2-0{\cdot}000086\theta^3)\times10^{-6}$ volts for annealed ingot iron; $E=(15{\cdot}92\theta-0{\cdot}0106\theta^2-0{\cdot}000056\theta^3)\times10^{-6}$ volts for hard-drawn ingot iron; and $E=(16{\cdot}56\theta-0{\cdot}0033\theta^2-0{\cdot}000122\theta^3)\times10^{-6}$ volts for annealed commercial iron. The thermoelectric force at different temp. and press., p kgrms. per sq. cm., of a junction of compressed and uncompressed metal was:

		Annealed ingot iron			Hard-drawn ingot iron			Commercial iron		
p . . .		2,000	6,000	12,000	2,000	6,000	12,000	2,000	6,000	12,000
E	10° .	−0·08	−0·27	−0·84	−0·01	−0·21	−0·57	−0·04	−0·22	−0·75
	20° .	−0·08	−0·28	−0·99	+0·02	−0·24	−0·74	−0·03	−0·29	−1·12
	30° .	+0·03	−0·10	−0·81	0·10	−0·11	−0·54	+0·04	−0·19	−1·10

	80° .	1·21	3·15	4·89	1·27	3·40	6·12	1·02	2·47	3·19
	100° .	1·67	4·60	7·68	2·30	6·69	12·80	2·34	5·68	9·56

E. Wagner found for a couple of simple iron wires, one element of which is at a press. of a kgrm. per sq. cm. higher than the other, $12{\cdot}5\times10^{-12}$ volt per degree between 0° and 100°, and that the current flows through the hot joint from the metal at the lower press. to that at the higher press. The subject was studied by A. E. Caswell. P. W. Bridgman found that the thermal e.m.f. from annealed ingot iron when one piece is subjected to a tension T up to 500 kgrms. per sq. cm., is $E=(0{\cdot}0120T-0{\cdot}0_5235T^2)\times10^{-6}$ volts at 52°, and $E=(0{\cdot}0223T-0{\cdot}0_242T^2)\times10^{-6}$ volts at 95°. The e.m.f. is from the unstretched to the stretched wire at the hot junction. H. Tomlinson observed that the thermoelectric force is increased by longitudinal traction, and also by a longitudinal magnetic force. K. Tsuruta discussed the effects of longitudinal stress on the thermoelectric properties of iron. S. L. Brown and L. O. Shuddemagen found for the thermoelectric force of iron against *cupric oxide,* and also against *ferrosic oxide,* when the cold junction is 20°, and the hot junction:

	CuO				Fe_3O_4			
	100°	322°	497°	642°	90°	265°	517°	693°
E.m.f. .	0·085	0·280	0·410	0·503	0·030	0·104	0·211	0·300 volt

G. Borelius and F. Gunneson quenched wires from a series of gradually rising temp., and made the wires into couples with untreated wires, and plotted the results against temp. The proportion of occluded gas modified the curves, but with gas-free metal, there were many breaks in the curves. R. Nübel studied the thermoelectric force of hydrogenized and ordinary iron, where the current flows from the uncharged to the charged metal. F. C. Thompson and E. Whitehead observed critical temp. in the thermoelectric force of iron against platinum. A. Goetz observed that with iron of a high degree of purity there is a great decrease in the thermoelectric force as the metal passes from the γ- to the α-state, and an increase on passing from the α- to the γ-state, so that the body centred lattice structure is thermoelectrically positive to the face centre. E. D. Campbell and H. W. Mohr investigated the thermoelectric potential of iron and iron-carbon alloys. W. Ogawa studied the activation of galena by iron salts for a **radiodetector**; I. Stransky, iron; and W. Jackson, steel-carborundum as a radiodetector.

G. K. Burgess and H. Scott's results for the **Peltier effect** are summarized in Fig. 277. A. Campbell found the neutral point in the Peltier effect with cadmium and iron is 144°; with zinc and iron, 196·7°; and he also observed the Peltier effect with iron and nickel-silver. The subject was discussed by E. H. Hall. U. P. Lely studied the effect with iron and copper. The Peltier effect, p volts, with iron against lead was found to be $P=(16{\cdot}18-0{\cdot}0178\theta-0{\cdot}000258\theta^2)(\theta+273)\times10^{-6}$ volts for annealed ingot iron;

$P=(15 \cdot 92-0 \cdot 0212\theta-0 \cdot 000168\theta^2)(\theta+273)\times10^{-6}$ volts for hard-drawn ingot iron; and $P=(16 \cdot 56-0 \cdot 0066\theta-0 \cdot 000366\theta^2)(\theta+273)\times10^{-6}$ volts for commercial iron. And the Peltier effect, P, in joules per coulomb, at different temp. and press., p kgrms. per sq. cm., for a junction of compressed and uncompressed annealed ingot iron, was:

		0°	20°	40°	60°	80°	100°
p	2,000	−3·3	+0·9	+5·6	+9·3	+8·8	+7·5
	6,000	−10·9	+2·6	+12·2	+24·7	+34·3	+14·9
	12,000	−38·3	+1·2	+15·7	+50·0	+62·2	+35·8

According to P. W. Bridgman, the **Thomson effect,** σ volts, with iron against lead was $\sigma=(-0 \cdot 0178-0 \cdot 000516\theta)(\theta+273)\times10^{-6}$ volts per degree for annealed ingot iron; $\sigma=(-0 \cdot 0212-0 \cdot 0003333\theta)(\theta+273)\times10^{-6}$ volts per degree for hard-drawn ingot iron; and $\sigma=(-0 \cdot 0066-0 \cdot 000732\theta)-(\theta+273)\times10^{-6}$ volts for annealed commercial iron. The thermoelectric effect, $\sigma\times10^{-8}$ joules per coulomb per degree, between the compressed and uncompressed annealed ingot iron, was:

		0°	20°	40°	60°	80°	100°
p	2,000	+17	+23	+25	+5	−10·6	−5·6
	6,000	+79	+56	+37	+79	−11	−121
	12,000	+347	+106	+63	+180	−56	−194

J. Young observed that with annealed wires between 40° and 300°, the Thomson effect increases with the carbon-content; it decreases regularly with a rise of temp. up to 200°, when it becomes irregular, and then passes through a minimum value. The curves for the thermoelectric force of iron or nickel against platinum show a break in the neighbourhood of the Curie point. This corresponds with a more or less rapid change in the Thomson effect, or the "specific heat of electricity." This subject was studied by J. Dorfman and co-workers; and the electronic theory of the phenomenon, by E. C. Stonier. H. E. Smith found that the Thomson effect with iron is $\sigma\times10^{-6}=-2 \cdot 125$ cals. per coulomb per degree; it decreases with tension by becoming less negative until the elastic limit is reached, when the effect increases with tension and follows a definite cycle on removing and restoring the strain. The Thomson effect in iron and steels was studied by J. Young, who found that the effect increases with the carbon-content and passes through a minimum value near 250°.

The so-called **Hall effect,** discovered by E. H. Hall[5] in 1879, refers to the phenomenon which occurs when an electrical current passing between two points in a thin metal plate is introduced into a magnetic field so that the plane is at right-angles to the magnetic field, whereupon the equipotential lines, located by the voltmeter, are distorted so that the electrical current no longer has the same potential as before. The e.m.f., E, set up is given by $E=-RHi/d$, where H denotes the magnetic field; i, the current; and d cm. the thickness of the plate—all other magnitudes are expressed in absolute units. If R denotes the Hall coeff., A. W. Smith found that $R\times10^6=10,300$ for iron with $H=17,000$ gauss at 18°; E. H. Hall and L. L. Campbell, $R\times10^6=7940$ for $H=5300$ at 13°; F. Unwin, $R=10^6=8700$ at 18°; H. Zahn, $R\times10^6=10,800$ for $H=6290$ at 18°; J. Königsberger and G. Gottstein, $R\times10^6=10,000$ at 18°, and H. B. Peacock gave $R\times10^6=16,000$ at 18° for films of iron $270\mu\mu$ thick. W. L. Webster studied the Hall effect with single crystals of iron; and A. Mazzari, the effect of very intense magnetic fields on the phenomenon. The Hall effect was also measured by E. Bossa, M. Cantone and E. Bossa, E. M. Pugh and T. W. Lippert, W. Y. Chang and W. Band, L. J. Neuman, H. B. Peacock, J. C. Steinberg, and P. I. Wold; and H. Atherthum obtained values between −253° and 18°, for values of H not stated; and W. Frey, values between 235° and 1100° for $H=4090$ to 5500, with a critical point between 620° and 920°:

	−283°	−190°	−79°	18°	235°	470°	620°	920°	1000°	1100°
$R\times10^6$	1140	1330	4090	11,230	4610	13,200	21,800	1620	735	459

O. M. Corbino observed that when a uniform radial current flows through a circular disc of metal, placed in a magnetic field normal to the plane of the disc, there is produced a circular current, the density of which is inversely proportional to the radius. The phenomenon is called the **Corbino effect.** If C denotes the circular current; I, the radical current; M, the mutual inductance between the current C and the coil placed near the disc; and m, the standard mutual inductance, then $MC=mI$. The value of m/H referred to that of copper, unity, is 16·4, and the corresponding value for the Hall effect, copper unity, is 21·9 in a field $H=3700$. Observations were made by E. P. Adams and A. K. Chapman. A. K. Chapman found that for iron, with a low field, the value of m/H is zero up to a field of about $H=760$ (Fig. 284), it then rises to a sharp maximum at 950°; falls to half the maximum value for $H=500$; and slowly increases up to $H=10{,}000$. Below $H=300$, the Corbino effect undergoes a reversal.

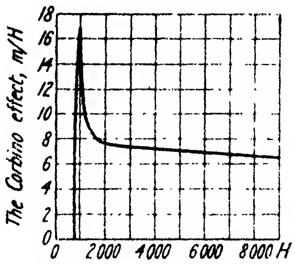

FIG. 284.—The Corbino Effect with Iron.

Ferromagnetic substances behave rather differently from diamagnetic and paramagnetic substances, for the transverse Hall effect in the latter cases are directly proportional to the magnetic field for all fields obtainable, whilst with ferromagnetic substances, direct proportionality holds only up to the region of maximum permeability, as indicated by E. M. Pugh; and above that point, A. W. Smith found that the rate of increase of the Hall effect with the field decreases. A. Kundt, and the early workers thought that the effect with ferromagnetic substances was proportional to the intensity of magnetization, I, rather than to the induction, B, the quantity always measured. At low fields, B and I could not be distinguished, but at higher fields, near the saturation point, the Hall effect was shown to be more nearly proportional to the magnetic intensity, I, than to either the magnetic induction, B, or the magnetic field, H. E. M. Pugh found the Hall effect with steel to be a single-valued, linear function of the intensity of magnetization, I, but neither a single-valued nor a straight-line function of either the magnetic induction, B, or the magnetic field, H. This applies to both the virgin curves and the broad hysteresis loops. A. W. Smith and R. W. Sears found that the Hall e.m.f., ϵ, for ferromagnetic substances can be written $\epsilon=R_0H+R_1I$, where R_0 is a constant nearly independent of the material, and R_1 is a constant which may have any value, positive or negative, depending on the material examined.

The so-called **Ettingshausen-Nernst effect,** discovered by A. von Ettingshausen and W. Nernst in 1886, refers to the phenomenon which occurs when a current of heat is flowing in the thin metal plate, and the plate is introduced into a magnetic field so that the plate is at right-angles to the field, whereupon difference of potential is developed under conditions where, without the magnetic field, no difference occurred. The e.m.f., E, set up is $E=QbH(dT/dl)$, where b cm. denotes the width of the plate; H, the magnetic field; and dT/dl the temp. gradient in the plate, of length, l cm., in degrees of temp. per cm.—all other magnitudes in absolute units. Let Q denote the Ettingshausen-Nernst coeff. F. Unwin found that $Q\times10^6=520$ for iron at 18°; H. Zahn, $Q\times10^6=1050$ for $H=6290$ gauss at 18°, and $Q\times10^6=-1660$ at 55°; E. H. Hall and L. L. Campbell, $Q\times10^6=+860$ for $H=5550$ at 31°; and at 60°, $Q\times10^6=-980$; and A. W. Smith gave $Q\times10^6=-810$ for $H=17{,}000$ to 18,000 at 60°. P. W. Bridgman discussed the relationship between the four phenomena.

The so-called **Ettingshausen effect,** discovered by A. von Ettingshausen in 1886, refers to the phenomenon which occurs when an electric current is passing between two points in a thin metal plate which is then placed in a transverse magnetic field, whereupon a difference of temp. is developed between the upper and lower faces where no difference exists in the absence of the magnetic field. Let dT denote the difference of temp. between two points ; H, the magnetic field ; l, the length of the plate ; and d, the thickness of the plate in cm., then, expressing magnitudes in absolute units, $dT=PH/d$. If P denotes the Ettingshausen coeff., E. H. Hall and L. L. Campbell found that $P\times10^9=-49{\cdot}3$ when $H=5300$ at 13° ; and $-61{\cdot}2$ at 84°. F. Unwin observed $P\times10^9=-43{\cdot}0$ at 18° ; H. Zahn, $P\times10^9=-57$ for $H=6290$ at 18°, and -67 at 20°.

The so-called **Leduc effect,** discovered by A. Leduc in 1886, refers to a phenomenon which occurs when heat is flowing between two points in a thin metal plate placed in a transverse magnetic field, whereupon a variation in the thermal conductivity occurs which does not take place when the plate is not in a magnetic field. If dT denotes the difference of temp. between two points ; H, the magnetic field ; b cm., the breadth of the plate ; and dT/dx the temp. gradient in degrees per cm.—and expressing magnitudes in absolute units, $dT=SHb(dT/dx)$. Let S denote the Leduc coeff. F. Unwin found that $S\times10^9=520$ at 18° ; H. Zahn, $S\times10^9=390$ for iron with $H=6290$ gauss at 18°, and 687 for steel at 55° ; for iron, E. H. Hall and L. L. Campbell gave $S\times10^9=560$ for $H=5000$ at 51° ; 429 for $H=6500$ at 44° ; 608 for $H=7300$ at 48°, and 632 for $H=17{,}000$ to 18,000 at 60° ; and A. W. Smith, $S\times10^9=392$ for $H=11{,}900$ at 56·9°. S. T'ao and W. Band studied the e.m.f. produced when a magnetic field is applied parallel to a temp. gradient.

According to F. Robin,[6] the spark from an electrostatic machine or induction coil produces on the polished surface of steel tiny craters which are formed by the flow of the metal under shock. These holes are visible under the microscope, but to the naked eye, the metal preserves its polished surface. Around this zone there is formed a yellowish aureole—possibly two—formed of oxide ; it is clearly marked in carbon steels with a low percentage of carbon, strongly marked in cast iron, and feebly marked in dead-soft steels. It is hardly visible with pure iron, chromium steel, and chromium-tungsten steel.

H. Schmick and R. Seeliger [7] studied the mechanism of the **arc discharge** with an iron cathode and found the loss of material is definitely not proportional to the current, and it varies primarily as the degree of cooling of the cathode. The loss is not confined to the local point, but is distributed over the whole neighbouring area. A. Günther-Schulze found the normal cathode potential fall of iron, V volts, to be, in :

	Argon	Neon	Nitrogen	Oxygen	Air
V	168	153	215	352	337 volts

The subject was studied by K. Rottgardt, A. Schaufelberger, R. Seeliger and M. Reger, G. Gehlhoff, G. Gehlhoff and K. Rottgardt, E. Warburg, H. E. Ives, E. Blechschmidt, V. L. Chrisler, W. G. Duffield and co-workers, W. Ramberg, W. Neuswanger, W. L. Cheney, E. Lau and O. Reichenheim, G. E. Doan, H. Schüler, R. Defregger, W. Heuse, F. H. Newman, E. H. Owen and P. Wright, H. Dziewulsky, and C. A. Skinner. M. Haitinger measured the intensity of the ultra-violet rays from the iron arc-light, and found it to be greater than in the case of all the other metals which were tried. The cathodic spluttering of iron was discussed by W. Crookes. H. Nagaoka and T. Futagami obtained cinematographic photographs of electrically exploding iron wires. R. Seeliger and H. Wulfhekel studied the loss of material from the cathode of the iron arc ; and H. P. Waran, K. Meyer and A. Günther-Schulze, and T. Baum, the cathodic spluttering of iron in the discharge tube. I. Klemencic studied the behaviour of iron towards electrical oscillations—*vide infra* for the influence of oscillations on magnetized iron. H. F. Richards [8] found that the **dielectric constant** of steel is not infinity, but 3·1.

§ 22. Magnetic Properties of Iron and Iron-Carbon Alloys

The laws of **magnetism** were worked out largely by experiments on the magnetic properties of iron and steel, but it is comparatively rare, in past years, to find full information available as to the nature of the specimens employed. The experiments, however, served their purposes in developing certain principles, and descriptions will be found in the works of J. A. Ewing,[1] T. F. Wall, F. Auerbach, E. Schmidt, W. von Westphal, and many others. Indeed, all textbooks on magnetism are mainly concerned with this element, since iron is king of the magnetic metals. Metals strongly attracted by a magnet are said to be **ferromagnetic**—*e.g.*, iron, steel, nickel, cobalt, and some alloys. Substances which are feebly attracted by a magnet, and which when placed in a magnetic field have a tendency to set themselves with their axes parallel to the lines of force, or have a tendency to pass from the weakest to the strongest part of the field, were said by M. Faraday to be **paramagnetic**—*e.g.* oxygen, and platinum. Ferromagnetism is a special case of paramagnetism. Substances which are feebly repelled by a magnet, and, when placed in a magnetic field, have a tendency to set themselves with their axes at right-angles to the lines of force, or to pass from the strongest to the weakest part of the field, are said to be **diamagnetic**—*e.g.* bismuth is more diamagnetic than any other metal. More substances are known which exhibit diamagnetism than paramagnetism. According to T. Carnelley, on examining M. Faraday's list of paramagnetic and diamagnetic substances:

> The following rule *invariably* holds good without a single exception in the case of the 38 elements to which it can be applied. Those elements belonging to the even series of the periodic system are always paramagnetic, whereas those elements belonging to odd series are always diamagnetic.

And H. E. J. G. du Bois added that, notwithstanding gaps, uncertainties, and exceptions, in the periodic classification of the elements :

> We can detect in the magnetic, as in all the other physical and chemical properties, a periodic variation. The series of paramagnetic elements, which, on the whole, are also very refractory, are found on the descending branches, or in the minima of the atomic volume curve for the solid elements, whilst the more easily fusible, diamagnetic elements occupy the ascending portions and the maxima of the curve.

The paramagnetic and diamagnetic states of many alloys depend on the strength of the applied magnetic field, and K. Overbach applied the term **metamagnetic alloys** to such alloys. For instance, a copper-zinc alloy is paramagnetic in weak fields, but the susceptibility rises to a maximum as the strength of the field increases, and the alloy then becomes diamagnetic. Brass becomes metamagnetic if a few thousandths of iron be present, whilst zinc with up to 4·7 per cent. of iron is independent of the field.

The effect of one magnet on another is greater, the greater the distance between the poles of the magnet, so that both the strength, m, of the poles of a magnet, and the distance between the poles are required in order to determine the effect of one magnet on another. The product of the pole strength, and the distance between the poles is called the **moment of the magnet**, M. The force of a magnet on a distant magnetic needle is doubled by doubling the distance between its poles ; and a magnet with poles half as strong as another magnet, would have the same magnetic moment, provided the poles of the weaker magnet were twice as far apart as the poles of the stronger magnet. The poles of the longer magnet would have only half the volume of steel as those of the second, so that if the moment of each magnet be defined by its volume, v, the quotient, $I = Mv$, is called the **intensity of magnetization,** and indicates the magnitude of the moment per unit volume, or the pole strength per unit area. If the moment be divided by the mass of the magnet, the quotient is called the **specific intensity of magnetization,** and indicates the magnitude of the moment per unit of mass.

When a substance placed in a magnetic field becomes magnetized, there is a relation between the magnetism it acquires and the magnetic force which acts upon it. The force of a magnetic field is represented by H, so that the field is said to be of strength H gauss. The lines of force between the unlike poles of two bar magnets are conducted better by some substances than others. The lines of force between the two magnets in air, are represented diagrammatically by Fig. 285, and when a piece of iron is placed in the gap, by Fig. 286. The crowding of the lines into the iron make it appear as if the lines of force find it easier to go through iron than through air ; the iron appears to be a better conductor for the lines of force than is the case with air. This is expressed by saying that the **magnetic permeability** of iron is greater than is that of air ; or, conversely, the **magnetic reluctivity** of air is greater than that of iron. The permeability of a medium is hence defined as its conducting power for lines of magnetic force when compared with that of air. If H denotes the number of unit lines of force per sq. cm., in the magnetic field, H measures the strength of the magnetic force ; and if B denotes the number of lines of induction per sq. cm. in the material when placed in the field, B measures the **magnetic induction** or **flux density** of the material. The magnetic permeability

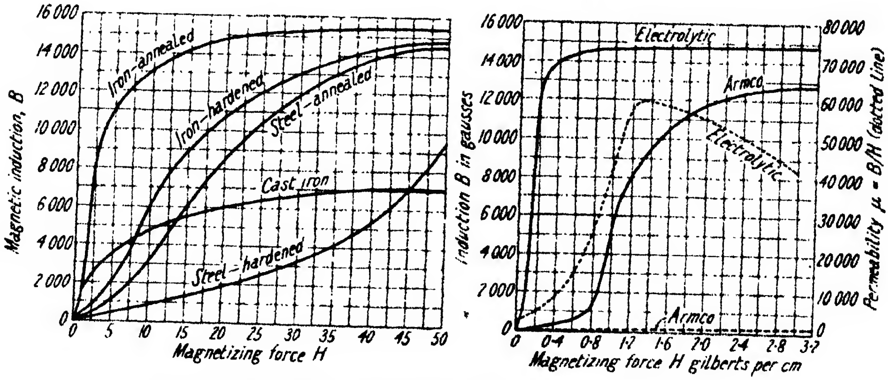
FIGS. 285 and 286.—Linear Force between two Unlike Magnetic Poles in Air, and with a piece of Iron in the Gap.

of the substance is measured by the ratio of B to H, and this ratio is symbolized by μ. Thus, the magnetic permeability $=\mu=B/H$.

Instead of representing the magnetizability of a substance in terms of the permeability, it can be expressed as a relation between the intensity of magnetization, I, and the strength of the magnetic force, H. The ratio of these two magnitudes is called the **magnetic susceptibility,** so that $\chi=I/H$. The magnetic induction, B, or the total number of lines of force per sq. cm. in a specimen, is equal to the sum of two lots—H lines due to the magnetic field, and $4\pi I$ lines per sq. cm. due to the effect of the field upon the specimen, or $B=H+{}^4I$. Since $I=\chi H$, and $B=\mu H$, it follows that $\chi=(\mu-1)I^4\pi$. If the permeability $\mu=1$, as is the case with air, the magnetic susceptibility $\chi=0$. In paramagnetic substances, where μ is greater than unity, the susceptibility is positive; and in diamagnetic substances, where the permeability μ is less than unity, the susceptibility is negative. Hence, when a paramagnetic substance acquires a magnetization I, which is in the same direction as the force, B is greater than H; and conversely for diamagnetic substances, B is less than H. The value $4\pi I$ is taken to represent the **saturation value** of the magnetism with the magnetic force, H.

When soft iron is magnetized, it loses its magnetization much more readily than hard steel. The power of retaining magnetization when the inducing influence is withdrawn is called the **retentivity,** or **remanence,** and the magnetism retained is called the **permanent or residual magnetism.** Soft iron may retain more residual magnetism than steel, but it is unstable and more readily lost than is the case with steel. Material which retains a good portion of its magnetization, despite disturbing influences, is said to have a large **coercivity.**

If a long, thin, unmagnetized iron rod be placed in the solenoid through which a current of any desired strength can be passed, and if the current be gradually increased while the values of the magnetizing force, H, then, the induction or flux density, B, and the intensity of magnetization, I, may be determined at different stages of the operation, so as to show the relation between the magnetism acquired by the iron rod, and the magnetic force acting upon it; the relations of the magnitudes can be represented by the permeability, μ, or BH-curve, since $\mu=B/H$; or by the susceptibility, χ, or IH-curve, since $\chi=I/H$. The values for B and H for some samples of iron and steel are shown in Fig. 287. With a magnetizing force of 2·5 gauss, annealed soft iron has $B=8000$; cast iron, 3000; hardened iron, 1000; and hardened steel, about 400. When $H=10$, the value for soft iron is becoming horizontal; but with hardened iron and annealed steel, until H is 40 to 45; and when $H=50$, the value of B for hardened steel is still rising, but the other metals are practically saturated. The curves show, in general, three stages of progress. At the beginning, when H is small, changes in the value of



FIGS. 287 and 288.—The BH- or Magnetic Induction Curves.

H produce only small changes in the value of *B*, where the permeability is small; in the next stage, where the curve rises rapidly, small changes in the value of *H* produce large changes in the value of *B*. The permeability thus rapidly increases to a maximum. In the third stage, the metal is saturated, and the curve is nearly horizontal, showing that changes in the value of *H* have very little influence on the value of *B*.

The measurements of E. Gerold on the effect of chemical composition on the magnetic induction are summarized in Fig. 289. The continuous curves are for carbon, the dotted curves are for silicon. The effect of additions of 1 per cent. of aluminium, silicon, copper, molybdenum, manganese, and chromium are indicated in Fig. 289.

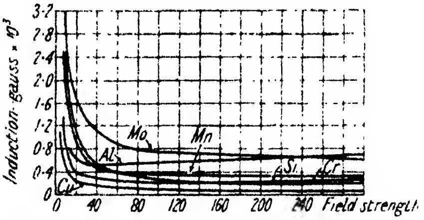


FIG. 289.—The Effect of Different Elements on the Magnetic Induction of Iron.

J. Coulson found that the magnetic moment of iron decreases on hydrogenization, attaining, in time, a value of 5 to 27 per cent. less than the original value. L. W. McKeehan found that the magnetic permeability of single crystals of iron, prepared by high-temp. treatment in hydrogen, are greater than that of crystals obtained by D. Foster, W. Gerlach, R. Chevallier, and K. Honda and S. Kaya by other methods. Observations showed that the high permeabilities were not due to the large size of the crystals, but rather to the treatment with hydrogen at a high temp. A comparison of the magnetization curves, Fig. 290, and the hysteresis loops, Fig. 291, of ordinary annealed iron, and of hydrogenized iron, due to P. P. Cioffi, shows that permeabilities of 130,000 can be obtained when the coercive force is 0·05 gauss, and the hysteresis loss—*vide infra*—for maximum induction B_m=14,000 is 300 ergs per c.c. per cycle. W. E. Ruder, E. Gumlich, and F. P. Wilson reported that the magnetic properties of iron are improved by heating the metal in hydrogen, although E. Gumlich, T. D. Yensen, and F. S. Tritton and D. Hanson did not get such good results by heating the metal in vacuo, in nitrogen, or slightly oxidized atmospheres. J. Würschmidt, L. W. McKeehan and co-workers, and T. W. and W. T. Richards studied the subject. N. A. Ziegler obtained high permeabilities with specimens containing several large crystals, and he considered that the results could be

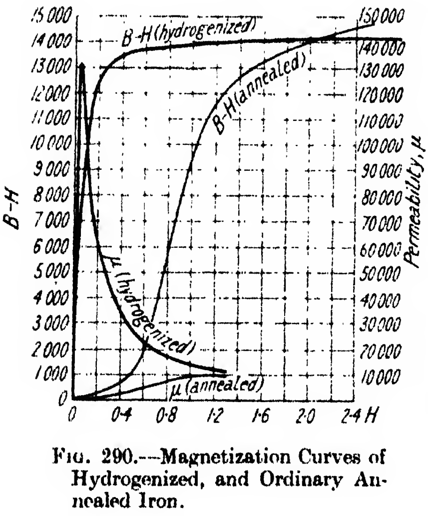

FIG. 290.—Magnetization Curves of Hydrogenized, and Ordinary Annealed Iron.

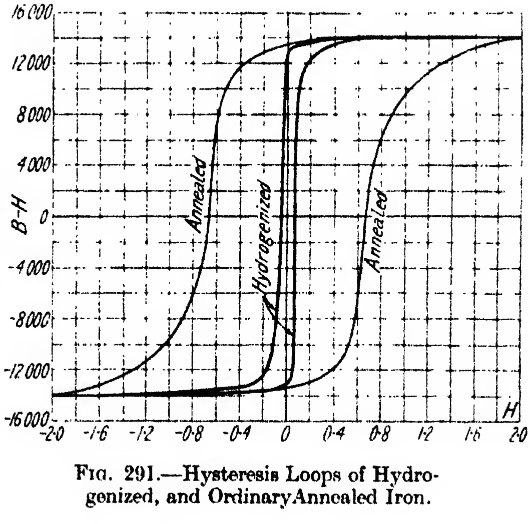

FIG. 291.—Hysteresis Loops of Hydrogenized, and Ordinary Annealed Iron.

obtained only with single crystals; A. Hayes reported higher permeabilities by melting iron in a low press. carburizing atm., and made no mention of the grain-size of the crystals. P. P. Cioffi considered that the high permeabilities obtained with hydrogenized iron are due to absorbed hydrogen, since if the high permeability iron be re-heated to a high temp. in a vacuum of 10^{-8} mm., it assumes the permeability of ordinary iron subjected to the vacuum treatment. The drop in permeability is attributed to the loss of absorbed hydrogen. R. Forrer and J. Schneider studied the effect of annealing iron in hydrogen; and H. Gries and H. Esser, the effects of occluded hydrogen, oxygen, and nitrogen.

W. Köster found that the effect of the precipitation of nitrogen at 100° on the coercive force diminishes linearly as the degree of cold-working is reduced, so that the coercive force of annealed steel increases as the cold-working is increased, on tempering at 100°, after a 5 per cent. reduction by cold-working, the coercive force attains a maximum and then falls off with further cold-working. When the nitrogen is again brought into soln., by tempering at 300°, the effect of cold-working on the coercive force is again restored, showing that the coercive force is compounded additively of an amount conditioned by the degree of cold-working, and an amount conditioned by the distribution of the structural constituents. The changes in the magnetic behaviour of cold-worked steel at temp. between 100° and 300° are to be attributed to the precipitation or soln. of nitrogen, and to no other cause.

The effect of heat-treatment on the magnetic properties of an eutectoid steel was examined by E. Maurer, C. W. Burrows and F. R. Fahy, and C. Nusbaum and co-workers. There is a rapid rise of the maximum and residual induction, and a more pronounced decrease in the coercive force with the cold-work which attends the drawing at temp. of 150° and 250°. The results for the induction, and the reluctivity of an eutectoid-carbon steel, quenched in water from 800°, by C. Nusbaum and co-workers are indicated by the curves, Fig. 292, representing three stages in the magnetization. In stage I, the magnetization curve showing the relation between the induction and magnetization force is nearly linear, and the molecular magnets have been displaced only slightly from their position of stable equilibrium; in stage II, the molecular magnets pass from a state of stability through an unstable state into a new position of stability—the curve in this region is very steep with magnetically soft substances, and more gradual with magnetically hard substances; whilst in stage III, the alignment of the molecular magnets approaches more and more to the direction of the magnetizing force as it increases in magnitude. The slope of the curve also decreases. The reluctivity curve also shows the three stages very well; but with magnetically soft substances, the first two stages almost vanish, and with magnetically hard substances, they become more pronounced. C. P. Steinmetz suggested that both of these are stages of instability, and that, if the specimen whose magnetic properties are being determined is simultaneously subjected to vibration or to an alternating magnetic field applied at right-angles to the unidirectional field, H, these two characteristic stages practically vanish; further, that it is probable that the stable relation between the field intensity, H, and the flux density, B, is expressed over the entire range from zero to infinity by the above linear relationship.

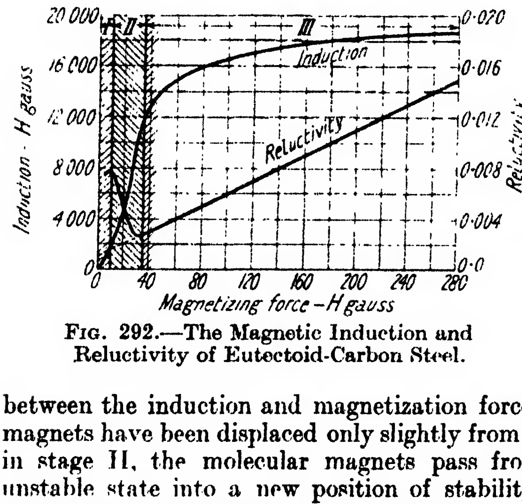

Fig. 292.—The Magnetic Induction and Reluctivity of Eutectoid-Carbon Steel.

C. Nusbaum and co-workers examined the effect of drawing at different temp. an eutectoid steel quenched from 800°. B. O. Peirce showed that for electrolytic iron and forms of iron approaching χ^{-1}, in degree of purity, the relation between the reciprocal of the susceptibility, and magnetizing force is linear—in one case, $\chi^{-1}=0{\cdot}0108+0{\cdot}000575H$. The regions I, II, and III are well-defined in the curves for eutectoid steel, but there is a slight deviation from the linear relation, as shown by the dotted lines. The temp. of drawing is indicated in the diagrams. According to G. Tammann, the intensity of magnetization of a solid soln. is less than that of the more magnetic of the two constituents and also less than would be calculated from a knowledge of the proportion of the constituents. K. Honda also showed that cementite is nearly one-tenth as magnetic as iron, and it becomes non-magnetic at 215°. As a quenched high-carbon steel is repeatedly drawn to increasingly high temp., the magnitude of the magnetic transformation of cementite increases and reaches its maximum in the neighbourhood of 300°. C. Nusbaum and co-workers take these facts to indicate that in the interval of temp. between 150° and 250°, the cementite is thrown out of solid soln., and thus that in martensite the cementite is in solid soln. It also indicates the completion of a previously suppressed transformation, which completion may be considered as the beginning of the metallographic constituent troostite.

In region I, the break in the reluctivity curve in the entire region is taken to show that two magnetically different constituents are present. The non-homogeneity may be due to one of two causes or both, viz. (1) the presence of another constituent, (2) the stresses set up in the material during the quenching operation. The effects of tension were discussed by E. Villari, and K. Honda and S. Shimizu—*vide infra*—and of compression by C. M. Smith and G. W. Sherman. The stresses undoubtedly play an important part, but are not necessarily the predominating factor.

In region II, the material behaves like a homogeneous substance. K. Honda has shown that in this region the carbon is in the form of cementite. There are thus present two magnetically different materials. This is taken to mean that the cementite is evidently distributed very uniformly in very finely divided particles (ultra-microscopic in size) throughout the entire mass of the ferrite, and there are no separate cementite and ferrite crystals. This colloidal soln. is generally considered to be troostite—*vide supra*. In region III, the colloidal soln. of cementite here begins to flocculate, forming aggregates of continually increasing size, which finally attain such dimensions as to produce a magnetically non-uniform or inhomogeneous material, as is indicated by a more or less marked break in the reluctivity line. The line of demarcation between regions II and III then marks the transition between the regions of magnetic homogeneity and non-homogeneity. Since this transition is so sharply defined, it may be chosen as the beginning of the metallographic constituent sorbite.

C. Nusbaum and W. L. Cheney examined the influence on the magnetic and other properties of an eutectoid carbon steel of different rates of cooling from 800°. Some of the results are summarized in Table XLI. The induction increases as the rate of cooling is varied from air-cooling to slow furnace-cooling. Microscopic observations of the different specimens show that the air-cooled material consists largely of sorbite with intervening patches of coarse pearlite containing free ferrite; with slower lime-cooling most of the sorbite passes into lamellar pearlite, whilst patches of coarse pearlite, and free ferrite are still present; in the specimens cooled more slowly in the furnace, there are patches of lamellar pearlite which decrease in size as the rate of cooling is diminished. The matrix of each consists largely of divorced pearlite—cementite particles in a matrix of ferrite. The grain-size of the cementite particles increases as the rate of cooling decreases. C. Nusbaum and W. L. Cheney conclude:

> With decrease in the cooling rate there is a marked increase in the value of the maximum induction for a given value of the magnetizing force, an increase in the magnitude of the maximum permeability, and a decrease in the magnitude of the coercive force. As the structure is changed from an essentially sorbitic one, through lamellar pearlite to divorced

pearlite, there is a gradual shifting of the break in the reluctivity line toward the origin. Also the difference between the magnitudes of the real and apparent values of the maximum intensity of magnetization is greatest when the structure is that of lamellar pearlite. There is a marked agreement between the values of the coercive force and the scleroscopic hardness, as influenced by the various cooling rates, except when the specimen is held at a temp. of 650° for a definite time.

TABLE XLI.—THE EFFECT OF RATES OF COOLING ON THE PROPERTIES OF EUTECTOID CARBON STEEL.

Time (min.) at 800°	Method of cooling	Time (min.) cooling from 800° to 650°	Maximum permeability.	Magnetic induction (H gauss)			Residual induction ($H_m = 150$)	Coercive force ($H_m = 150$)	Saturation intensity of magnetization (c.g.s. units)	Scleroscopic hardness.	Sp. resistance (microhms)
				15	150	100					
—	Air-cooled	·	385	5,150	16,100	20,050	10,050	13·4	1564–1520	43·3	0·2025
—	Lime-cooled	—	437	6,150	16,300	20,000	10,540	12·4	1550–1500	42·3	0·2006
12	Furnace-cooled	56	630	9,300	16,100	20,030	12,300	10·18	1580–1490	33·0	0·1941

20	Furnace-cooled	200	698	10,000	16,300	20,000	13,360	9·2	1612–1430	29·9	0·1931
13	Furnace-cooled	90	633	9,300	16,100	20,080	11,970	9·2	1540–1400	33·6	0·1963

According to C. W. Burrows, the permeability at room temp. increases with a rise of temp. for small inductions, and decreases for high ones; and the change in the induction per degree rise of temp. is greatest in the region of maximum permeability. R. L. Sanford's observations are summarized in Fig. 293. T. Spooner studied the phenomenon with silicon steels.

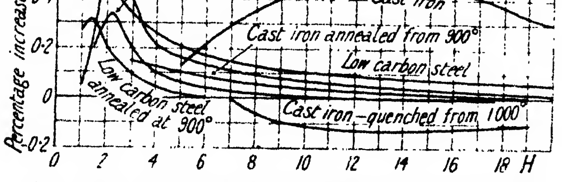

FIG. 293.—The Effect of Temperature on Magnetic Induction.

L. W. Wild measured the magnetic intensity and coercive force of some steels after being quenched from about 900°, and after 24 hrs'. re-heating at different temp. There is usually a large drop in the coercive force between 200° and 300°, and this is attributed to the cementite coming out of soln. and thereby becoming magnetic. The humps in the curves at about 500° are attributed to the cementite partially entering into soln., and not precipitating on cooling. The nickel steel behaves very much like the carbon steel; the chromium steel with 87 per cent. of iron has about 67 per cent. of the saturation intensity of iron and is scarcely affected by the tempering; the coercive force on tempering does not drop so steeply as with other steels. The rise at about 900° is more marked than it is with tungsten steels. There is a hump at 400° in the coercive force curve of chromium steel, at 600° with tungsten steel, and at 700° with nickel steel. H. Pécheux found the permeability decreases regularly with increasing carbon-content for annealed steels, but this relation does not hold good for the same samples after tempering. E. A. Watson considered that in a correctly hardened steel for magnets, the non-magnetic γ-iron should be completely transformed so that austenite is not present, nor should there be any segregation of the carbide and ferrite so that the change associated with Ar_3-arrest should be suppressed. The desirable constituent is the first transformation product from the γ-state. A. A. Dee could detect no difference in the magnetic properties of steels quenched from 300°, although, according to F. C. Thompson and E. Whitehead, the carbide change can be suppressed by suitably cooling from this temp.—*vide supra*. According to G. A. Ellinger, the first application of heat in the tempering of quenched, 0·75 per cent. carbon steel is attended by an increase in magnetization which is believed to represent stress release, caused by the precipitation of carbon from the supersaturated solid soln. of carbon in α-iron. The degree of tempering depends upon temp. and time, the first stage being completed at 200° in about 6½ hours. The precipitated carbon combines with iron in the range between 200° and 300° to form iron carbide. This combination is progressive with time, being completed at 300° in about 1 hr. From 300° to 700° no further magnetic changes occur upon holding the specimen at constant temp., consequently no further constitutional changes take place in this range, but the carbide coagulates to form larger and larger particles. An increase in the magnetization at about 235° indicates the decomposition of austenite, the decomposition being completed in about 45 mins. at that temp.

W. Köster observed that the coercive force of plain carbon steels increases linearly with the carbon-content irrespective of whether the cementite is globular or lamellar, but the rate of increase is smaller with the globular cementite. The coercive force of a steel with banded pearlite is two to three times as great as that of a similar steel in which the cementite is globular. J. R. Adams and F. E. Goeckler studied the influence of the history of the metal on the coercive force and residual reduction; and E. Maurer and F. Stäblein measured the coercive force of cementite. A. W. Smith and co-workers found that increasing the percentage of carbon in steels decreases the magnetic permeability by increasing the amount of carbides in soln., and owing to the asymmetry in the atomic structure making the alignment of the molecular magnets difficult. With annealed bars, the carbides separate from the solid soln., and the effect of carbon is much less. The maximum reluctivity is a linear function of the carbon-content of hardened steel up to 0·8 per cent. of carbon, for annealed chromium steel it is a maximum with about 0·5 per cent. of carbon, and a minimum with about 0·8 per cent. According to R. L. Dowdell, steels for magnets should be treated so that they have the greatest hardness possible without acquiring an undue tendency to cracking. T. D. Yensen and N. A. Ziegler observed that the elements, boron, carbon, zinc, nitrogen, oxygen, sulphur, cobalt, copper, manganese, and nickel, which lower the A_3-point and raise the A_4-point, have a bad effect on the magnetic properties of iron; those which raise the A_3-point and lower the A_4-point—*e.g.* aluminium, arsenic, silicon, tin, and vanadium, but not phosphorus and titanium—have a good effect on the magnetic properties; whilst the insoluble elements have very little effect on the magnetic properties.

As shown by W. Schmidt, and others, steel responds to weak magnetizing forces more quickly than iron; and the susceptibility of soft steel for small magnetizing forces is greater than that of iron. For fields below 0·06 c.g.s. unit, the susceptibility of soft steel to that of iron is as 4 : 3; for fields of about 1·0 c.g.s. unit, the susceptibilities are about the same; and for fields of greater strength, the susceptibility of iron exceeds that of steel. T. D. Yensen's values for vacuum-fused electrolytic iron, and armco iron are summarized in Fig. 288. The results show that whilst the induction curve for armco iron gives an initial bend characteristic of iron in general, the bend becomes very much less pronounced with iron of a high degree of purity, and T. D. Yensen said that "it is not inconceivable that it may disappear for the perfect iron crystal."

The permeability of iron at the beginning of magnetization is very small. C. Gutton and J. Mihul found the permeability of soft iron is constant for small field-strengths up to $H=1$ gauss, and it then increases with the field-strength. C. Baur, and J. A. Ewing found that for values up to $H=0{\cdot}384$, the magnetic susceptibility can be represented by $\chi=14{\cdot}5+110H$; the permeability by $\mu=183+1382H$; the intensity of magnetization by $I=14{\cdot}5H+110H^2$; and the magnetic induction by $B=183H+1382H^2$. Lord Rayleigh found that the proportionality holds good when the magnetic field is excessively reduced, and that the formulæ $\chi=6{\cdot}4+5{\cdot}1H$, and $\mu=81+64H$ hold good for values of H ranging up to 1·2 c.g.s. units. The viscosity or time-lag which occurs in the effect is most noticeable when the magnetizing force, H, is feeble.

C. Fromme observed that with moderately strong magnetizing forces the curves for the permeability and induction, and for the susceptibility and intensity of magnetization have points of inflexion; and this phenomenon was also observed by J. Haubner, W. R. Crane, L. W. Wild, A. Perrier, J. A. Ewing, R. H. M. Bosanquet, and S. Bidwell. J. A. Ewing and W. Low showed that with very strong fields, the induction, B, has no apparent limit, whilst there is a finite or saturation value for the intensity of magnetization, I. Thus, with Swedish wrought iron, in strong fields:

H .	6,690	8,900	95,100	10,000	10,360	10,810	10,880	11,200
B .	2,796	29,730	30,820	31,210	31,630	31,720	32,060	32,360
I .	1,700	1,660	1,700	1,690	1,700	1,670	1,690	1,690
μ .	4·18	3·34	3·24	3·12	3·09	3·05	2·94	2·90

whilst with cast iron:

H .	3,900	6,400	7,710	8,080	9,210	9,700	10,610
B .	19,660	21,932	22,830	23,530	25,580	24,900	25,600
I .	1,250	1,240	1,200	1,230	1,220	1,210	1,190
μ .	5·04	3·42	2·96	2·91	2·67	2·57	2·46

The intensity of magnetization reaches a saturation value beyond which no sensible increase occurs even though the strength of the field be doubled; but there is no sign of any limit to the value of B. K. K. Darrow gave 1706 gauss as the saturation capacity of iron at 20°, and 1742 gauss at −253°. He also gave 19,000 as the permeability of electrolytic iron. P. Weiss' value for the saturation capacity agrees with that given by K. K. Darrow. E. Dussler and W. Gerlach found that the saturation capacity of iron falls off with a rising temp. In a single crystal, in the tetragonal direction, at 20°, saturation was reached at about 150 gauss; at 629°, at 4·5 gauss; at 680°, at 3·5 gauss; and at 738°, at 2·5 gauss. H. E. J. G. du Bois also observed that iron at 0° in moderately strong fields, shows the following relations between the magnetizing force, H, and the intensity of magnetization, I:

H .	100	200	400	600	800	1000	1200
I .	1410	1520	1627	1677	1697	1705	1710

K. Honda and S. Shimizu gave for Swedish iron at different temp.:

−186°	H .	2·23	5·00	15·4	44·7	135·0	221·8	385	543
	I .	77	578	1085	1302	1464	1543	1636	1681
21·5°	H .	1·76	3·39	7·00	33·7	108·8	225·4	390	547
	I .	86	431	858	1264	1424	1536	1623	1660
714°	H .	0·13	0·26	0·50	1·39	2·48	22·46	258·6	377
	I .	49	115	338	533	597	744	829	834
1214°	H .	92	286	442	—	—	—	—	—
	I .	1·4	2·8	3·1	—	—	—	—	—

Observations were made by H. Esser. J. R. Ashworth discussed the relationship between the strength of the alternating current and the intensity of magnetization; E. H. Williams, and J. A. Ewing and W. Low, the effect of transverse joints on the magnetism of iron bars; and R. L. Edwards observed that the magnetic properties of iron films suffer an abrupt change when the thickness exceeds about $50 m\mu$, and an abrupt decrease in the coercive force. The subject was studied by W. Köster, C. Maurain, A. J. Sorensen, and J. H. Howey. H. E. Malmström observed no ageing effect. R. L. Sanford and co-workers found that as the diameter of steel wire decreases by wear, the magnetic permeability increases for low values of H, and increases for high ones. H. G. Byers and A. F. Morgan found that the magnetization of passive steel is more difficult than that of ordinary steel. H. Pender and R. L. Jones, and A. G. Hill studied the effect which a variable magnetic field during annealing has on the magnetic properties; and

K. Honda and Y. Shimizu, and G. Tammann and co-workers, the effect of cold-work.

A selection from the data of E. Gumlich and co-workers is given in Tables XLII and XLIII. Here H denotes the strength of the magnetic field; B, the induction; μ, the permeability; R, the reluctivity; H_c, the coercive force; η, the factor in C. P. Steinmetz's equation;, and I_∞, the saturation value. Observations were also made by S. Curie, T. Matsushita, E. M. Pugh, L. Holborn, S. Guggenheim, and R. A. Hadfield and B. Hopkinson. P. Weiss gave for the saturation value of purified iron, $I_\infty=1706$, and $4\pi I_\infty=21440$; B. O. Peirce, $I_\infty=1733$, and $4\pi I_\infty=21780$; A. Campbell, $I_\infty=1717$, and $4\pi I_\infty=21580$; and E. Gümlich, $I_\infty=1720{\cdot}5$, and $4\pi I_\infty=21620$. For iron alloys with p per cent. of carbon, E. Gumlich gave $4\pi I_\infty=21620-1580p$, when p is less than 1 per cent., and the alloy is slowly cooled, while for higher values of p, he gave $4\pi I_\infty=20100-930(p-1)$; for alloys quenched from 850°, when p is less than 1·2 per cent., $4\pi I_\infty=21620-3200p$; and when quenched from 1100°, when p is less than 1·1 per cent., $4\pi I_\infty=21620-2060p$. P. Weiss and R. Forrer calculated by extrapolation that the saturation intensity of a gram of iron is 12,393. C. F. Burgess and A. H. Taylor studied the permeability of purified electrolytic iron; and H. Sachse, of iron dispersed in alumina, silica, or strontium sulphate. N. A. Ziegler found that the magnetic permeability of unicrystalline iron is many times as great as that of polycrystalline iron. C. Nusbaum and co-workers observed a marked increase in the maximum induction of steels as the rate of cooling decreased; the maximum permeability also increased; but the coercive force diminished.

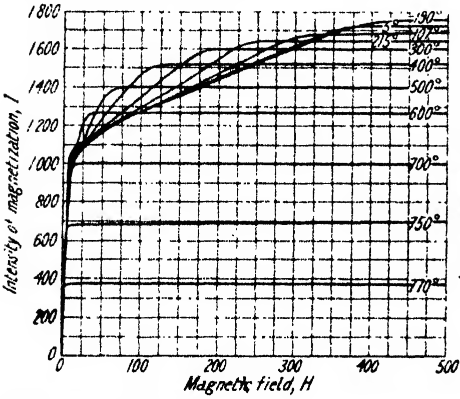

FIG. 294.—The Intensity of Magnetization of Polycrystals of Iron.

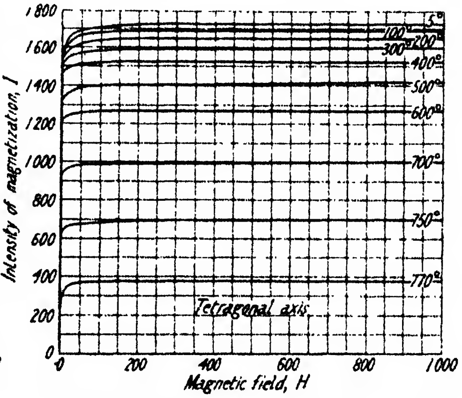

FIG. 295.—The Intensity of Magnetization of a Single Crystal of Iron (Tetragonal Axis).

W. Gerlach, and K. Honda and S. Kaya observed that the characteristic features of the magnetization curve of an iron rod of single crystals of iron are: (i) The curve is almost straight up to an intensity of magnetization of 1000 c.g.s. units; (ii) then the curve shows two sharp breaks or bendings; (iii) the saturation of magnetization is much more easily attained than in the case of polycrystals, its value being 1707 (20° C.) (this saturation value almost coincides with the value 1706 (19° C.) determined in a very strong field produced by an electromagnet); and (iv) the residual magnetism of single crystals is very small. The hysteresis-loss of the rods of single crystals and of those consisting of a gradual increasing number of polycrystals of iron were also measured. The results of K. Honda, H. Masumoto and S. Kaya are summarized in Figs. 294 to 297. K. Honda and S. Kaya studied the magnetization curves of single crystals and found that in the (111)-plane, the curves in the direction of the tetragonal, trigonal, and digonal axes, are almost straight up to intensities of magnetization of 1,400, 900, and 1,000.

The curves then show sharp breaks or bendings twice, sometimes one more break is observable, but is not so conspicuous as the other two. The saturation of magnetization is much more easily attained with single crystals than with polycrystals, and its value amounts to 1717. The saturation in the direction of the tetragonal axis is reached at 70 gauss, and in the digonal and trigonal axes at 650 and 450 gauss, respectively. In the (100)-plane, the direction of the tetragonal axis is more easily magnetizable than that of the digonal. In the (110)-plane, the directions of the tetragonal, digonal, and trigonal axes are in a decreasing order of magnetizability. In the (111)-plane, the space-lattice consists of a series of equilateral triangles. Below a field of 300 gauss, the direction of the sides of the triangle (the *b*-axis) is more magnetizable than the bisector of the triangles (the *a*-axis); but above that field, the contrary is the case. The characteristic features of the curves for magnetization in different directions are as follows: In the (100)-plane, both parallel and perpendicular components of magnetization vary with a period of 90°. For the parallel component, the direction of the tetragonal axis has the maximum magnetization, and that of the digonal, the minimum magnetization; but for the perpendicular component, the magnetization vanishes in the direction both of the tetragonal and digonal axes and attains a maximum or minimum between them. Below a field of 3 and above 500 gauss, the parallel component of magnetization in the (100)-plane is almost independent of the direction of the field. As the field increases beyond 3 gauss, the amplitude of the periodic change becomes greater, attains a maximum and afterwards gradually decreases. In the (100)-plane, these two components of magnetization vary with a period of 180°. For the parallel component, the principal and secondary maxima takes place respectively in the directions of the tetragonal and digonal axes, and the minimum in the directions of 55° and 125° from the tetragonal axis. For the perpendicular component, the magnetization vanishes in the directions of the tetragonal, trigonal, and digonal axes, and attains a maximum or a minimum between them. The amplitude of this periodic change varies in a similar way to the case of the (100)-plane. In the (111)-plane, the two components of magnetization vary with a period of 60°. In weak fields, the parallel component of magnetization in the direction of the sides of the equilateral triangles forming the space-lattice is a maximum and that in the direction of the bisectors of the vertical angle of the triangle is a minimum; but in a stronger field above 300, the opposite is the case. The perpendicular component of magnetization vanishes in these two directions and attains a maximum and a minimum between them. The magnetization of strips of iron depends on the orientation of the crystals with respect to the applied magnetic field. W. E. Ruder observed that the permeability of crystals having their cube edges perpendicular

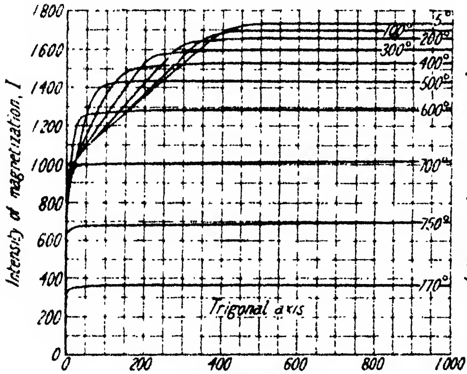

FIG. 296.—The Intensity of Magnetization of a Single Crystal of Iron (Trigonal Axis).

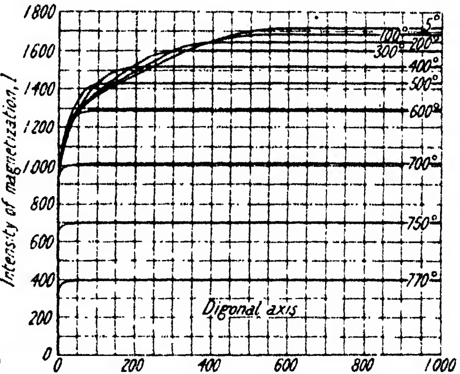

FIG. 297.—The Intensity of Magnetization of a Single Crystal of Iron (Digonal Axis).

and parallel to the direction of the applied flux is 10 to 25 times that which obtains when the crystals have their cube edges at an angle. The lowest magnetic permeability occurs when all the edges are 45° with the direction of the flux. The subject was also investigated by W. L. Webster, F. C. Powell, N. Akuloff, W. Gerlach, K. Beck, H. Gries and H. Esser, G. J. Sizoo, and N. A. Ziegler. W. Gerlach found that remanent magnetism is absent in ferromagnetic single crystals of iron of ordinary size; and J. Frenkel and J. Dorfman consider that the phenomena of retentivity and hysteresis, observed in ordinary ferromagnetic bodies, are connected with the inner stresses characteristic of their structure.

According to N. Akuloff, if a single crystal of iron or nickel be magnetized to a certain intensity, first in the direction of the principal axis, and then to the same intensity in any other direction, the difference in the resulting changes in length of the crystal parallel to the direction of magnetization, and the difference between the relative changes in electrical resistance and the area between the magnetization curves or the alteration in the internal energy, are all proportional to each other. N. Akuloff showed that for a single crystal of iron magnetized to its saturation value, the longitudinal and transverse changes of length accompanying changes in the direction of magnetization relative to the crystal structure can be explained by means of forces arising from the magnetic dipoles; and there is a direct proportionality between the energies involved in such changes in length and the energies required to produce the corresponding change of direction of magnetization. Both phenomena are due to the deviation of the same carrier of magnetic moment from its normal position of minimum energy in the crystal. According to P. Weiss and R. Forrer, the phenomenon of spontaneous magnetization shows that an unmagnetized body at ordinary temp. consists of small volumes magnetized in different directions so that the resultant effect is to give zero magnetic moment to the whole. Under the influence of a magnetic field, some of these elements change their directions or produce their resultant moment. According to K. Honda and coworkers, and W. Gerlach, the coercive force and hysteresis loss which occur in single crystals correspond to the energy loss in breaking up the circuits of flux in the iron, and the more nearly perfect the crystal, the smaller the hysteresis loss. The magnetization thus occurs in two ways: (i) by a change from one cubic axis to another and it occurs in weak fields of a few gauss; (ii) by a break from the cubic direction and it occurs only in strong fields. According to W. L. Webster, the value of the intensity of magnetization at which the break occurs will depend on the direction of the magnetic field relative to the crystal axes. When all the small elements in the crystal of iron have had their direction of magnetization changed to coincide as far as possible with the cubic directions nearest to the applied field, consistently with the condition that there should be no transverse magnetization, then any further increase of bulk magnetization must be produced by forced deviations from these cubic axes towards the direction of the applied field, and the knee will appear. The curves, Fig. 298, are based on those of K. Honda and S. Kaya. With an applied field along a cubic axis, the second process will not appear at all and the initial rapid rise should continue right up to complete saturation. For the (110) and (111) directions the transition should take place at intensities $\sqrt{\frac{1}{2}}$ and $\sqrt{\frac{1}{3}}$ of the saturation values. G. J. Sizoo found that with single crystals in which all mechanical strains had been eliminated by prolonged heating, hysteresis was present only in the region of low field-strength. There are discontinuities in the magnetization curve, and in the region above the

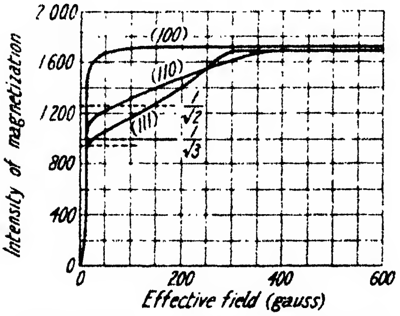

FIG. 298.—Magnetization Curves of Single Crystals of Iron.

last discontinuity, the specimen is completely magnetized; at this point, the hysteresis branch forms a continuation of the reversible part of the magnetizing curve. The retentivity has the same general value as for ordinary polycrystalline iron.

H. F. Parshall observed that the permeability of cast iron is diminished if cooled too rapidly, since combined carbon reduces the permeability. According to J. H. Partridge, the highest values for the induction and permeability are obtained with annealed cast iron. For high permeability, the graphite should be in the form of temper carbon; the combined carbon, low; and cementite absent. Cementite, added H. Nathusius, is a sure indication of poor magnetic properties. W. Köster and H. Tiemann studied the effect of annealing. H. F. Parshall said that between 2 and 3 per cent. of graphite has no perceptible effect on the permeability. An excess of sulphur favours combined carbon and reduces the magnetic quality. F. Goltze also found sulphur to be prejudicial to the magnetic properties of cast iron. H. F. Parshall concluded that silicon annuls the effect of sulphur, and no inferiority was observed until the proportion exceeded 2 per cent. P. Reusch said that silicon precipitates graphite, and precipitated graphite lowers the magnetic induction. H. Nathusius said that silicon improves the magnetic properties of cast iron. F. Goltze, and J. H. Partridge observed that silicon decreases the magnetic induction, and the coercive force and the hysteresis loss are reduced with silicon in cast and annealed iron. An excess of phosphorus over 0·7 per cent. reduces the magnetic quality; F. Goltze said that phosphorus reduces the permeability: and J. H. Partridge, that phosphorus has but little effect on the magnetic properties. H. F. Parshall showed that manganese has little effect when present in its usual amounts, and this agrees with P. Reusch's observations. F. Goltze, and J. H. Partridge found that manganese reduces the induction of cast and annealed iron, but with annealed iron, the coercive force and hysteresis loss are increased, and the remanent magnetism decreased. A. Schweitzer observed that up to 3 per cent. of aluminium reduced the magnetic properties of iron. J. H. Partridge observed that aluminium decreases the magnetic induction, permeability, and remanent magnetism, and raises the coercive force and hysteresis loss; whilst with the annealed iron, up to 1 per cent. decreases the induction and maximum permeability, but increases the coercive force and hysteresis loss. Amounts between 1 and 3 per cent. increase very much the induction and permeability, and decrease enormously the coercive force and hysteresis loss. J. H. Partridge said that chromium acts like manganese and is prejudicial to magnetic induction both in the cast and annealed alloy, and that nickel behaves similarly. The presence of sufficient nickel, or nickel and manganese makes *non-magnetic cast iron*. The iron should be entirely austenitic. The presence of cobalt increases the magnetic induction and remanent magnetism, and increases the maximum permeability of cast iron. The subject was discussed by H. O'Neil, P. Nicolau, and R. L. Sanford. W. F. Barrett found that the order of magnetic permeability of the alloys of iron is different from what is the case with the order of electrical conductivity. The most permeable alloys observed were those with silicon and aluminium; the magnetic permeability of an alloy with 2·5 per cent. of silicon (*q.v.*) exceeds that of annealed iron of a high degree of purity up to a field of 10 c.g.s. units; and with aluminium alloys, the magnetic permeability up to a field of 60 c.g.s. units exceeds that of the iron. The increased magnetic susceptibility of these alloys may be due to their action in removing traces of iron oxide from the metal.

R. Gans, and W. Steinhaus and E. Gumlich showed that the ideal, reversible permeability curve of mild steels is infinite in weak fields. C. Biéler-Butticez studied the effect of cold-work on the magnetic properties of iron. A. Kussmann and B. Scharnoff observed no relationship between the magnetic hardness or coercive force and the mechanical hardness with alloys of iron and nickel with copper, aluminium, and chromium; but C. Nusbaum observed that the coercive force of an eutectoid carbon steel is in a good agreement with the scleroscopic hardness when the steel has been cooled at different rates. W. M. Hicks found that aluminium, phosphorus, and arsenic decreased the coercive force and hysteresis loss of iron, and aluminium largely increased the permeability. G. Malmberg, and H. E. Diller discussed the effects of small proportions of different elements on the magnetic permeability of iron— *vide infra,* the alloys of iron.

The permeability was measured by A. M. Armour, M. Ascoli and F. Lori, J. M. Baldwin, R. Beattie and H. Gerrard, R. Becker, G. Belloc, R. Bown, A. Campbell, H. le Chatelier, W. L. Cheney, C. Chistoni and G. G. de Vecchi, S. S. Clark, R. E. B. Crompton, G. Delbart, H. E. Diller, C. V. Drysdale, E. Dumont, A. Durward, F. Erhardt, J. W. Esterline and R. B. Treat, J. A. Ewing, H. Frank, O. Frölich, R. Gans, F. Goltze, A. Gray, R. C. Gray, E. Gumlich and co-workers, E. P. Harrison, E. Haupt, C. Heinke, P. Holitscher, R. Hugues, A. Iliovici, H. Kamps, Y. Kato, A. E. Kennelly, W. N. Kernot, I. Klemencic, J. Königsberger, A. Koepsel, W. Köster, H. Lange, G. C. Marris, J. A. Mathews, D. Mazzotto, J. T. Morris and T. H. Langford, E. Müllendorff, W. H. F. Murdoch, B. Neumann, P. Nicolau, J. H. Partridge, B. O. Peirce, A. Perrier, Lord Rayleigh, P. Reusch, E. Rhoads, J. Sahulka, G. F. C. Searle, E. Schmidt, W. Schmidt, E. K. Scott, R. Shida, B. S. Summers, T. Swinden, R. van Tongel, M. E. Thompson, S. P. Thompson, A. M. Thiessen, J. Trowbridge and E. P. Adams, A. Turner, G. R. Wait, H. S. Webb, M. Wien, R. L. Willis, E. Wilson, and J. Würschmidt ; and H. Kamps studied the effect of a layer of oxide on the magnetic properties of iron.

A. W. Rücker measured the step-by-step magnetization of iron. S. Procopiu, and T. Spooner studied the effect of a superposed alternating field on the magnetic permeability of iron. E. W. Marchant found that the permeability of iron subjected to an oscillatory discharge of 10,000 to 100,000 cycles per second is not sensibly different from the result obtained by ballistic tests. The damping of the oscillations was more rapid with thicker iron wires ; and with cores of solid iron, the discharge was reduced to one-half oscillation. J. R. Martin, E. Krauter, W. Kartshagin, and W. Arkadieff measured the magnetic properties of iron for alternating fields from zero to very high frequencies ; R. Gans, and G. Vallauri for slowly rotating fields ; whilst M. J. O. Strutt, and L. Tonks measured the effects of a high-frequency rotating field—from 52,000 to 170,000 cycles per second. W. K. Mitiaeff reported an anomalous change in the permeability of iron at radio-frequencies, but it could not be verified by G. R. Wait and co-workers. R. Urbschat, E. M. Guyer, G. Laville, B. Wedensky and K. Theodortschik, O. M. Corbino, W. H. Eccles, W. K. Mitiaeff, J. B. Hoag and H. Jones, and C. Gutton and I. Mihul studied the permeability of iron at high frequencies ; and S. K. Mitra, the demagnetization of iron by electromagnetic oscillations of frequency up to 500,000 per sec. L. Tonks, and J. Grant also studied the behaviour of iron in electromagnetic fields of high frequency. M. Tschetverikova observed the demagnetization of iron in damped, magnetic, alternating fields, and with short Hertzian waves $\lambda=28$ to 1700 cm. Slow alternatic fields demagnetize iron only when the field-strength is below 2·3 gauss. No demagnetization was observed with undamped waves, and B. Wedensky and K. Theodortschik observed that there is an anomaly. Demagnetization phenomena were studied by R. Forrer and J. Martak in the permeability of iron in oscillating magnetic fields, but R. Bown, and G. R. Wait and co-workers observed no change in the permeability of iron exposed to radio-frequency vibrations.

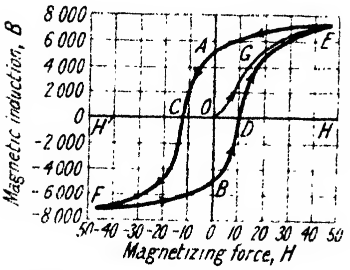

FIG. 299.—Cyclic Magnetization-Hysteresis Loop.

If a long, thin, unmagnetized rod be placed in the solenoid, and the current be gradually increased from zero to a maximum value, *OH*, Fig. 299, the resulting *BH*-curve will be represented by, say, *OGE*, where *HE* represents the maximum flux density or induction. Let the current be now reduced to zero, when the curve *EA* is obtained : here *OA* represents the flux density or residual magnetism or remanence. Let the current now be reversed in direction, thus tending to magnetize in the opposite direction, and gradually increased to a maximum *OH′*. The curve *ACF* is now obtained. Here *OC* represents the value of the reversed magnetizing force necessary to reduce the flux density to zero, or to wipe out the residual magnetism, or remanence. Here *OC* is the so-called **coercive force,** or a kind of *magnetic hardness*. On again decreasing the magnetizing current to zero, and reversing so as to increase the induction to its maximum value, the curve *FBDE* is traced. If the cycle be repeated, the curve will be retraced, but the initial path, *OGE*, is not followed unless the specimen is first completely demagnetized. The magnetic effects are liable to persist, or lag behind the applied force. Thus, the value of *B* when *H* is decreasing is always greater than when *H* is increasing. When *H* is zero, *B* still has a definite value, and a reversal of the magnetizing force is necessary to bring *B* to zero.

The time-lag of the intensity of magnetization, *I*, on the change of magnetizing force, *H*, is called the **magnetic viscosity.** When annealed wrought iron is subjected to a magnetizing force, and the force is changed, the magnetic viscosity shows itself as a lapse of time before the corresponding change in magnetic intensity is complete. The effect is most pronounced with small magnetic forces or with very small changes of the magnetizing force. C. Lapp found that electrolytic iron exhibits magnetic viscosity and that the viscosity is diminished by prolonged ageing at 130° to 190°, but at the expense of the magnetic properties of the metal. Annealing the electrolytic iron at 300° to 500° has the reverse effect. The reciprocal of the permeability of iron is termed the **reluctivity,** and T. F. Wall gives the values shown in Fig. 300 for the reluctivities of some ferromagnetic metals—annealed iron, annealed steels, cobalt, nickel and Heusler's alloy. C. Nusbaum and co-workers studied the relation between the reluctivity and the structure of eutectoid carbon steel—*vide supra*, Fig. 300.

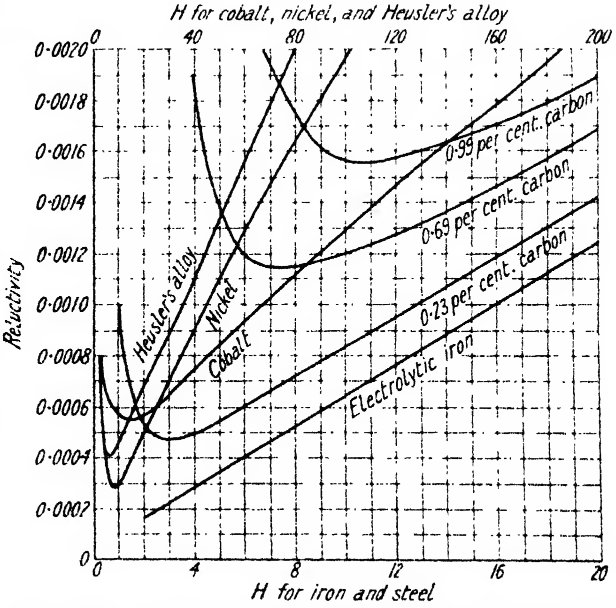

FIG. 300.—The Reluctivities of some Ferromagnetic Metals.

J. A. Ewing applied the term **hysteresis** to the lagging of the magnetic induction, or flux density, behind the magnetic force which produces it. E. Warburg showed that the area of the hysteresis loop is proportional to the energy lost in the specimen owing to the change in its magnetic condition. The energy, *W*, dissipated owing to the so-called **hysteresis loss,** represented by the area of the loop *FCAEDB*, Fig. 299, can be expressed in ergs per c.c. per cycle. This was verified by J. A. Ewing, J. Hopkinson, and Lord Rayleigh. The dissipation of energy produces a thermal effect which is observed during cyclic reversals of the magnetization.

The phenomenon was studied by J. A. Ewing, G. Kapp, A. Tanakadate, L. T. Robinson, J. P. Joule, W. R. Grove, J. G. S. van Breda, J. Jamin and G. Roger, F. W. Constant, M. Fukuda, L. Pilleux, A. Cazin, E. Edlund, Lord Kelvin, R. Gans, K. Uller, H. A. Dickie, W. M. Mordey and A. G. Hansard, C. E. Guye and A. Schidlof, H. Nathusius, A. Gradenwitz,

F. Niethammer, K. Seyama, M. E. Ricea and B. McCollum, E. E. F. Creighton, M. G. Lloyd and J. V. S. Fisher, R. Beattie and P. M. Elton, A. Ebeling and E. Schmidt, F. F. Martens, A. D. Adams, F. C. Langenberg and R. G. Webber, M. Brylinsky, R. G. Loyarte, N. Danielsen, C. E. Webb and L. H. Ford, E. Spuhrmann, S. W. Richardson and L. Lownds, L. M. Potts, A. Dina, R. Hiecke, G. F. C. Searle and T. G. Bedford, T. Gray, F. G. Bailey, G. G. Gerosa and co-workers, H. Nagaoka, W. Kunz, C. G. Knott, A. Abt, J. Swinburne and W. F. Bourne, W. H. Preece, J. Schneider, N. Nikitin, J. Trowbridge, J. Trowbridge and W. N. Hill, H. Herwig, J. Borgmann, E. Müllendorff, E. A. Watson, A. Kühns, P. Duhem, F. A. Weihe, E. Höller, H. F. Parshall, C. Maurain, E. Wilson, E. Schmidt, G. Hannack, A. Wassmuth, M. G. Lloyd, R. Richter, J. Herrmann, P. Weiss and V. Planer, G. Vallauri, J. H. Andrew and co-workers, P. H. Dudley, B. G. Churcher, C. W. Burrows and F. P. Fahy, N. J. Gebert, S. R. Williams, R. L. Sanford and co-workers, C. Nusbaum, H. Alfven, R. H. de Waard, W. Neumann, D. Foster, and E. Warburg and L. Hönig.

E. Warburg observed that 68 per cent. of the energy represented by the area of the hysteresis loop is dissipated as heat; A. Tanakadate observed 80 per cent.; I. Klemencic, 100 per cent.; and F. A. Weihe, 80 per cent. for iron, and 73 per cent. for steel. The subject was studied by W. B. Ellwood. According to W. B. Ellwood, on traversing the hysteresis loop from 290 to 20 gauss, heat is evolved by the iron; on passing from 20 to −6 gauss, the iron cools suddenly; from −6 to −90 gauss, the iron rapidly becomes warm; and as the field passes from −90 to −290 gauss, the iron is cooled. C. H. Willis emphasized the value of a high proportion of silicon in steel when it is desired to prevent losses by hysteresis and eddy currents. J. R. Ashworth studied the changes in the energy of iron cooling through the critical temp.; and N. W. McLachlan, the heat produced when iron is magnetized by high-frequency alternating currents. E. Condon discussed a possible directional hysteresis in iron.

A. J. Sorensen, R. L. Edwards, J. D. Hanawalt and L. R. Ingersoll, E. P. T. Tyndall, and L. C. Jackson discussed the magnetic properties of thin films of iron. C. Maurain found the thinnest film of iron showing magnetic properties was a millionth of a millimetre in thickness. E. F. Burton and B. Phillips observed that the magnetic susceptibility of a colloidal soln. of iron in methyl alcohol is stronger than it would have been if the iron were present as a ferric salt, and yet weaker than iron alone. It is concluded that each particle of iron is surrounded by a compound of iron—say, the hydroxide. The subject was studied by H. Isnardi, C. G. Montgomery, and R. Gans; whilst B. Speed and G. W. Elmen investigated the magnetic properties of compressed powdered iron.

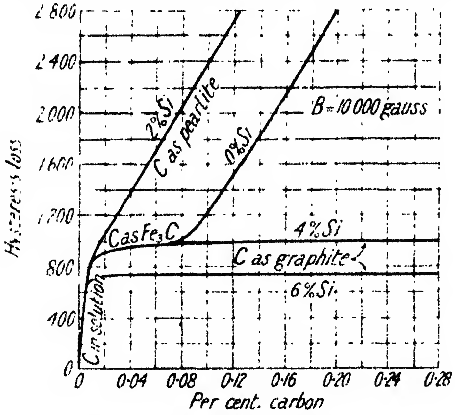

FIG. 301.—The Effect of Carbon on the Hysteresis Loss of Iron-Silicon Alloys.

T. D. Yensen summarized his observations on the effect of carbon and silicon on the hysteresis losses, in ergs per cm. cube per cycle for $B=10{,}000$, in Fig. 301. Every 0·001 per cent. of carbon raises the hysteresis loss about 10 per cent. provided less than 0·008 per cent. of the carbon is present in solid soln. so as to form part of the iron lattice. Nitrogen and oxygen are thought to behave similarly. With electrolytic iron containing 0·005 per cent. of carbon, the maximum permeability increased with addition of carbon from 25,000 to 61,000 with 0·06 per cent. of carbon, and 0·4 per cent. of oxygen. It is assumed that here the added carbon deoxidized the iron and left in the metal no oxygen and only about 0·005 per cent. of carbon. For hydrogenized iron, *vide supra*. S. Saito studied the saturation value of cementite and of the complex carbides with tungsten and with chromium.

T. D. Yensen showed that the hysteresis losses of iron are influenced by the grain-size. J. R. Ashworth studied the anhysteresis of iron, and the hysteresis of iron cooling through the critical temp.

The time lag in the magnetization of iron was attributed by C. Lapp to magnetic viscosity, and not to induced currents as supposed by R. M. Bozorth. J. Hopkinson and E. Wilson, E. Donati, and T. R. Lyle and J. M. Baldwin studied the rate of propagation of magnetism along iron rods. O. Grotrian showed that with a cylinder of iron magnetized in the direction of its axis, with low saturation, the magnetization of the periphery is greater than that of the axial portions. M. Ascoli and F. Lori discussed the distribution of induced magnetism in iron. I. Klemencic observed that the magnetic permeability of iron is different in circular and axial directions, and the phenomenon may be called magnetic double refraction. The permeability with soft iron is smaller around the axis than in the direction of the axis; and in the process of drawing hard iron or steel, the metal obtains a stronger permeability axially than in the circular direction. W. Penkert showed that when a long, straight bar is excited by a magnetizing coil saturated at the centre, the lines of force which pass through the coil do not keep in the iron up to the end, but emerge into the air at all points along the length of the bar. This explains why the induction of the bar falls off continuously as the distance from the central source of magnetization is increased.

According to W. M. Mordey, the slow change which occurs in the permeability of iron is not due to progressive magnetic fatigue caused directly by repeated reversals. Neither magnetic nor electric action is necessary for its production. It is a physical change resulting from a prolonged heating at a very moderate temp. The change is greater if pressure be applied during the heating, and it is not produced when iron is not allowed to rise in temp. more than a few degrees above atm. temp. A similar effect is produced by hammering, rolling, or heating to redness and cooling quickly, and the iron returns to its original state when re-annealed. The iron does not return to its original conditions if kept unused, and at ordinary temp., for long or short periods. D. Mazzotto found that the effect of ageing is a maximum at 131°. The subject was discussed by R. L. Dowdell, H. Kühlewein, and T. E. Green.

T. Sone examined the magnetic properties of electrolytic iron deposited in a magnetic field, and he found that the curve of initial magnetization lies considerably higher that it does with specimens obtained in a zero field; the loop of the hysteresis curve is also wider than it is with ordinary iron, but the magnetic field applied during electrolysis does not sensibly affect the hysteresis curve. The hysteresis curve of electrolytic iron deposited in a magnetic field becomes flatter with the lapse of time as the molecules settle down slowly to a state of equilibrium. Annealing hastens this change. H. Hanemann and P. D. Merica observed a close and nearly linear relation between the elastic limit of soft iron, and the values of the stress at which permeability maxima occur as the metal is elongated.

H. Barkhausen observed some discontinuities in the magnetization of certain ferromagnetic materials, which have been called the **Barkhausen effect.** The Barkhausen effect, dB/dH, represents the change of induction dB with change of magnetic field dH; the rate of change of induction being represented by dB/dt, and the rate of change of the magnetic field by dH/dt. H. Barkhausen, and B. van der Pol attributed the effect to the sudden re-orientation of groups or changes of molecular magnets, possibly all the magnets in a single crystal turning simultaneously. There is a larger effect in hard-worked than in annealed materials. The change occurs on the deeper parts of the hysteresis loops of hard-worked iron and permalloy. E. P. T. Tyndall found that the size of the discontinuities does not depend on the grain-size of silicon steel; and G. J. Sizoo made a similar observation with regard to electrolytic iron. R. M. Bozorth observed that the larger discontinuities on the steeper parts of the hysteresis loop correspond with the complete reversals of magnetization of about 10^{17} atoms, or a vol. of 10^{-6} c.c.

The effect has been studied by W. Gerlach, W. Gerlach and P. Lertes, J. D. Ball and W. E. Ruder, E. C. Stoner, B. del Nunzio, I. Langmuir and K. J. Sixtus, A. von Hippel and co-workers, W. Brandt, D. G. C. Luck, F. J. Beck and L. W. McKeehan, P. Weiss and G. Ribaud, K. Zschiesche, S. R. Williams, R. M. Bozorth and co-workers, F. Preisach, J. Frenkel and J. Dorfman, O. Tesche, A. Cisman, E. P. T. Tyndall and J. M. B. Kellogg, S. Procopiu, S. Procopiu and T. Farcas, K. J. Sixtus, K. J. Sixtus and L. Tonks, H. Biron, K. Steimel, and J. Pfaffenberger. C. W. Heaps and J. Taylor found that with high speeds of magnetization there are more and smaller discontinuities as the speed is slightly reduced; and with large reductions of speed, there are fewer discontinuities in ordinary specimens than for high steels. The mechanical Barkhausen effect obtained by twisting or stretching occurs with iron and annealed nickel, and it almost disappears when the magnetization approaches saturation. A hard steel ball of fine homogeneous structure showed no discontinuities. D. Foster observed no breaks in the knee of the magnetization curve of single crystals of iron. R. Forrer also observed that the Barkhausen effect is strongly influenced by internal strains. E. P. T. Tyndall did not accept the hypothesis of W. Gerlach and P. Lertes, and K. Zschiesche said that the effect depends on magnetostriction, but it is in agreement with the work of L. W. McKeehan, and C. W. Heaps and J. Taylor. The strains set up by magnetostriction—*vide infra*—when relieved discontinuously produce the jumps of induction. H. Rindfleisch studied the effect of helium and neon on the Barkhausen oscillations.

The magnetization curves and hysteresis loops of single crystals of iron made by W. Gerlach show breaks or abrupt changes of slope; and this was also confirmed by E. Dussler and W. Gerlach, H. Gries and H. Esser, and G. J. Sizoo. On the other hand, D. Foster, E. Wollman, and D. Foster and R. M. Bozorth observed no breaks in the curve. The discrepancy is due to the need, in the former case, for applying corrections for the field intensity which usually goes through a rather sharp maximum in the same range of magnetization as is occupied by the knee of the curve. R. Goldschmidt discussed the relation between permeability and hysteresis.

C. P. Steinmetz obtained an empirical relation between the work, W, lost by hysteresis effects, $W=\eta B^{1\cdot6}$, when η is constant for any one specimen, and it is called the *coefficient of hysteresis*. J. A. Ewing said that 1·59 is more in accord with the published data than 1·6 for the general constant. The formula is applicable for the range of magnetization used in electrical engineering, but is not applicable for very weak or very strong magnetic fields. The subject was investigated by J. A. Ewing and H. G. Klaassen, W. Elenbaas, A. E. Kennelly, J. A. Fleming and co-workers, M. Nakamura, H. F. Parshall, etc. The values of η for soft iron ranges from 0·001 to 0·003; for annealed high carbon steel, 0·008; and for hardened steel, 0·025. Some values for steels with different heat-treatments are indicated in Table XLIII. C. P. Steinmetz observed that for many kinds of iron, the ratio η/H_c, is a constant—here H_c denotes the coercive force. For H with a maximum of 500, S. Curie obtained linear relation between the coercive force and the hysteresis coefficient. The following values were given by C. P. Steinmetz, W. F. Barrett and co-workers, A. Ebeling and E. Schmidt, E. Gumlich and E. Schmidt, S. Curie, and C. Benedicks:

$H_{\text{max.}}$.	40	45	90	100	150	205	500	505
η/H_c .	0·00131	0·00105	0·00103	0·00110	0·00105	0·00092	0·00072	0·00062

$H_{\text{max.}}$ . . .	4·9	10·1	14·4	18·9	23·5	30	82
η/H_c . . .	0·0066	0·0026	0·0023	0·00155	0·00128	0·00114	0·00098

C. Benedicks studied the relation $\eta/H_c=0\cdot00067+0\cdot0257/H_{\text{max.}}$; E. Gumlich and E. Schmidt, and C. Benedicks, the relation $\mu=aR/H_{c\text{max.}}$, where R denotes the remanence, and a is a linear function of the coercive force, $a=\alpha+\beta H_c$, where α and β are constants; and C. Benedicks, the relation $R=I_\infty H_c/a$. D. Foster found that with single crystals of iron, the hysteresis loop is characterized by extremely steep sides with sharp corners and high remanence. The coercive force for $H_{\max.}=30$ gauss is 0·4 gauss, and in respect to the effect of orientation there is a qualitative agreement with earlier work. The initial permeability is about 175. The maximum permeability occurs at a field intensity of about 0·8 gauss. N. Akuloff observed that the remanence and hysteresis loss with single crystals can be expressed as a function of the magnetization, and are not affected by mechanical stresses, but L. W. McKeehan and co-workers do not agree with this statement.

According to T. D. Yensen, the values given by different investigators for the magnetic permeability of the purest available forms of "iron" have risen in a remarkable way, from H. A. Rowland's 2,500 obtained in 1873, to his own value of 61,000 obtained in 1928. His summary of the results is given in Table XLIV.

TABLE XLIV.—THE MAGNETIC PERMEABILITY OF "IRON."

Material	Max. permeability	Permeability H (gilberts per cm.)			B=10,000		Coercive (gilberts per cm.)	Hysteresis loss (ergs per c.c. per cycle)	Authority

Values greater than $\mu=40{,}000$ were obtained by using electrolytic iron previously fused in vacuo, and by the addition of 0·15 per cent. of silicon, values exceeding $\mu=50{,}000$ were obtained. The effect of the silicon was attributed to its cleansing action in removing oxides. By extrapolating values for iron with traces of impurities, indications were obtained that iron will be obtained with an enormous permeability, and a zero hysteresis. Annealed, electrolytic iron with only 0·06 per cent. of carbon has been obtained with a permeability of 61,000, and a hysteresis loss of 300 ergs per c.c. per cycle. E. Wilson studied high permeability iron. R. L. Sanford and W. L. Cheney found the maximum induction and coercive force for Norwegian iron to be 15,900, and 5·0 respectively; for Bessemer steel, 15,900, and 9·0; for 0·85 per cent. carbon steel—annealed, 14,310, and 13·0; oil-quenched, 9380, and 53·0; and water-quenched, 9800, and 56·5.

C. Maurain examined the magnetic properties of iron deposited in a magnetic field; B. Speed and G. W. Elmen, the magnetic properties of powdered, electrolytic iron compressed into rods. R. Börnstein was unable to determine the relation between the density of iron and magnetization, but W. Trenkle observed that with compressed rods of iron powder and clay, with equal magnetizing forces, the magnetization and susceptibility of iron powder alone is always greater than that of a mixture of iron powder with a substance which cannot be magnetized. The magnetic saturation of iron powder is greater than that of the diluted powder. If the massive rod is distinguished from a rod composed of powder only by its density, the magnetization of iron falls with its density, and the magnetic saturation is less as the density is smaller. Hence, the magnetic force required to attain an eq. value of saturation is greater for iron alone than for diluted iron. Variations in density do not produce so great an effect on the course of magnetization, as variations of the dimensions of the elliptical or cylindrical form of the rods. W. Köster discussed the influence of inclusions in iron and steel on the coercive force.

H. Trosien, and T. Spooner investigated the effect of a superposed alternating field on the hysteresis loss. M. von Moos and co-workers, and O. von Auwers did not find that the hysteresis losses in watts increased proportionally with grain-size; and if N denotes the number of grains per sq. mm., the loss in watts $=\frac{1}{3}aN+b$, where a and b are constants.

Vibration increases the magnetic susceptibility of iron, and reduces the retentiveness and hysteresis. Three centuries ago W. Gilbert showed that a bar of iron can be magnetized by hammering it while it is situated in the earth's magnetic force. According to J. A. Ewing, a bar of iron held vertically and subjected to no mechanical disturbance, acquires only a very feeble trace of magnetism owing to the weakness of the vertical component of the earth's magnetism, but if sharply tapped, it becomes a fairly strong magnet, which persists after the bar has been withdrawn from the field, until it is expelled by further tapping or by the application of a moderately strong magnetic force of opposite sign. The magnetism acquired by an iron ship in building, and that acquired by the shock of rupture when iron or steel is broken in the testing machine are also examples of the phenomenon. Soft, annealed iron is most susceptible to the vibration, so that a gentle rubbing will impart magnetism to soft iron in the earth's magnetic field, or remove much of the residual magnetism left when a strong magnetizing force has ceased to act. The magnetic effects of hysteresis almost entirely disappear from soft iron if the piece be gently tapped during the application and removal of the magnetizing force. This subject was further investigated by W. Scoresby, E. Warburg, E. Wiedemann, G. Wiedemann, M. L. Frankenheim, L. Külp, M. Otto, R. Jouaust, G. Mars, C. Fromme, F. G. A. Berson, W. Brown, H. and F. Streintz, E. Villari, E. Fossati, J. A. Ewing, J. A. Ewing and H. G. Klaassen, J. Hopkinson and E. Wilson, G. Henrard, and E. D. Campbell and G. W. Whitney. H. Gewecke studied the effect of temp. on the retentiveness.

H. Tomlinson examined the effect of temp. and other conditions on the constants a and b in the relation $B=aH+bH^2$, where a denotes the initial permeability. The dissipation of energy depends on the value of b; and he found that the internal friction in any complete cycle may be decreased by repeating the cycle so that the molecules appear as if they are *accommodated* to the process. The accommodation of freshly annealed iron can be largely aided by repeatedly raising the temp. of the metal to 100°, and then allowing it to cool. The accommodation is disturbed by slight mechanical shocks, small changes of temp., or by magnetization beyond certain limits. Under these influences, the internal friction or viscosity may for a time, or even permanently, be considerably increased. The values of a and b are temporarily increased when the temp. is raised from 0° to 100°.

L. Tonks found that the susceptibility decreases with increasing frequency; the hysteresis angle tends to increase with frequency, and for a given frequency reaches a maximum for I at about 500; whilst the hysteresis energy loss per cycle, E, increases with frequency for constant magnetic intensity, and decreases for constant field. The exponent, a, in the equation $E=AH^a$ increases from 2·9 to 3·37 as the frequency is increased from 52,000 to 172,000 cycles per second. The subject was studied by W. E. Sumpner, M. MacLaren, N. H. Williams, S. W. J. Smith and J. Guild, B. Wedensky, B. Wedensky and K. Theodortschik, G. R. Wait, E. F. W. Alexanderson, J. Zenneck, and K. Kreielsheimer.

W. Gilbert observed that when an iron needle is red-hot, it is not attracted by the loadstone, but it is again attracted when the needle has cooled—*vide supra*, allotropes of iron. The phenomenon was also observed by J. Canton, R. Boyle, P. Erman, G. G. Hallström, H. B. de Saussure, P. Barlow and C. Bonnycastle, M. Mauritius, W. Ritchie, T. J. Seebeck, M. Faraday, E. Becquerel, T. Cavallo, A. Brugmans, and C. Matteucci. C. A. Coulomb studied the period of vibration of a heated magnetic needle in a field of known intensity. S. H. Christie noticed that when a magnet is heated, a sensible loss of magnetism occurs at about 38°; that the diminution of magnetic moment is not a linear function of the temp. because the rate of change increases with the temp., and that the moment of the magnet is increased, cooled by a freezing mixture, but returns to its original value when the original temp. is restored. H. A. Rowland found that the magnetic susceptibility of iron for small fields is greater at high temp. than at low ones, while for large fields, the reverse is true. C. Baur found that the rate of increase of permeability is greater for high than for low temp., while as a critical temp. is approached, the permeability decreases rapidly for strong and weak magnetic fields and finally approaches unity. R. Pictet found that with a compound horseshoe magnet, the strength of the magnetic attraction was 57·31 grms. at 30°; 61·04 grms. at 0°; 68·15 grms. at −50°; and 75·80 grms. at −100°. J. R. Ashworth found that when a magnet is heated to $\theta°$, and cooled, the relation of the intensity of magnetization, I, to temp. is represented by $I=I_0(1+a\theta)$, where the coeff. a is negative; but with drawn wire, a may be positive so that the magnet increases in magnetization as the temp. rises. The coeff. is positive only when the wire is in the commercial drawn state, for it becomes negative when the wire is annealed, or glass-hard. H. M. Loomis, and C. C. Trowbridge discussed the magnetic permeability at low temp.

The permeability was further investigated by W. Arkadieff, J. R. Ashworth, T. Berglund and A. Johansson, F. G. A. Berson, H. E. J. G. du Bois, R. Cazaud, H. le Chatelier, O. Claus, E. H. Crapper, E. Czerlinsky, L. Dufour, L. Dumas, E. Dumont, T. A. Edison, S. Evershed, F. P. Fahy, M. Faraday, L. Fraichet, C. Fromme, R. Gans, J. M. Gaugain, J. E. F. Gordon and W. Newall, J. Greger, K. W. Grigoroff, C. E. Guillaume, E. Gumlich, C. Hansteen, J. von Harlem, E. P. Harrison, S. Hilpert, K. A. Holmgren, K. Honda, K. Honda and S. Shimizu, K. Honda and Y. Ogura, J. Hopkinson, P. Joubin, G. Kapp, W. Kreielsheimer, A. T. Kupffer, J. Lamont, P. H. Ledeboer, F. Lydall and A. N. S. Pockington, N. N. Malov, H. Nathusius, R. A. Newall, F. Ollendorff, H. K. Onnes and A. Perrier, F. Osmond, A. Perkins, H. F. Parshall, E. Piola, D. Radovanovitch, P. Riess and L. Moser, A. W. Rücker, R. L. Sanford, W. Schneider, E. H. Schulz and W. Jonge, T. Schwedoff, W. Scoresby, J. B. Seth and co-workers, C. Shenfer, S. W. J. Smith and co-workers, F. Stäblein, A. F. Stogoff and E. I. Peltz, E. Take, H. Tomlinson, J. Trowbridge, C. R. Underhill, K. Volkova, A. Wassmuth, P. Weiss and J. Kunz, P. Weiss and H. K. Onnes, F. Wever and P. Giani, G. Wiedemann, M. Wien, L. R. Wilberforce, S. R. Williams, R. L. Wills, H. Wilde, W. Wolman and H. Kaden, and W. R. Wright, etc.

J. Hopkinson found that for small fields—say, 3 dynes—with wrought iron, a rapid rise of permeability begins at about 600°, reaches a maximum at 775°, and falls abruptly to unity at 785°; while for large fields, the permeability remained practically constant up to 600°, and then fell rapidly to unity. Mild steel behaved in a similar manner except that the permeability had a smaller maximum, and became unity at 735°; whilst for hard steel, the lowering of the maximum was more pronounced, and disappeared at 690°. During the cooling, the magnetism of wrought iron reappeared at practically the same temp. as that at which it disappeared, but with steels there was a marked lag which increased with the carbon-content. D. K. Morris observed that annealed Swedish iron gave temperature-permeability curves with a distinct minimum near 550°, and that this result was not obtained with charcoal iron. R. L. Wills observed that the maximum permeability occurs with weaker fields as the temp. is raised, and that the relation is nearly linear. With alloys, as the proportion of iron decreases, the difference of temp. between the disappearance and reappearance of magnetism is increased. W. del Regno, A. Regner, J. G. Gray and H. Higgins, F. Osmond, C. E. Guillaume, and E. Dumont also studied the subject with alloy steels. According to J. A. Fleming and J. Dewar, the permeability of annealed Swedish iron for all fields is less at low temp., while for un-annealed and hardened iron, it increases as the temp. is lowered. T. Claud observed that a reduction of the temp. lowered the hysteresis and permeability. K. Honda and S. Shimizu observed that the permeability and hysteresis loss in liquid air decreased for small fields, but increased for large ones. C. W. Waggoner obtained similar results for low-carbon iron. J. A. Fleming observed that annealed, low-carbon iron has an increased permeability for all fields at low temp., while in liquid air, annealed high-carbon steel has a smaller permeability. In a broad way, it appears as if a low temp. decreases the permeability of iron with a large proportion of carbon, and an opposite effect is produced with iron having a small percentage of carbon. J. Stauber found a lowering of the temp. diminished the hysteresis loss of these steels, but with higher magnetizing fields 30 gauss—both permeability and hysteresis-loss increased with a decrease of temp. C. Barus and V. Strouhal observed that the prolonged action of steam on magnets reduces their magnetic power very considerably; but if re-magnetized, they are less sensitive to deterioration from heat and vibrations. R. Forrer and J. Schneider found that the magnetization of iron annealed at 200° to 400° and at 450° to 900° is different, and, in consequence, they supposed that there are two allotropes, both of which are stable at ordinary temp.

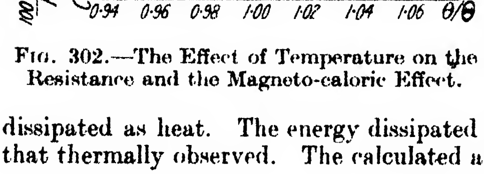

FIG. 302.—The Effect of Temperature on the Resistance and the Magneto-caloric Effect.

W. B. Ellwood studied the change of temp. which occurs during magnetization. F. Bitter also studied the magneto-caloric effect. K. Honda and co-workers found for the heat evolved during magnetization, the net energy of magnetization is less than 50 per cent. of the total energy, and the greater part of the applied energy is dissipated as heat. The energy dissipated on magnetization nearly coincides with that thermally observed. The calculated and observed data are:

	Calculated total energy of magnetization (ergs)	Calculated loss of energy on magnetization (ergs)	Observed evolution of heat (ergs)	Calculated energy stored by magnetization (ergs)
Carbon steel . . .	$4·6 \times 10^4$	$2·38 \times 10^4$	$2·2 \times 10^4$	$2·23 \times 10^4$
Tungsten steel . .	$8·73 \times 10^4$	$5·31 \times 10^4$	$4·1 \times 10^4$	$3·43 \times 10^4$
Magnet steel . . .	$20·7 \times 10^4$	$13·2 \times 10^4$	$15·0 \times 10^4$	$7·50 \times 10^4$

H. H. Potter measured the magneto-caloric effect as a function of temp. The quantity is represented as a product of the sp. ht., *c*, and the rise of temp. The results for fields of 7000 gauss are indicated in Fig. 302, along with the effect of temp. on the change in the resistance produced by a magnetic field of 7000 gauss. Θ denotes the Curie temp., 1050° K. The changes in resistance are proportional to changes in magnetic energy.

M. B. Moir found that the magnetic quality of steel and cast iron improves as the temp. rises from 150° to 190°. The subject was studied by F. Robin,

S. W. J. Smith and F. Guild, and L. Néel. P. Curie studied the variation in the magnetic properties of diamagnetic, paramagnetic, and ferromagnetic substances for temp. ranging up to 1370°. Diamagnetic water, quartz, and potassium nitrate kept the same magnetic susceptibility over a wide range of temp., whilst the susceptibility of bismuth steadily falls as the temp. rises to the m.p.; it drops abruptly at the m.p., but the susceptibility of the molten metal remains independent of a subsequent rise of temp. The susceptibility of paramagnetic substances like oxygen falls as the temp. rises, so that the susceptibility between 20° and 450° varies inversely as the absolute temp. According to **Curie's law,** the product of the magnetic susceptibility and the absolute temp. over this range is nearly constant, and this value is called **Curie's constant.** With ferromagnetic substances like iron, the case is not the same. The results with different field-strengths, H, are summarized in Fig. 303. The curve for the intensity of magnetization for $H=25$ is nearly parallel with the temp. axis up to about 550°, but when $H=100$, the intensity of magnetization falls steadily as the temp. rises, and both begin to drop very rapidly as the temp. reaches 750°, the so-called *Curie point*—*i.e.* the temp. at which the metal passes from the ferromagnetic to the paramagnetic state—and at 800° the magnetic intensity is very small. It is therefore necessary to magnify the ordinate scale about a thousand times in order to show the results graphically. This has been done in Fig. 303. At A, 930°, the slope of the curve decreases, and is very slight up to B, 1280°, where all at once the intensity of magnetization becomes 50 per cent. greater. After this the curve has a downward slope to C. At about 750°, ferromagnetic iron changes continuously into a paramagnetic substance; the corresponding change with magnetite is 530°, and with nickel 340°. The facts can be interpreted a different way by plotting the specific susceptibility against temp., as has been done in Fig. 304. The breaks in the curves correspond with the change from α-iron to β-iron at 678°, when the iron ceases to be strongly magnetic; as the temp. rises farther, the susceptibility increases, then falls rapidly to 920° when there is a change from β-iron to γ-iron; the decrease in the susceptibility with rise of temp. is very small up to about 1400°, when there is an abrupt rise as γ-iron changes into δ-iron; thereafter there is a gentle decline in the susceptibility. P. Dejean, R. B. Fehr, and N. Crane studied the transformations of iron at the Curie point. R. Forrer said that the two Curie points observed with ferromagnetic metals represent two different properties. One can be attributed to spontaneous orientation of the elementary magnets, and the other to hysteresis. Three temperature regions can be distinguished for ferromagnetic metals. In the first, at low temp., spontaneous orientation and hysteresis occur together. In the second, between the two Curie points, only one of these conditions is met with. In the normal case it is hysteresis (*e.g.* nickel, iron, cobalt, etc.), otherwise it is spontaneous orientation (*e.g.* the ferro-cobalts). In the third region neither of these properties is found. For ferromagnetic magnetization the

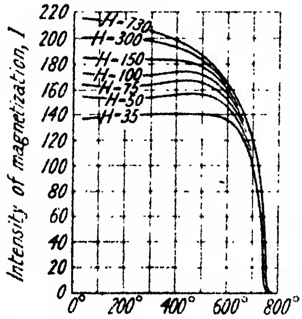

FIG. 303.—The Effect of Temperature on the Magnetization of Iron.

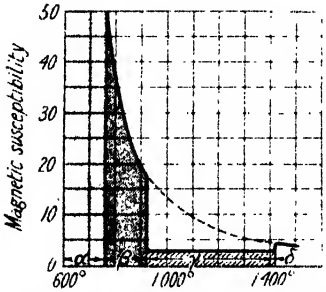

FIG. 304.—The Effect of Temperature on the Magnetic Susceptibility of Iron.

two properties are necessary. M. Faraday suggested that all metals might be ferromagnetic at low enough temp., and that it happens with iron and nickel that the transformation temp. is higher than the ordinary temp. of the atmosphere.

By plotting the relation between the intensity of magnetization and field-strength at different temp., P. Curie showed that as near the Curie point as 740·5°, there is a considerable rise in the intensity of magnetization as the field-strength increases; and a few degrees rise of temp., say, to 744·2°, reduces the intensity of magnetization to about half its value at 740·5° for, say, $H=320$; while the intensity at 820° is too small to be represented on the diagram. The line is curved at 740·5°, and is linear at 749·9° and upwards. P. Curie emphasized the analogy in the form of the curves connecting, on the one hand, the density and temp. of a gas near its critical state, and on the other, the intensity of magnetization and temp. of iron near the critical temp. Compare Figs. 303 and 304. R. Ruer, and R. Ruer and K. Bode gave 769° for the temp. of magnetic transformation. K. Honda found that the critical point of carbon steels is not affected by the intensity of the magnetic field; and L. H. Adams and J. W. Green, that it is not affected by pressure. P. Dejean compared the results obtained with a cylindrical bar with those of a similar bar composed of 120 small cylinders. S. Hilpert considered that it is not necessary to assume the formation of β-iron between 700° and 760° to account for the magnetic and sp. ht. anomalies at this temp. The change may be the result of an absorption of energy which attends the breaking up of the polar arrangement of the magnetic molecules by their more energetic vibration at high temp. E. Dussler measured the dependence of the magnetization of crystals of iron on temp. along both the diagonal and tetragonal axes between the temp. of liquid air and the Curie point. At all temp. the B-H curve is initially linear and inflects suddenly, slowly attaining saturation. The linear portion of this curve is independent of temp., but the higher the temperature the smaller is the field at which saturation is attained and the lower is the saturation magnetization. The variation with temp. of the magnetization at the point of inflexion and the saturation value both follow an exponential law.

J. R. Ashworth, following up a suggestion of P. Curie, developed a relation between magnetism and temp. analogous to J. D. van der Waals' relation between the press. and temp. of gaseous and liquid fluids—**1**. 13, 4. If H denotes the magnetic field-strength; I, the intensity of magnetization; I_0, the maximum intensity of magnetization; $a'I_0^2$, the maximum intrinsic field; R, the reciprocal of Curie's constant in vol. units; and T, the absolute temp., then J. R. Ashworth's equation for ferromagnetic substances has the form $(H+a'I^2)\left(\frac{1}{I}-\frac{1}{I_0}\right)=R'T$, which is based on $(p+aD^2)\left(\frac{1}{D}-\frac{1}{D_0}\right)=RT$, where p, D, and T respectively denote the press., density, and absolute temp. of the fluid, and a, D_0 and R are constants. For iron, the constants are $(H+7{\cdot}6I^2)(I^{-1}-0{\cdot}0_35935)=3{\cdot}56T$. As with the equation of J. D. van der Waals, constants may be calculated for the critical state when $T_c=785°+273°$. The subject was further discussed by W. Peddie. K. Honda and S. Kusakabe studied the effect on the magnetization of temp. near the critical point; and observations were made by L. F. Bates, T. Spooner, and S. Wologdine. R. H. Fowler and P. Kapitza studied the relation between magneto-striction and the Curie point. H. G. Movius and H. Scott noted the similarity of the magnetic transformations of ferrite and cementite.

Observations on electrolytic iron were made by A. L. Holz, J. Stauber, M. Otto, W. Leick, and K. Schild. W. Leick found the results with iron deposited from soln. of different salts to be about the same, but E. M. Terry observed that differences exist for small fields and vanish for fields over 100 dynes. After annealing at 1000°, the samples become practically the same for all fields. Discontinuities in the magnetic properties were found by D. K. Morris to occur at 150°; by C. Maurain, at 180° and 300°; by W. H. Dearden and C. Benedicks, at 120°;

J. H. Andrew and co-workers, between 50° and 150°; F. C. Thompson and E. Whitehead, 160° to 200°; and by S. R. Roget, at 135°. K. Honda, and S. W. J. Smith found a change on heating with cast iron and high-carbon steel at about 160°, and it was completed at 215°; and on cooling, the change starts at 215°, and finishes about 160°. The magnitude of this change is roughly proportional to the amount of free cementite present. K. Honda also observed a thermal change between 130° and 215°. The actual temp. varied with the strength of the magnetizing field.

E. M. Terry's magnetization curves, obtained with different field-strengths, between —190° and about 780°, for un-annealed electrolytic iron, and for the iron annealed at 780°, are shown in Fig. 305. E. M. Terry's values for the permeabilities are shown in Fig. 306. There is a sudden rise in the permeability for low fields just before the α-iron is transformed into β-iron. The highest value for the permeability was 11,000 with a field of $H=0{\cdot}5$ dyne. H. Wilde said that the magnetism of magnetic substances decreases with a rise of temp., and that the apparent increase which may occur is due to a surface resistance which may disappear by raising the temp., by increasing the magnetizing force, or by decreasing the mass of the substance. D. K. Morris obtained a maximum of 14,600 for $H=0{\cdot}2$ dyne with Swedish iron; R. L. Wills, 17,200 for $H=0{\cdot}172$ dyne with wrought iron. The effect of annealing was studied by H. Kamps, and G. Dillner and A. F. Enström.

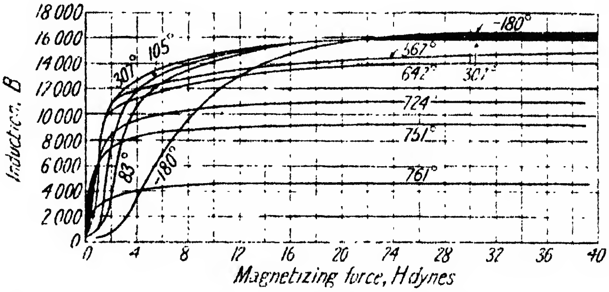

FIG. 305.—Magnetization Curves for Annealed Electrolytic Iron at Different Temperatures.

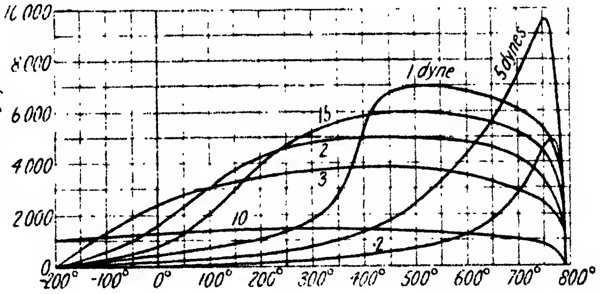

FIG. 306.—The Effect of Temperature on the Permeability of Annealed Electrolytic Iron.

D. K. Morris observed three maxima before the critical point is reached, and these correspond approximately with the breaks in the cooling curve observed by W. C. Roberts-Austen at 250°, 533°, and 766°. No sign of a depression in the temperature-permeability curves such as was obtained by D. K. Morris for wrought iron, at 550°, with all except the strongest fields, was observed. F. Osmond attributed this to a lowering of the temp. of transformation from α- to β-iron. Since E. M. Terry did not observe the effect with electrolytic iron, the phenomenon is not a characteristic of iron, but rather of iron associated with impurities. The effect of annealing is to increase the maximum permeability about 50 per cent., whilst for small fields, the increase is many-fold, Fig. 306. For example:

	23°	780°	1000°	1100°	1200°	1300°
Maximum permeability .	1,040	3,070	9,080	11,000	8,750	7,120

C. C. Duell tried to explain the drop in magnetization of cementite steels in the range from 150° to 220°, by assuming that carbon is soluble in α-iron but that the carbide is not, and that the drop in magnetism is due to certain atoms of free carbon going into soln. as carbide. The cementite line *ES* can be extended until it intersects the zero carbon line at *X*, Fig. 307, which is near 220°. This is taken to be the limiting point of the solubility of carbon in iron, so that near this temp. carbon can go into soln., but carbide cannot. The second, singular point on the magnetic curve at 300° marks the formation of the carbide. The carbon in martensite exists as carbon and not carbide ; and the formation of iron carbide, which begins at about 300°, corresponds with the formation of troostite from martensite. The presence of alloying elements causes the A_3-line to occur at progressively higher or lower temp., so that in the absence of carbide, the continued addition of carbon causes the A_3-line to change with progressively lower temp. along the line *GSY*, Fig. 307. G. Hannack found that with tungsten steels the remanence, and maximum induction decrease as the percentage of carbon increases, whilst the coercive force increases. S. W. J. Smith and co-workers found that the residual moment of a magnetized rod of annealed steel is reversed when the temp. is raised to 180°. The effect occurs only with iron containing the laminated ferrite–cementite eutectoid. R. L. Sanford observed that the reluctivity of homogeneous iron is a linear function of the magnetizing force, but the linear relationship does not apply when a tension or stress is applied to the wire. H. Kühlewein studied the magnetic after-effect.

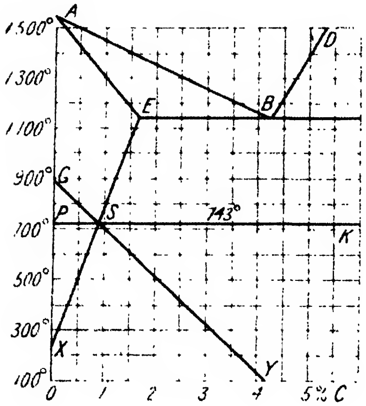

Fig. 307.—Hypothetical Course of the Carbon and Cementite Solubility Curves.

G. J. Sizoo found that increasing the grain-size of electrolytic iron decreases the coercive force and the work of hysteresis, but increases the maximum permeability, whilst the remanence remains constant. Some results are indicated in Table XLV. O. von Auwers found that the grain-size affects the coercive force, remanence, and permeability, but not the saturation value and sp. resistance. The effect of grain-size is less marked after heating in hydrogen, and still less by heating in vacuo. The influence of grain-size on the magnetic properties is secondary in nature, being dependent on surface contamination by oxides and carbides. W. Köster found that the size and arrangement of finely-divided particles in ferromagnetic alloys have a considerable influence on the magnetic properties.

Table XLV.—The Effect of Grain-size on the Magnetic Properties of Electrolytic Iron.

Mean diam. of crystals in mm.	Coercive force in gauss	Remanence in gauss	Maximum permeability	Hysteresis work $B_{\max.}$ = 10,000 ergs. per c.cm.

0·7	0·462	9460	7550	1750
0·6	0·465	9360	6970	1740
0·3	0·515	9300	6850	1780
0·1	0·794	8050	4090	5200

G. Wiedemann showed that the first effect of a change of temp. on the magnetism of iron and steel is not reversible. With residual magnetism, a cyclic process of heating and cooling, or of cooling and heating, reduces the magnetism. Observations in this direction were made by H. I. Wild, M. Mauritius, O. Claus, O. Unverdorben, G. Claude, A. T. Kupffer, G. Poloni, J. M. Gaugain, F. G. A. Berson, C. Baur, and L. Favé. According to J. A. Ewing, if the magnetizing force of iron is maintained during a cyclic process of heating and cooling, or of cooling and heating, there is an increase of magnetism. In both cases, in general, after many repetitions of the changes of temp., the change of magnetism becomes cyclic. In the earliest stages there appears to be, as J. A. Ewing expresses it, a progressive shaking in of magnetism if that is induced, and a progressive shaking out of magnetism if that is residual. The phenomenon is often conspicuous in the first cycle, and it can often be traced in the second or even later cycles. By repeating the cycle of temp. changes often enough, these progressive changes disappear, and the effects of heating and cooling—magnetizing force constant—are reversible. J. A. Ewing found that no hysteresis occurred in the changes which were observed with moderate variations of temp., but when the range of temp. includes the critical region where magnetization disappears on heating and reappears on cooling, a marked hysteresis occurs. The disappearance and reappearance of magnetization connected with $\alpha\beta$-change do not occur at the same temp. This is particularly the case with the alloy steels (*q.v.*) observed by J. Hopkinson, and others. D. K. Morris found that the hysteresis of the *BH*-curve becomes enormously reduced as the temp. approaches the chief critical point, and the hysteresis tends to disappear. Thus, with a sample of iron annealed at 1150°, with cycles of magnetization between the limits $B=4550$, the hysteresis losses, in ergs per cm. cube per cycle, were:

	18°	137·5°	249°	352°	457°	634°	695°	764·5°
Hysteresis loss .	613	555	508	475	379	264	178	81

In addition to the changes just indicated, heating produces a slow deterioration in the magnetic properties, reducing the permeability, and raising the hysteresis. The action is very slow at comparatively low temp. The heat generated in a transformer by currents in the coils, and by hysteresis in the core makes the temp. in the transformer higher than that of its surroundings, and thus reduces the efficiency of transformers. G. W. Partridge studied the effects; and J. A. Ewing found that the results are not due to the repeated reversals of magnetism; nor are they due to a kind of fatigue produced by repeated reversals of mechanical strain. W. M. Mordey observed that the increased hysteresis is solely due to the prolonged heating; and S. R. Roget confirmed this by observations on the effect of prolonged exposure at temp. between 50° and 700°. A few weeks' exposure at 50° produces an appreciable effect in raising the hysteresis, and lowering the permeability. K. Daeves found the losses in dynamo and transformer sheets increase regularly by 0·1 watt-kgrm. for every 0·04 per cent. of carbon for steels with 0·04 to 0·11 per cent. of carbon. As silicon rises from 3·7 to 4·2 per cent., the loss diminishes by 0·05 watt-kgrm. for every 0·04 per cent. of silicon, but increases slightly with higher proportions of silicon. Phosphorus up to 0·02 per cent. slightly increases the loss, but beyond that point there is an improvement. Manganese between 0·05 and 0·3 per cent. has no perceptible influence.

According to E. M. Terry, the temp. of transformation from the ferromagnetic to the paramagnetic state is near 785°, which is in agreement with the data for the transition temp. of α- to β-iron (*q.v.*). J. Hopkinson gave 786° for soft iron with 0·01 per cent. of carbon; 734° for mild steel with 0·126 per cent. of carbon; and 695° for hard steel with 0·962 per cent. of carbon. D. K. Morris gave 780° for a sample with 0·08 per cent. of carbon; R. Ruer and F. Goerens gave 769°; E. Gumlich, 765°; T. Ishiwara, 780°; P. Weiss and G. Föex, 775°; while for cementite, K. Honda and H. Takagi gave 215° for temp. of magnetic transformation. The magnetic transformation of the iron-carbon alloys were studied by G. Rümelin and R. Maire.

Reverting to P. Curie's law that the magnetic susceptibility varies inversely as the absolute temp., χI=constant, P. Weiss obtained a relation between the intensity of magnetization, and inferred that in the temp. immediately above that of the magnetic transformation, Curie's point, the susceptibility should be inversely proportional to the excess of temp. above the transformation point. P. Weiss and H. K. Onnes calculated values for the magnetic moment per gram-atom, which P. Weiss called the *gram-magneton*; and this magnitude, when divided by Avogadro's number, gives the moment of what he regarded as the ultimate magnetic corpuscle which he called the *magneton*. The magneton is supposed to play a *rôle* in magnetism, like that played by the electron for electricity. The number of magnetons per molecule is related to Curie's constant in a simple manner. From the results of P. Pascal, P. Weiss and G. Föex, O. Liebknecht and A. P. Wills, and E. Feytis, it was found that the calculated number of magnetons per molecule rarely depart by more than 1 or 2 per cent. from the integral values required by the theory. The subject was studied by J. Kunz, B. Cabrera, W. W. Stifler, etc. K. Honda and co-workers, however, found that Curie's law is not general, and consequently P. Weiss' magnetism is open to question. H. K. Onnes and co-workers found that the relation χT=constant is in some cases valid down to the temp. of liquid nitrogen, and below this temp., the constant continually decreases in value. In some cases, the constant decreases continuously from room temp. downwards, so that the relation $\chi(T+\delta)$=constant holds down to the temp. of liquid nitrogen, but not at lower temp. Again, the susceptibility may change little with temp., and between the temp. of liquid nitrogen and liquid hydrogen, is almost independent of temp.

E. M. Terry found that the magnetic susceptibility of electrolytic β-iron, between 780° and 920°, follows Curie's law only approximately, because the curve showing the relation between the reciprocal of the susceptibility and temp. is not a straight line, but concave upwards. Curie's law is not even approximately obeyed in the γ-region, for there is an interval of nearly 500° throughout which the susceptibility remains almost constant. At 1407°, there is an abrupt increase as γ-iron passes into the δ-form. Throughout the δ-region, up to the m.p., 1530°, the susceptibility decreases almost linearly with temp.; the susceptibility shows a marked decrease on melting, so that the molten iron has values approximately corresponding to an extension of the curve for γ-iron. The susceptibility curve for iron passing through the A_3-arrest shows a marked hysteresis with the A_3-arrest. The steepest part of the curve occurs at 918° on a rising and at 903° on a falling temp. No real hysteresis was observed with the latter, but the return to γ-iron on the cooling curve is gradual, not abrupt. Observations on the Curie point were also made by T. Ishiwara, P. Weiss and G. Föex, K. Renger, D. Radovanovitch, K. E. Guthe, P. Curie, R. H. Fowler and P. Kapitza, R. Forrer, and W. Schmidt. As indicated above, the Curie point of cementite corresponds with the A_0-arrest, at about 220°. K. Honda and H. Endo found the magnetic susceptibility, χ, of cementite to be:

	800°	900°	1000°	1100°
χ . . .	$24{\cdot}3\times10^{-5}$	$24{\cdot}0\times10^{-6}$	$23{\cdot}7\times10^{-6}$	$23{\cdot}5\times10^{-6}$

According to K. Renger, the effect of field-strength, H gauss, on the transformation point, θ, is represented by $\theta=757+0{\cdot}14\sqrt{H}$,

H . . .	0	1,438	2,903	5,095	8,144	10,430	11,930
θ . . .	757°	762·0°	764·5°	767·0°	770·0°	771·5°	772·6°

C. Benedicks gave the results indicated in Table XLVI for the effect of chemical composition and heat-treatment on the magnetic properties of steels. C. Benedicks represented the effect of carbon on the intensity of magnetization, I, when ΣC denotes the carbon value as in the case of the electrical resistance (*q.v.*), by

$$I_{\max.}=1000\sqrt{5{\cdot}23-(\Sigma C+0{\cdot}59)^2}-710$$

E. Gumlich's results for the effect of carbon on the coercive force, in c.g.s. units,

TABLE XLVI.—THE EFFECT OF THE COMPOSITION OF STEEL ON ITS MAGNETIC PROPERTIES.

are summarized in Fig. 308, and S. Curie's curve for the effect of carbon on the remanence or retentivity of steel is shown on the same diagram. A. W. Smith and co-workers found the minimum reluctance, the reciprocal of the maximum permeability is a linear function of the carbon-content to 0·8 per cent. for hardened steels, and for annealed steels it is somewhat greater. E. Maurer and K. Schroeter proposed estimating the austenitic content of hardened steel from the magnetic saturation capacity. The observations of the effect of the tempering temp. by J. H. Andrew and co-workers are summarized in Table XLVI. A. W. Smith and co-workers observed that the minimum reluctivity, *i.e.* the reciprocal of the maximum permeability, is a linear function of the carbon-content up to 0·8 per cent. for hardened steels, and for annealed steels the rate of increase is rather greater; and for annealed chromium steels, the value is a maximum at about 0·5 and a minimum at about 0·8 per cent. carbon. According to W. L. Cheney, the tempering of hardened iron-carbon alloys between 200° and 250° causes a rapid rise in the induction, which becomes less marked with increasing temp., eventually reaching a maximum and then decreasing. At the same time marked changes take place in the coercive force, especially for tempering temp. between 200° and 300°, when the greatest decrease occurs, and at 470°, where there is a sharp increase. In some cases two values are obtained for the saturation intensity of magnetization; this is shown by microscopical examination to be due to the presence of two constituents in the material. The maximum permeability of certain alloys shows great differences as compared with small differences in other properties, due to changes in the second stage of the process of magnetization. In the annealed alloys the steepness of

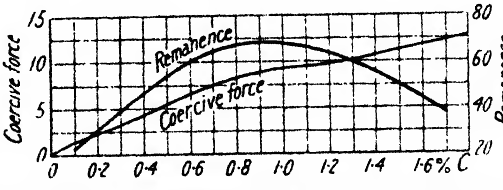

FIG. 308.—The Effect of Carbon on the Coercive Force of Steel.

the magnetization curves and the maximum permeability vary with the carbon-content. The intensity of magnetization has a double value for all carbon percentages below 1·5 per cent. and a triple value for the 1·55 per cent. carbon alloy, and decreases with the carbon-content. As a result of the investigation it is shown that any slight changes of structure produced by heat-treatment cause marked changes in the magnetic properties of iron-carbon alloys. P. Weiss and R. Forrer discussed the magnetic properties of cementite. M. Nakamura studied the effect of carbon and silicon on the magnetic properties of electric steel, and found that the permeability is increased as the proportion of carbon decreases. If the decrease is too great, the deoxidation of the steel is incomplete, and the permeability is decreased. With less than 0·12 per cent. carbon, the permeability is usually low. Silicon increases the permeability up to a certain limit dependent on the proportions of carbon and manganese, and it acts in virtue of its deoxidizing qualities. The permeability increases as the proportion of manganese decreases up to a certain limit, beyond which it becomes smaller.

O. von Auwers, T. D. Yensen, and G. J. Sizoo observed that with increasing grain-size, the coercive force, and hysteresis decrease, and the maximum permeability increases. The effect is also marked with the remanence. The relations between the magnetic properties and hardness have been the subject of investigations by J. Lamont, C. Ruths, J. M. Gaugain, C. Fromme, C. Baur, A. von Waltenhofen, T. Gray, A. Righi, W. Metcalf, R. Pictet, etc.; and the specific effects of the carburization of iron, by C. A. Coulomb, P. Barlow, J. Müller, H. Meyer, J. Jamin, A. von Walthofen, A. R. S. Trève, A. R. S. Trève and L. Durassier, C. R. Underhill, L. Holborn, W. Negbaur, J. Hopkinson, K. Zickler, J. A. Ewing and W. Low, J. C. Poggendorff, R. Pictet, G. B. Airy, L. M. Cheesman, W. Beetz, A. L. Holz, G. Ascoli, J. Trowbridge, G. Poloni, W. Metcalf, A. Righi, and C. Barus and V. Strouhal. T. Matsushita and K. Nagasawa found a maximum at about 400°. T. Matsushita measured the magnetic hardness or coercive force of quenched steels.

V. S. Messkin discussed the effect of cold-work on the magnetic properties of steel; and E. Gumlich and E. Volhardt, the influence of rolling on the magnetic properties. According to V. S. Messkin, the remanence of a plain carbon steel with 0·78 per cent. of carbon decreases considerably with light rolling, but increases again with heavier rolling; the maximum permeability changes similarly, but with a greater reduction than 30 per cent. it decreases again. The coercive force increases steadily during rolling, and attains about double its original value when the thickness has been reduced about 80·8 per cent.; with subsequent annealing, the coercive force decreases rapidly with rise of temp. up to 450°, and thereafter more slowly. The maximum remanence is obtained after annealing at 600°, and it is greater than before rolling. The cold deformation of steel produces on the magnetic qualities an effect similar to that obtained by quenching. P. Goerens studied the effect of heat-treatment on the remanence and permeability; and on the coercive force and hysteresis loss in ergs per cm. cube; and also on the effect of cold-work on the maximum permeability and coercive force of steels. According to E. Maurer, there is no perceptible difference in the magnetic properties of steels worked cold and at a blue-heat.

C. S. Yeh found that in the range of press. up to 12,000 kgrms. per sq. cm., the change of magnetization with a constant field, H, is linear. With a field range of 0 to 100 gauss, the press. coeff. of magnetization per unit vol. is negative for iron. The perceptible change of magnetization has a maximum of $-5·5$ per cent. per 1000 kgrms. per sq. cm. for $H=1·2$. The percentage change decreases rapidly on both sides of the maximum, and approaches the axis asymptotically for large values of H.

The observed press. coeff. for slightly carbonized iron are:

H . .	0·26	0·52	0·78	0·93	1·30	1·82	4·69	52·0
B . .	244	1048	1915	2800	5480	7050	11,200	18,760
dB/B_0 .	−1·30	−1·88	−2·66	−2·38	−1·89	−1·46	−0·73	−0·01

For purified iron, the temp. and press. coeff. are :

H		0·43	0·86	1·30	1·73	2·16	4·32
Temp. coeff.	$p=0$	+0·147	+0·232	+0·263	+0·126	+0·072	—
	$p=7050$	+0·177	+0·247	+0·264	+0·135	+0·79	—
Press. coeff.	25°	−3·25	−4·80	−5·51	−4·36	−3·14	−1·20
	100°	−0·99	−3·69	−5·39	−3·70	−2·61	−1·23

The results for iron with 0·10 per cent. of carbon are :

H	0·57	1·70	2·83	4·53	11·32	22·64	33·96
B	300	1920	4870	7640	12,210	15,000	16,170
dB/B_0	0·57	−1·59	−1·52	−1·06	−0·58	−0·25	−0·10

The results for iron with 0·30 per cent. of carbon are :

H	0·69	1·24	14·8	1·98	2·96	3·96	4·94
B	263	614	851	1588	3610	5510	7090
dB/B_0	−1·66	−1·80	−1·88	−2·05	−2·36	−2·02	−1·70

The percentage change of magnetization is thus very sensitive to the proportion of carbon present. The absolute value of the press. coeff. of magnetization per unit vol. is less at a higher temp. The retentivity of iron decreases under press. Observations were also made by H. Nagaoka and K. Honda, and F. C. Frisbie.

About 1847, C. Matteucci noticed an increase in the magnetism of an iron bar when it is pulled lengthwise ; G. Wertheim confirmed this ; and E. Villari observed that the character of this effect is reversed if the magnetization is strong enough. As a result, the effect of pull is to increase the magnetism of a weakly magnetized bar, and to reduce the magnetism of a strongly magnetized bar. The phenomenon is now called the **Villari reversal**, and it was rediscovered by Lord Kelvin about 1878. If the relation between the intensity of magnetization and the magnetizing force when no pull is applied, and again when the rod is under tension be plotted, Fig. 309, there will be a point where the two curves intersect. This point is called *Villari's critical point.* It corresponds with the field-strength at which the pull does not affect the intensity of magnetization. The subject was investigated by J. A. Ewing, who found that the effects of stress are, in general, much greater with metal hardened by mechanical work than with soft, annealed iron. Each curve, Fig. 309, for annealed iron lies at first higher and then lower than the curve for any greater load, corresponding with the fact that the presence of a load is favourable to magnetization when the intensity of magnetization is small, but unfavourable when it is great. A pulling load is unfavourable to residual magnetism left after a strong field has been applied, though it is favourable to the residual magnetism left after magnetization by a weak field. The influence of pull on residual magnetism is of the same kind as its influence on induced magnetism, showing the large effect which a moderate pull has in augmenting the susceptibility with respect to feeble magnetizing forces, and when the state approaches saturation, the presence of load is unfavourable to magnetization. Even with the weakest fields, the susceptibility is increased only when the load is moderate. Too great a load is prejudicial whether the magnetization be weak or strong. The upper lines of abscissæ, Fig. 309, refer to the upper three curves, and the lower abscissæ to the

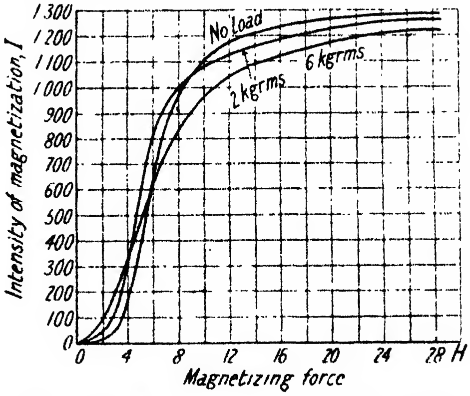

FIG. 309.—Magnetization of Annealed Iron while subjected to Longitudinal Pull.

lower three curves. J. B. Seth and co-workers followed the change in the intensity magnetization produced by stretching an iron wire in a weak magnetic field. The subject was studied by H. Tomlinson.

When the magnetizing force is kept constant, and the longitudinal pull is varied, the changes which occur in the intensity of magnetization are, in general, similar to those indicated in Fig. 309, but they are complicated by hysteresis effects. The initial effects of applying stress resemble those produced by vibration even though no vibration occurs during the loading, and they do not disappear when the stress is removed. Starting from *a*, Fig. 310, J. A. Ewing showed that a wire hardened by stretching, demagnetized, and exposed to a magnetizing force of 0·34 c.g.s. units has very little magnetization. The effects of applying and removing the load are illustrated by the dotted curve *abc*, but when the load is applied and removed a second time, the magnetic changes become nearly cyclic, as shown by the continuous lines in the same diagram. This shows that in the first loading, there is a progressive increase of magnetization superposed on a cyclic effect. If a stronger field is applied, the effects of the first loading are increased enormously, and after that, the magnetic changes are nearly cyclic. The effect of loading and unloading progressively decreases the residual magnetization and the cyclic changes are of the same general type as those which occur when the magnetization is excited by an external field. The subject was discussed by A. Heydweiller, L. Fraichet, K. Honda and S. Shimizu, H. Nagaoka and K. Honda, and C. Chree.

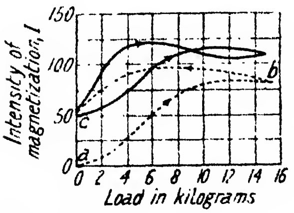

FIG. 310.—The Effect of Applying a Load to Magnetized Iron.

The hysteresis effects of magnetism with changes of load do not depend on the rate at which the load is applied, nor on the interval of time which elapses before the observations are made. After the condition obtained by the application of a load is reached, the magnetization does not appreciably alter. The effects of hysteresis disappear almost entirely when the test-piece is exposed to mechanical vibration or tapping during or after the changes of load. The repetition of loading with annealed iron produces a cyclic state in which there is less total magnetism than is the case with the hardened metal; a light loading will produce an increase, and unloading a decrease, of magnetism; with moderately heavy loads, these effects are reversed.

The stress-strain diagrams, previously considered, show the existence of reversible and irreversible molecular changes during the loading and unloading of an iron wire; the thermoelectric properties of iron under the influence of variations of pull, also show the existence of analogous molecular changes; while the loading and unloading of iron, within the elastic limit, before beginning magnetization, also affects the magnetic susceptibility, owing to the irreversible changes in the orientation of the molecules. These residual effects of past loads on the magnetic susceptibility exhibit hysteresis with regard to the loads which cause them; and the residual effects may be annulled by subjecting the piece to magnetization by reversals, and by tapping the piece smartly so as to cause vibration. For instance, J. A. Ewing found that if a magnetization curve be taken with iron wire subjected to a pull of 3 kgrms., and if, after complete demagnetization, the load be raised to 4 kgrms., and 1 kilogram be removed, and a second magnetization curve be taken, the two curves will be different in spite of the fact that the wire may have been previously subjected to many times that amount of load, so that it appeared to be mechanically in a stable state.

C. Matteucci showed that when a rod of soft iron, exposed to a longitudinal magnetizing force, is twisted, its magnetism is reduced by torsion in either direction. The subject was examined by M. Choron, G. Wertheim, E. Becquerel, C. A. Coulomb, H. Gerdien, H. Tomlinson, A. Banti, F. Braun, L. Zehnder, A. Campetti, C. Barus,

K. Schreber, F. J. Smith, H. Nagaoka, H. Nagaoka and K. Honda, H. Bouasse and A. Berthier, W. Brown, J. E. Pellet, E. Warburg, S. Meyer, G. Wiedemann, and Lord Kelvin. As with the effects of all stresses, there is an initial, irreversible effect which is revealed when the cycle of strain is repeated. This initial effect depends on the past history of the metal, but in soft iron the cyclic effect is such that twisting to either side reduces the induced magnetization, and untwisting increases it. Lord Kelvin found that the changes of magnetization under these conditions exhibit hysteresis. The changes in the magnetism induced in an iron wire by a constant magnetic field, as one end of the wire is twisted to and fro, while the other end is held fixed, ultimately assume the general form of Fig. 311. If the effects of hysteresis were eliminated by vibration, a single parabolic curve would appear with its vertex at the top of the diagram. Accordingly, in the absence of hysteresis, the influence of torsion in reducing the induced magnetism is indefinitely small for small angles of twist, and at first increases in proportion to the square of the twist.

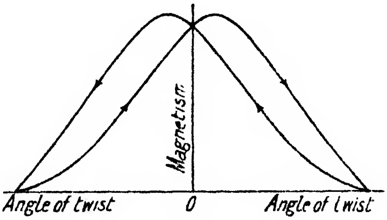

FIG. 311. -The Effect of Twist on the Magnetism of Iron.

Lord Kelvin showed that what he called an aelotropic quality is developed in the magnetic susceptibility of iron, for if the metal is subjected to longitudinal or transverse pull or push, the susceptibility will be greater along than it is across the lines of pull, or the susceptibility will be less along than it is across the lines of push, provided the magnetization is not strong enough to pass Villari's critical point. In a torsional strain, each portion of the twisted rod suffers a simple shearing stress which is made up of a pulling stress in a direction inclined at 45° to the direction of length, and an equal pushing stress inclined at 45° and at right-angles to the pulling stress. This produces a kind of helical magnetization in which there is a circular component superposed on the original longitudinal magnetization. The lines of magnetization no longer coincide in direction with the lines of magnetic force. The effect of a small angle of torsion on the longitudinal component of magnetization is small, but as the angle of torsion increases, the growth of the circular component reduces the longitudinal magnetization, for magnetization in one direction lessens the magnetization in other directions. The influence of magnetic aelotropy is always present with torsional stresses, although the effects may be masked by other influences *e.g.* hysteresis.

As shown by G. Wiedemann, and Lord Kelvin, longitudinal magnetization may be produced by twisting a circularly magnetized wire; and G. Wiedemann, and C. G. Knott observed that if an iron wire be circularly and longitudinally magnetized, it becomes torsionally strained or twisted although no external mechanical force has been employed. J. A. Ewing, D. E. Hughes, L. Zehnder, and H. Nagaoka found that there is a sudden development of circular magnetization when a longitudinally magnetized rod is suddenly twisted, or when a longitudinal magnetizing force is suddenly applied to a rod held in a state of torsion. The joint effects of pull and torsion were studied by H. Nagaoka, L. Zehnder, C. G. Knott, etc. The effect of magnetization on the bending of iron and steel was discussed by G. Wertheim, and C. M. Guillemin.

J. P. Joule said that the total volume of an iron rod is not altered by magnetization, and the subject was studied by G. Wertheim, H. Buff, H. Nagaoka, H. Nagaoka and E. T. Jones, E. T. Jones, H. Nagaoka and K. Honda, K. Honda and K. Kido, K. Honda and S. Shimizu, S. Shimizu and T. Tanakadate, I. Kruckenberg, P. McCorkle, L. W. McKeehan and co-workers, J. Orland, J. Orland and P. del Pulgar, P E. Shaw and S. C. Laws, C. Benedicks, F. C. Powell, J. H. Handley, J. R. Hobbie, S. R. Williams, S. R. Williams and O. Koppius, A. Schulze, A. Esau, G. Dietsch and W. Fricke, W. N. Bond, T. Hayasi, M. Kersten, P. Kapitza, P. Asteroth,

L. W. Austin, L. W. Austin and K. Guthe, W. L. Webster, W. Brown, R. A. Houstoun, M. Cantone, C. W. Burrows, G. Kirchhoff, H. von Helmholtz, S. Sano, I. Kolacek, S. J. Lochner, A. Heydweiller, R. Gans, H. Rensing, L. W. McKeehan, C. W. Heaps, C. G. Knott, A. de la Rive, W. Beetz, A. M. Mayer, W. F. Barrett, A. Righi, C. Chree, B. Rosing, A. Berget, A. Bock, P. I. Bachmetjeff, L. T. More, A. Schulze, B. B. Brackett, J. S. Stevens, E. Rhoads, G. A. Shakespear, C. Barus, E. van Aubel, D. O. S. Davies, L. Tieri, and J. C. McLennan.

It will be observed that in the **Joule effect,** when a magnetic (or ferromagnetic) field is produced along a ferromagnetic bar, the bar is lengthened or shortened in the direction of the field, according to the nature of the metal and the intensity of the induction; and conversely, a lengthening or shortening of the bar produces a variation in the intensity of the longitudinal magnetization. In **Wiedemann's effect,** a longitudinally magnetized, ferromagnetic bar is twisted when an electric current, which creates a transverse magnetic field, is passed along it; and conversely, in the **Matteucci effect,** when a longitudinally magnetized bar is twisted, an e.m.f. is produced along the bar.

C. G. Knott, and S. Bidwell found that the transverse contraction exceeds the longitudinal expansion, so that the total volume is reduced, δv—**magnetostriction**—thus, for tubes with H=50,125, and 250 c.g.s. units, the respective values of $\delta v \times 10^7$ were −5·9, −12·3, and −13·0. If the total volume is reduced by magnetization, the *specific gravity* will be increased. K. Honda and K. Kido found an expansion for the magnetostricton of iron with H over 370, and a contraction for smaller values of H, thus:

H	23·0	77·2	125·1	193·9	273·8	371·9	571·6
$\delta l/l \times 10^6$	1·70	3·03	2·54	1·77	0·68	−0·42	−1·68

The phenomenon was also studied by C. G. Knott and A. Shand, W. F. Barrett, A. M. Mayer, E. Piazzoli, A. Schulze, A. S. Kimball, A. Wassmuth, W. Fricke, R. Gans and J. von Harlem, and G. Hoffmann. K. Honda and S. Shimizu's observations for the change in length $\delta l/l \times 10^{-6}$ with variations of temp. are illustrated by Fig. 312. A. Schulze's results on the change in length of different kinds of iron and different heat-treatments are summarized in Fig. 313.

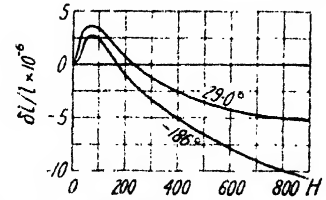

FIG. 312.—The Effect of Temperature on the Magnetostriction of Iron.

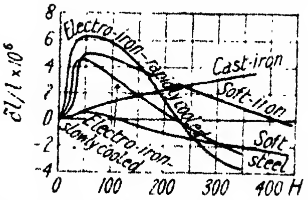

FIG. 313.—The Effect of Purity and Heat-treatment on the Magnetostriction of Iron.

K. Honda and T. Terada found the magnetostriction, or change of length with magnetization, $\delta l/l \times 10^{-6}$, with a tension of 1627 grms. per sq. mm., increases from −0·22 to 1·80 as H increases from 3·8 to 35·3, and it then decreases to −4·34 as H rises to 384; and with a tension of 5538 grms. per sq. mm., the change in length $\delta l/l \times 10^6$ decreases from −0·06 with H=3·2 to −6·58 with H=380. The change of elasticity, $\delta E/E \times 10^2$, is small, and with a load of 1627 grms. per sq. mm., it gradually increases with the field from 0·9 to 1·7 as H changes from 10 to 100, and it then falls to 1·4 as H changes to 350; while with a load of 4754 grms. per sq. mm., it changes from 0·4 to 0·8 as H changes from 10 to 350. The change in the coeff. of rigidity $\delta K/K \times 10^2$ with a load of 3113 grms. per sq. mm. is represented by −0·03 for H=24·5, 0·40 for H=146·2; and 0·25 for H=385. The change in Poisson's ratio, $\delta\sigma/\sigma \times 10^2$, is such that it passes from −2·2 for H=10 to −10·2 for H=350, when the load is 3270 grms. per sq. mm. The change of magnetization δl_i with longitudinal loading and δl_c with cyclic loading for loads in tension T grms. per sq. mm., is:

T	1562	3086	4648	6211	7777 grms. per sq. mm.
$H=1\cdot25$ δl_i	6·8	23·2	56·8	100·9	146·3
$H=1\cdot25$ δl_c	0·9	1·9	3·2	4·5	6·9
$H=366\cdot6$ δl_i	−2·7	−5·1	−8·0	−10·6	13·3

K. Honda and T. Terada also found that with a constant tension the magnetization increases rapidly in low fields and gradually approaches saturation. They also examined the effect with a constant twist, and with a combined twist and tension on the magnetization. In all cases the reciprocal nature of the changes of strains by magnetization and of the changes of magnetization by strain were established. For instance, magnetic elongation under constant tension and of magnetization under constant tension; of elongation by tension under a constant field, and the change of magnetization by tension under a constant field; of magnetic twisting under a constant couple, and magnetization under a constant twist; and of the change of rigidity under a constant field; and the change of magnetization by twist under a constant field. J. B. Seth and co-workers studied the effect of stretching on the intensity of magnetization of single crystals of iron. J. S. Rankin found that high-carbon steels show a smaller magnetostriction than soft carbon steels, but that the effect of hardening a steel by tensile overstrain increases the magnetostriction, though this change in extension does not depend simply on the amount of tensile extension. It is assumed, in agreement with W. L. Webster, that when a rod is overstrained, the axes of a large proportion of the constituent crystals veer into the direction of the longitudinal axes of the rod, and it is necessary only that a majority of the grains be so arranged to account for the increased magnetostriction. For N. Akuloff's observations with single crystals, *vide supra*.

G. W. Pierce studied the effects which occur when a magnetized rod has superposed on it an alternating axial magnetic field of a frequency in the neighbourhood of the natural mechanical frequency of the rod. The rod when under the influence of magnetostriction can be made to act like quartz crystals under the influence of piezoelectricity. If a ferromagnetic rod or tube is clamped so that it lies along the axis of a coil, the combination becomes an electrical vibrational instrument. This phase of the subject was studied by K. C. Black.

The magnetostriction of single crystals of iron was observed by W. Gerlach, E. Dussler and W. Gerlach, H. Kornfeld, G. S. Mahajani, and N. Akuloff. K. Honda and Y. Mashiyama found that in the (100)-plane, taken in the direction of the tetragonal axes (100), the longitudinal effect of the magnetic expansion is positive for all magnetizing fields; it increases at first rapidly, and afterwards slowly. The transverse effect is just the reverse of the longitudinal one. As the inclination of the direction of the tetragonal axis to the direction of the field increases, the longitudinal expansion in strong fields becomes less, and at an inclination of 15°, the expansion-field curve already shows an inconspicuous maximum at 200 gauss. At an inclination of 30°, the maximum is already attained at 80 gauss, and the decrease of expansion in stronger fields is considerable, the expansion changing into contraction at above 400 gauss. At an inclination of 45° (100), that is, in the direction of the digonal axis, only a small expansion is observable below 120 gauss, above which a marked contraction is noticed. The transverse effects are just the reverse of those of the longitudinal, except in the direction of 45°, in which a small initial contraction is not observable. The longitudinal effect of the magnetic expansion is maximum in the direction of the tetragonal axes and minimum between them; the expansion-orientation curves are sinusoidal, having a period of 90°. The amplitude of the curves increases with the field. The transverse effect is just the reverse of the longitudinal, so that no further remarks are necessary.

In the (110)-plane, in the direction of the tetragonal axes, the longitudinal expansion is a maximum; in the direction of the digonal axes, a small maximum is found; and in the direction of the trigonal axis, a minimum is observable. Thus the expansion-orientation curves have a period of 180°, instead of 90° as in (100)-plane. The transverse effect in the same plane is just the reverse of the longitudinal with respect to the orientation. In the (111)-plane, for three orientations, 0°, 15°, 30°, of the crystal with respect to the magnetic field, the longitudinal effects are all similar; that is, as the field is increased, the magnetic expansion increases slowly at first and then rapidly, and after reaching a maximum, it steadily decreases, till it changes into a contraction. As the inclination increases from 0° to 30°, the expansion gradually increases, and, on the other hand, the contraction decreases. The transverse effect is the reverse of the longitudinal above described.

According to N. Akuloff and co-workers, if a single crystal of iron be magnetized up to an intensity I, first in the direction of the principal axis, and next, to the same intensity, in any other direction, then the differences between the changes in length, dl/l, of the crystal parallel to the directions of magnetization, are proportional to the differences between the corresponding changes of resistance, dR/R, and to the energy changes, $\sigma_s-\sigma_0$, between corresponding magnetization curves in the HI-diagram, or $a(dl/l)_s-(dl/l)_0=b(dR/R)_s-(dR/R)_0=c(\sigma_s-\sigma_0)$. The crystal lattice is supposed to be distorted by the rotation accompanying the change in the direction of magnetization away from the direction of easiest magnetization. There is therefore a difference in length of unit rods parallel to the different crystal directions when complete magnetization occurs. When a cube of iron, on an atomic scale, is completely devoid of magnetization, it becomes slightly distorted when it acquires its normal spontaneous magnetization. It becomes longer along the cubic axis of magnetization than it does along the axes at right-angles. Hence, continued W. L. Webster, demagnetized iron is considered as a mosaic made up of asymmetrical small volumes with their direction of distortion distributed equally along the three cubic axes. The resultant dimensions of a cube of demagnetized iron will be symmetrical, but will be a complicated average between the two dimensions of the distorted magnetized cube. When magnetization takes place along a cubic axis there must be a longitudinal expansion, with a lateral contraction gradually increasing as the various volume curves become parallel. For the (110)-direction, as magnetization proceeds there is at first a concentration of the axes of distortion of the many small volumes along the two cubic axes nearest the direction of magnetization. There must therefore be an initial expansion continuing till the third axis has been completely abandoned. Further increase of magnetic intensity can only be produced by deviation from the cubic axes, and the corresponding contraction is sufficiently large to overwhelm the expansion due to increasing uniformity.

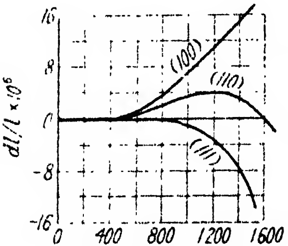

FIG. 314.- The Magnetostriction of Single Crystals of Iron.

With the (111)-axis, the three cubic directions are symmetrically disposed and there is no real increase in uniformity before the deviational distortion appears; consequently no initial expansion is observed. It may be pointed out that the contraction should set in for all directions at a point corresponding to the bend in the I/H curve, a result with which the experiments are in reasonable agreement.

H. G. Dorsey measured the magnetostriction of different carbon steels, and some of his results for the magnetostriction as a function of the field-strength, H, are summarized in Fig. 316, and as a function of the intensity of magnetization, I, in Figs. 315 and 316. He showed that the maximum elongation decreases with the carbon-content up to 0·9 per cent. carbon, and then increases; it may be represented by $(\delta l/l\times10^8+C-4\cdot2)(\delta l/l\times10^8-3\cdot1C+2\cdot13)=0$, where C denotes the percentage of carbon; and if K denotes the magnetic susceptibility $(K+185C-194)(K-40C+4)=0$. Similarly, but not so definitely, the value of H at which the iron rods retract to their original length drops to a minimum value at about 0·9 per cent. carbon. $\delta l/l$ is practically the same $-1\cdot4\times10^{-6}$ when $H=300$. The rods were still contracting when the field-strength attained 1600; but for $H=1500$, the greater the carbon-content, the less the contraction. The modulus of elasticity decreases with the proportion of carbon, or the amount of shortening in strong fields varies directly as the modulus. Slowly cooled steels have greater elongations and susceptibilities than when quenched. There are accidental exceptions for soft iron. Magnetostriction depends on the previous history of the specimen. The percentage elongation in the middle of a 40-cm. rod of soft iron is nearly three times as great as for the entire rod. The values also depend on the lengths of the rods used for observations. R. H. Fowler and P. Kapitza studied the relation between magnetostriction and the Curie point; and S. R. Williams, and S. L. Quimby, the theories of magnetostriction.

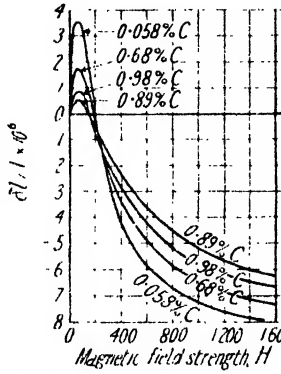

FIG. 315.—Magnetostriction as a Function of the Field-strength.

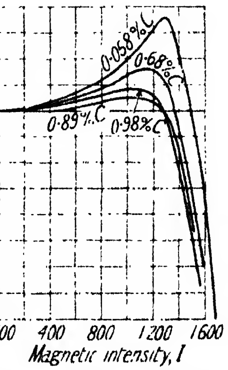

FIG. 316.—Magnetostriction as a Function of the Magnetic Intensity.

J. Coulson examined the effect of occluded *hydrogen* on the magnetization of iron, and found a drop of 5 to 19 per cent.; and A. Kussmann and H. J. Seemann, the effect of cold-rolling. The *elasticity* of iron and steel exercises but a feeble influence on the magnetization. G. Wertheim showed that if iron be exposed for a long time to a magnetizing force, the coeff. of elasticity is reduced a little, and the reduction persists after the magnetizing force is withdrawn. K. Honda and T. Tanaka found that the moduli of elasticity, E, and rigidity, K, of carbon steels are increased by magnetization. Thus, for iron alone:

H . .	9·5	27·2	90·4	213	332	405
$\delta E/E \times 10^2$.	0·143	0·384	0·553	0·665	0·700	0·700
H . .	13·2	33·8	76·1	134	202	465
$\delta K/K \times 10^2$.	0·40	1·03	1·62	2·02	2·20	2·45

The rate of increase in weak fields is greater than in strong fields. H. Tomlinson studied the influence of magnetism on the internal friction and torsional elasticity of metals, and found: (i) When the deformations produced by the oscillations are small, the internal friction of a torsionally vibrating wire of iron or steel is not affected by sustained longitudinal magnetization of moderate amount. The internal friction is also not affected by the sustained magnetization even when the latter is carried to the point of saturation, provided the magnetizing current, previously to experimenting, be reversed a great number of times. When no previous reversals have been made the internal friction is slightly increased by intense magnetism. (ii) When the deformations produced by the oscillations are large the internal friction is very sensibly increased by sustained longitudinal magnetization of large amount. (iii) The torsional elasticity is entirely independent of any sustained longitudinally magnetizing stress which may be acting upon an iron or steel wire, provided the deformations produced by the torsional oscillations be small. When the deformations are large, the number of oscillations executed in a given time is very slightly lessened by sustained longitudinal magnetization of large amount. (iv) When the magnetizing current is interrupted and, to a greater extent, when it is reversed repeatedly whilst the wire is oscillating, the internal friction is increased, provided the magnetizing stress be of moderate amount. The increase of internal friction may become very considerable when the magnetizing stress is great. When the number of interruptions or reversals in a given time of the magnetizing current exceeds a certain limit the effect on the internal friction begins to decline. (v) When the deformations produced by the oscillations are small, the torsional elasticity is not affected by either repeatedly interrupted or reversed longitudinal magnetization even when the magnetizing stress is large. (vi) There exists a limit of magnetic stress within which no permanent rotation whatever of the molecules is produced. This limit may be widened by previous repeated reversals of a large magnetizing stress. (vii) The passage of a moderate electric current, whether sustained or interrupted, through a torsionally vibrating wire of iron, steel, or nickel does not affect, except by heating, either the internal friction or the torsional elasticity, provided the deformations produced by the oscillations be small. (viii) The effect of longitudinal magnetization, even when carried to the point of saturation, on the longitudinal oscillation of an iron or steel wire, is *nil*. (ix) The passage of an electric current, whether sustained or interrupted, through a longitudinally oscillating wire of iron or steel does not, except by heating, affect the number of oscillations executed in a given time. (x) When the deformations produced by the oscillations do not exceed a certain limit, the internal friction cannot apparently depend upon the *permanent* rotation of the molecules about their axes. When, however, the deformations exceed this limit, the internal friction becomes very sensibly larger, and does partly, if not mainly, depend upon the permanent rotation to-and-fro of the molecules about their axes. The limit can be widened by allowing the wire to rest after suspension with oscillations at intervals, by annealing, and by repeated heating and cooling. According to A. Esau and H. Kortum, when ferromagnetic substances are vibrating under torsion, and simultaneously subjected to an alternating, longitudinal magnetic field, a maximum vibration occurs when the period of the field is less than the natural period of the system. Y. Kidani and R. Sasaki found a minimum in the temp. curve showing the tensile strength of magnetized steel, and there is also a change of temp. in the resistance to compression test as the metal passes from the elastic to the plastic state. The lines of magnetic induction of the metal in the elastic state are increased during the tensile test, and decreased in the compression test; the magnetic induction lines of the metal in the plastic state are decreased during both tests. There is no appreciable change of magnetic induction during the compression of a test-piece having no initial permanent magnetization. M. F. Fischer observed that the similarity of the magnetic changes accompanying repeated stresses and those produced by the removal of externally-applied static stresses indicates that the observed changes may be due to the partial relief or redistribution of initially existing internal stresses. C. W. Burrows, H. Styri, C. R. Jones and C. W. Waggoner, and C. W. Waggoner studied the relation of the tensile stress to the magnetic properties of carbon-iron alloys. K. Tangle, J. S. Stevens and H. G. Dorsey, G. Moreau, A. Gray and A. Wood, N. J. Gebert, R. L. Sanford, G. Guzzoni and D. Faggiani, L. von Hamos and P. A. Thiessen, H. Styri, E. Giebe and E. Blechschmidt, F. Bitter, L. Fraichet, C. Chree, P. Mishin and V. Bazilevich discussed the relation between the mechanical and magnetic properties of steel; and A. Kussmann and H. J. Wiester, the effect of a magnetic field on the ageing of hard steel

B. Wedensky and K. Theodortschik found that the magnetic permeability of iron in weak fields of wave-length 54 to 705 metres is not constant. There is a sharp maximum for $\lambda=100$ lying between two minima. Observations were also made by W. Arkadieff. R. G. Loyarte gave for the relation between the frequency, n, of the Hertzian oscillations and the magnetic permeability:

$n \times 10^6$ . .	0	3·75	5·4	6·33	7·48	300	495
μ . . .	158	114	114	122	122	58·4	42·2

A. Kussmann and B. Scharnoff found that in solid soln., in which the mechanical hardness, electrical resistance, etc., are higher than with pure metals, the coercive force, or magnetic hardness is only slightly changed. No direct connection between mechanical and magnetic hardness was observed. In heterogeneous mixtures, the coercive force is much higher, independently of the mechanical hardness. This is attributed to the tension set up by the contraction of the ferromagnetic material in the mixture. E. G. Herbert, and H. Esser and H. Cornelius found that work-hardened metals are still further hardened by magnetic treatment; and the subject was studied by A. Kussmann and H. J. Wiester, and Y. Matuyama. K. S. Seljesater and B. A. Rogers, W. Jellinghaus, L. W. Wild, and K. Heindlhofer studied the magnetic testing of hardness. The application of magnetic analysis to detect flaws, and the correct heat-treatment was discussed by R. L. Sanford and co-workers, P. H. Dudley, J. A. Mathews, E. G. Herbert, C. W. Burrows and F. P. Fahy, S. R. Williams, N. J. Gebert, C. Nusbaum, R. L. Sanford, A. V. de Forest, J. Würschmidt, W. B. Kouwenhoven, E. Maurer and K. Schroeter, and J. S. Hoffhine.

E. Wartmann observed that magnetization had no influence on the sound figures produced by iron or steel plates. C. G. Page observed that a sound may be produced in the magnetization of iron or steel rods. The phenomenon was studied by M. Delezenne, J. P. Marrian, C. Matteucci, G. Wertheim, H. Buff, P. I. Bachmetjeff, R. M. Ferguson, P. Reiss, W. Beatson, A. de la Rive, and M. Ader. According to N. Ruhmkorff, the hardness of the filings of magnetized iron is greater than is the case with non-magnetized iron; but W. Rollmann could detect no difference. M. Trève stated that iron cast from the molten state in a magnetic field is finer grained than if cast in the ordinary way. W. F. Barrett said that iron which has solidified in the molten state in a magnetic field is harder and tougher than if cast in the ordinary way; but these statements have not been confirmed. W. Brown measured the subsidence of the torsional oscillations of iron wires when subjected to the influence of direct and alternating magnetic fields up to 800 c.g.s. units. He also measured the fatigue of iron wires when subjected to the influence of longitudinal and transverse alternating magnetic fields. E. Bauer discussed the relation between the magnetization and the dilation and compressibility. K. Honda and T. Tanaka found that the elastic constants of steel are increased by magnetization.

C. Barus could not obtain satisfactory evidence of the various effects of magnetic force by means of a static method of measurement, and he thus failed to verify H. Tomlinson's results obtained by a vibration method. He showed that during the first phase of annealing, the effect of magnetization on the rigidity of steel is almost *nil*, but the effect becomes marked in the second phase of annealing. If the wire be supposed to pass continuously from the hard to the soft state, the increase of the magnetic coeff. of rigidity, μ, is particularly pronounced after the variations of the thermoelectric, the galvanic, and the viscous properties have practically subsided. C. Barus found for magnetized steel:

			Viscosity $\phi \times 10^6$	Rigidity $\mu \times 10^3$
Steel	Glass-hard		3	0·06
	Annealed at	100°	4	0·08
		190°	4	0·08
		360°	22	0·42
		450°	25	0·48
	Soft		41	0·78
Soft iron			95	3·63

R. Seidek and A. Pompe observed that the resistance of an iron wire to tensile stress is increased by the magnetization of the metal in a definite proportion to the increasing strain on the metal, and similarly reduced in an almost equal proportion as the strain is diminished. Repeated strainings of one and the same wire tend to produce in it a constant magnetic condition. R. Cazaud studied the self-magnetization of steels during torsion. Torsion produces a negative variation on the magnetic flux in mild steels containing less than 0·5 per cent. of carbon, and a positive variation with steels in which the carbon-content exceeds 0·5 per cent. With extra hard steels, cast steels, and some alloy steels of martensitic structure, the variation of flux with torsion is continuous. Repeated torsions cause the steels to approach a state of magnetic saturation; and cold-working tends to increase the variations produced in the magnetic flux of torsion. S. R. Williams found that the permeability of cast-iron rods is changed by tension, and concluded that J. T. Rood's observation to the opposite effect is wrong.

P. G. Maggi reported that the *thermal conductivity* of iron is altered by magnetization. According to H. Tomlinson, the thermal conductivity of a bar of soft iron is diminished by temporary longitudinal magnetization, and increased by transverse magnetization, whilst in the case of steel of different degree of hardness, magnetization produces the same kind of effect. The change with soft iron is at least 10 per cent.—possibly more; whilst the change for thermal and electrical conductivities is not very different. A. Naccari and M. Bellati could detect no influence of magnetization on the thermal conductivity of iron, but A. Battelli, A. Lafay, and E. Fossati observed the alteration in this property with magnetization. Indeed, D. Korda said that thermal conductivity decreases along the lines of magnetic force and is unaffected across them *vide supra*, thermal conductivity. H. M. Brown found that with a longitudinal magnetic field of 10,000 gauss, the ratio of the thermal conductivity 0·179 cal. per sq. cm. per degree with no field, to the conductivity in the magnetic field is 0·9886; and with transverse fields of 8000 and 4000 gauss, the ratios are, respectively, 1·000, and 0·996. P. S. Epstein studied the *specific heat* of ferromagnetic materials; J. A. Becker, the effect of magnetization on the absorption of X-rays; J. H. J. Poole, the effect on the photo-electric properties; and E. Reeger, the magneto photo-phoresis of aerosols. J. R. Ashworth discussed the relations between the magnetic and thermal constants. B. V. Hill found that the sp. ht. decreases with an increase in magnetic permeability.

N. W. Fischer thought magnetized iron to be a worse and J. H. Abraham a better *electrical conductor* than non-magnetized iron. Both observations were considered by K. W. Knochenhauer to be doubtful. E. Edlund observed that the *electrical resistance* of iron by temporary magnetization is increased in the direction of its magnetic axis by about 1 in 3000. W. Beetz also found an increase in the resistance in the direction of the magnetic axis, but not with transverse magnetization. W. G. Adams observed a decrease in the resistance of hard steel, and an increase with soft steel on magnetization. Observations were made by Lord Kelvin, G. de Lucchi, A. Gray and E. T. Jones, G. Barlow, J. A. Mathews, F. Auerbach, E. D. Campbell, W. Guertler, E. Gumlich, N. H. Frank, A. Garbasso, H. Tomlinson, M. Cantone, P. Kapitza, W. Meissner and H. Scheffers, O. Stern, O. Stierstadt, D. A. Goldhammer, and H. Herwig—*vide supra*, electrical resistance. The relation between the electrical conductivity and ferromagnetism was discussed by J. Dorfman and R. Jaanus, and E. D. Campbell. J. R. Ashworth discussed the relation between the thermal and magnetic properties of iron; and for the effects of polarized light on magnetized films of iron—*vide supra*, optical properties. M. de Broglie, T. D. Yensen, K. T. Compton and E. A. Trousdale, and A. H. Compton and O. Rognley studied the action of X-rays on the supposed ultimate magnetic particle of iron, and concluded that the most minute crystal aggregations in solid iron are not oriented by a magnetic field; that the ultimate magnet cannot be a group of atoms like the chemical molecule; and that the atom as a unit cannot account for ferromagnetism. J. C. Stearns tried unsuccessfully to detect a change in the intensity of the X-ray beam reflected from a crystal of silicon steel under the influence of a magnetic field; and he concluded that electrons revolving in orbits within the atom cannot account for ferromagnetism. C. W. Heaps studied the effect of a transverse magnetic field on the electrical resistance of iron. The changes of resistance with longitudinal and transverse magnetic fields was studied by C. G. Knott. L. Grunmach observed an increase of resistance in fields up to 8000 gauss, beyond which a decrease occurred. C. G. Knott observed no initial increase. He found that under the influence of longitudinal magnetization the electrical resistance of iron and steel is increased, but this increase is notably diminished when the longitudinal magnetizing force is superposed cyclically upon a steadily sustained transverse magnetization. In the highest transverse fields used, the change of resistance due to the superposed longitudinal field was in most cases very small. Under the influence of a transverse magnetization the electrical resistance of iron and steel is diminished, and this diminution becomes markedly greater when the transverse field is superposed cyclically upon a steadily maintained longitudinal field. In certain cases the change of resistance due to the transverse magnetizing force was more than doubled when this field was superposed upon the steadily maintained longitudinal field.

The effects of magnetization on the resistance of single crystals of iron, observed by W. L. Webster, are indicated in Fig. 317. In spite of the enormous change of length for the (100)-direction, there is practically no change of resistance. There is also a parallelism. Consequently the change of resistance is caused by the distortion of some sort of electron lattice by the pulling away of the magnetic axes of the electrons from their normal cubic direction; and a cube of iron magnetized along a cubic axis remains electrically isotropic in spite of its magnetostrictive distortion. These conclusions are borne out by the transverse magneto-resistance effect. In this case there is a small change of resistance roughly proportional to the applied field, which appears in all cases and is probably of the same nature as the change occurring in all metals, ferromagnetic or not. There is, in addition, a change depending for sign and magnitude on the directions of the current and magnetic field. This is the definitely crystalline effect, and it has the important property of vanishing whenever the magnetic field is parallel to a cubic axis—that is, whenever the magnetic condition of the iron is normal.

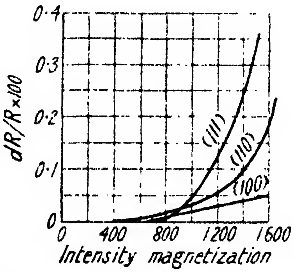

Fig. 317.—The Effect of Magnetization on the Resistance of Single Crystals of Iron.

For N. Akuloff's observations with single crystals, *vide supra*. For the effect of a magnetic field on the *electrode potential* of iron, *vide supra*. E. M. Pugh found that a break in the linear relations of the Hall effect coincides with the maximum permeability. According to J. Trowbridge, the magnetic permeability of iron wires exercises an important influence upon the decay of electrical oscillations of high frequency. The influence is so great that the oscillations may be reduced to half an oscillation on a circuit of suitable self-induction and capacity for producing them. It is probable that the time of oscillation on iron wires may be changed. Consequently, currents of high frequency, such as are produced in Leyden jar discharges, magnetize iron.

C. Barus and V. Strouhal observed that the *thermoelectric force*, *E*, of the copper-iron couple is very slightly greater with magnetized iron; for non-magnetized iron, $E=0{\cdot}0_31305(\theta-\theta_1)-0{\cdot}0_6262(\theta^2-\theta^2{}_1)$; and for magnetized iron $E=0{\cdot}0_31308(\theta-\theta_1)-0{\cdot}0_6261(\theta^2-\theta^2{}_1)$. The couple with magnetized and non-magnetized wire has a thermoelectric force of $E=0{\cdot}0_637(\theta-\theta_1)+0{\cdot}0_815(\theta^2-\theta^2{}_1)$. H. Tomlinson, W. H. Ross, C. W. Heaps, R. Schaffert, S. Seass, A. Battelli, M. Chassagny, and P. I. Bachmetjeff also made observations on this subject. In 1856, Lord Kelvin (W. Thomson) showed that a thermo-couple consisting of magnetized and unmagnetized iron of the same hardness and form, furnishes an electric current in one case from unmagnetized to longitudinally magnetized iron through the hot junction, and in another from transversely magnetized to unmagnetized iron through the hot junction; consequently, also from transversely to longitudinally magnetized iron through the hot junction. A. Battelli observed an increased

Peltier effect with magnetized iron, but magnetization has no perceptible influence on the *Thomson effect*. W. K. Mitiaeff found that the magnetic permeability of iron in a constant field of 600 gauss is reduced by *electromagnetic waves* of length 55 to 114 metres—*vide supra*. G. A. Carse and D. Jack observed no difference in the electron emission from magnetized and unmagnetized iron.

According to H. A. Rowland and L. Bell, they embedded two iron rods in insulating material, so that the point of one and the side of the other were laid bare by removing the insulation, and placed the rods in a beaker between the poles of an electromagnet, and connected them with a galvanometer. Then, when they are acted on by chemical reagents, no current is produced when perpendicular to the lines of force; and when parallel, a current is produced, the sharp-pointed rod forming the negative element; soon afterwards reversal takes place. The direction of the current is independent of that in the magnet. Similar, but much weaker, effects are produced with nickel and cobalt. The action is greatest with substances which, like nitric acid, attack the iron without the evolution of hydrogen. The reversal can be annulled by preventing motion in the liquid by means of gelatin or sand. The e.m.f. varies from 0·0001 to 0·02 volt. The evolved hydrogen probably acts mechanically in reducing the current. The protection of the pointed end from the reagents is due to the increased energy required to remove the iron. No differential action was observed with plane surfaces, but where a point occurs, some protection ensues, so that elevation increases in size.

P. Weiss, and P. Weiss and R. Forrer gave 11 and 15 for the magnetic moment of α-iron; and 14 for γ-iron. The subject was studied by N. Akuloff, C. J. Gorter, P. Weiss and G. Föex, R. W. Roberts, E. C. Stoner, S. J. and L. J. H. Barnett, R. H. Fowler and F. C. Powell, W. J. de Haas, O. Laporte and A. Sommerfeld, C. Sadron, A. Sommerfeld, P. Weiss and co-workers, and A. Wolf. Basing an argument on the supposed constitution of magnetic oxide of iron, F. Gross assumed that iron has the constitution

$$\begin{array}{l}\mathrm{Fe}\\ \ddot{\mathrm{F}}\mathrm{e}\end{array}\!>\mathrm{Fe}$$

P. Weiss, and L. A. Welo and O. Baudisch measured the magnetic moments of iron salts; and S. S. Bhatnagar and co-workers found that there is a slight increase in the paramagnetism when iron salts are adsorbed on charcoal, and when adsorbed on charcoal the salts are diamagnetic. This is thought to favour the view that the adsorption is a process of chemical combination. J. H. van Vleck studied the susceptibility of the iron salts. P. Collet and F. Birch discussed the paramagnetism of the iron in potassium ferricyanide; L. A. Welo, in $Fe_3(CH_3COO)_6(OH)_2Cl$. R. H. Weber found the atomic magnetism of iron in $\frac{1}{2}Fe_2(SO_4)_3$ and $FeSO_4$ to be respectively 0·01521 and 0·01276. The magnetic properties of various iron compounds were studied by L. Cambi and co-workers, G. Föex, L. C. Jackson, and W. Klemm and co-workers; the photo-magnetic effect of salts in soln., by D. M. Bose and P. K. Raha; and the magnetic properties in relation to the periodic law, by P. Weiss.

W. Sucksmith and L. F. Bates, and F. Coeterier and P. Scherrer studied the gyromagnetic effect. O. W. Richardson showed that if the magnetic properties of ferromagnetic substances are due to the rotation of electron orbits in the atom, a change in the magnetic moment, M, should be accompanied by a change in the angular momentum, U, such that $U/M=2m/e$, where m and e are the mass and charge of an electron respectively. If K denotes the ratio $U/M : 2m/e$, then K for iron is about half the theoretical value, for $K=0{\cdot}503$. Observations were made by O. Dahl and J. Pfaffenberger, A. P. Chattock and L. F. Bates, S. J. and L. J. H. Barnett, A. Serres, W. Sucksmith, and J. W. Fisher. F. Ehrenhaft studied the magnetophoresis and the electrophoresis of iron.

T. D. Yensen observed that there is no evidence of any change in the crystal units of iron when subjected to a strong magnetic field, and hence it is probable that the magneton is an atomic property. The theory of ferromagnetism was discussed by N. Akuloff, H. S. Allen, J. R. Ashworth, O. von Auwers and co-workers, S. J. Barnett, W. F. Barrett and W. Brown, E. Bauer, R. Becker and co-workers, F. Bitter, F. Bloch, D. M. Bose, L. Brillouin, L. Bruninghaus, B. Cabrera, F. W. Constant, C. G. Darwin, J. Dorfman and co-workers, J. A. Eldridge, W. B. Ellwood, E. Englert, P. S. Epstein, H. Fahlenbrach, G. F. Fitzgerald, A. V. de Forest, R. Forrer, R. H. Fowler and F. C. Powell, J. Frenkel, J. Frenkel and J. Dorfman, O. E. Frivold, R. Gans, W. Gerlach, O. Halpern, W. Heisenberg, T. Hirone and T. Hikosaka, K. Honda, E. Howells, D. R. Inglis, J. C. Jackson, W. Jäger and W. Meissner, P. Jordan and V. Fock, J. Kelen, K. Kreielsheimer, J. Kunz, O. Laporte, G. N. Lewis, G. H. Livens, F. H. Loring, R. G. Loyarte, H. Ludloff and C. Reymann, L. W. McKeehan and co-workers, G. S. Mahajani, E. Merritt, A. E. Oxley, L. Pincherle, F. C. Powell, S. L. Quimby, F. Regler, J. C. Slater, J. H. Smith, J. C. Stearns, E. C. Stoner, W. Sucksmith, R. Swinne, E. Teller, E. M. Terry, N. Tunazima, F. Tyler, E. Vogt, W. L. Webster, P. Weiss, P. Weiss and R. Forrer, L. A. Welo, E. H. Williams, R. L. Wills, J. F. T. Young, and F. Zwicky.

§ 23. The Chemical Properties of Iron

According to G. Tammann,[1] the effect of cold-work on iron is to make the metal less noble, or more basic. The lower limit of the temp. of reactions between solids was found by G. Tammann to correspond with the temp. at which the space-lattice of a solid begins to change. Fairly good agreement was observed for the beginning of the reaction between tungsten, molybdenum, copper, titanium, beryllium, phosphorus, manganese, aluminium, or silicon and iron, and iron-nickel or iron-cobalt alloys. The subject was studied by E. Scheil.

F. Duran and C. H. Teckentrup found that the absorption of **argon** by electrolytic iron is purely adsorption. F. Fischer and F. Schröter observed no evidence of combination when iron is sparked beneath liquid argon. V. Kohlschütter and R. Müller investigated the spluttering of iron electrodes in gaseous argon; and V. Kohlschütter and co-workers, F. Fischer and co-workers, B. Walter, and J. Stark discussed whether or not the phenomenon is due to the formation of an unstable endothermal compound. Similarly also with **helium.** W. A. Tilden found that helium is less readily absorbed by iron than is the case with hydrogen. A. Sieverts and E. Bergner found that argon and helium do not show a measurable solubility in solid iron at 1200° and 1400°, or in molten electrolytic iron at 1500°, whilst W. Ramsay and M. W. Travers detected no diffusion of argon or helium through iron. The subject was studied by E. Martin, and W. Frankenburger and co-workers. The gases occluded by meteoric irons are mainly the carbon oxides, nitrogen, methane, and hydrogen; though W. Ramsay, and H. D. Campbell and J. L. Howe reported the presence of occluded argon and helium in meteoric iron. F. Paneth and W. D. Urry found that iron meteorites contain up to $36{\cdot}15\times10^{-6}$ c.c. of helium per gram; and terrestrial iron, $1{\cdot}05\times10^{-6}$ c.c. per gram.

M. Poljakoff[2] observed that when **hydrogen** at 3 to 5 mm. press. is passed over iron at 400° to 800°, no luminescence occurs, but if a small stream of oxygen or air is added to a point remote from the metal, a violet, green, or yellow luminescence occurs. The luminescence is not produced by a mixture of hydrogen and oxygen.

Iron readily absorbs or occludes gases, and it may take up ten to twenty times its own vol. of gas when it is heated in a furnace, and the gas consists mainly of carbon monoxide and dioxide, nitrogen, and hydrogen. The gases are given off when the metal is heated in vacuo. A number of observations by (1) G. Allemann and J. Darlington, (2) G. W. Austin, (3) T. Baker, (4) E. Becker, (5) G. Belloc, (6) O. Boudouard, (7) L. Cailletet, (8) G. Charpy and S. Bonnerot, (9) J. W. Donaldson, (10) P. Goerens, (11) P. Goerens and J. Paquet, (12) E. Goutal, (13) T. Graham, (14) L. Guillet, and R. A. Hadfield, (15) H. M. Howe, (16) R. Hugues, (17) L. Jordan and J. R. Eckman, (18) P. A. Klinger, (19) E. Maurer, (20) P. Oberhoffer and E. Piwowarsky, (21) P. Oberhoffer, E. Piwowarsky, and

O. von Keil, (22) J. Parry, (23) H. M. Ryder, (24) L. Troost and P. Hautefeuille, (25) A. Vita, and (26) T. Zyromsky are summarized in Table XLVII.

Other observations were made by E. Améen and H. Willners, J. O. Arnold, G. W. Austin, L. Baraduc-Muller, P. Bardenheuer and W. Bottenberg, O. Bauer, H. Bessemer, H. Braune, H. le Chatelier and B. Bogitch, J. E. Fletcher, R. K. Gratigny, G. Guillemin and B. Delachanal, L. L. Hasse and H. Shenck, P. L. T. Hèroult, O. Herting, W. Hessenbruch, B. Hird, H. M. Howe, G. d'Huart, D. E. Hughes, R. Hugues, J. E. Hurst, J. E. Johnsen, W. H. Johnson, S. Kern, P. A. Klinger, F. Körber and H. Ploum, J. W. Langley, A. Ledebur, G. Lewkonja and W. Baukloh, A. G. Lobley and C. L. Betts, A. McCance, A. Magnus and B. Klar, E. von Maltitz, E. Maurer, V. S. Meskin and Y. M. Margolin, A. S. de Osa, N. Parravano and A. Scortecci, N. Parravano and C. R. del Turco, E. Piwowarsky, E. Piwowarsky and H. Esser, H. Ploum, F. Rapatz, W. Rohn, T. E. Rooney and G. Barr, E. H. Schulz, C. J. Smithells, T. C. Sutton and H. R. Ambler, W. A. Wesley and co-workers, N. A. Ziegler, etc., are summarized in Table XLVII. The effervescence and spitting of molten steels was discussed by H. D. Hibbard. Observations on the absorption of hydrogen by iron and steel were made near the middle of last century by H. St. C. Deville, E. Frémy, L. Troost and P. Hautefeuille, H. St. C. Deville and L. Troost, L. Cailletet, and T. Graham. Later observations were made by A. J. Allmand, G. P. Baxter, M. le Blanc, C. F. Burgess, J. Cournot, J. Grant, W. Hessenbruch, E. Heyn, G. d'Huart, A. Ledebur, H. Lee, D. J. McNaughton, E. Martin, J. H. Meidinger, E. Muller and K. Schwabe, B. Neumann, J. Parry and A. E. Tucker, N. B. Pilling, F. Rapatz, T. W. Richards and G. E. Behr, W. C. Roberts-Austen, F. Schmitz, E. H. Schulz, A. Sieverts, H. S. Taylor and R. M. Burns, M. Thoma, A. Villachon and G. Chaudron, H. Wedding and T. Fischer, and J. H. Whiteley.

J. Parry noticed that the solubility of hydrogen in iron increases with a rise of temp. As a rule, the solubility of gases in water decreases with a rise of temp., whereas in the case of molten metals, the solubility increases. In non-aqueous solvents, there are often minima in the solubility curves, and even in the case of water there are indications that it behaves more like non-aqueous solvents when its temp. is raised, and the complexity of its molecules—**1.** 9, 7 is simplified. If the effect of temp. on the solubility of gases in molten metals is in accord with the principle of accommodation—**2.** 18, 4—the solubility will increase with a rise of temp. when the process of dissolution is endothermal, and it will decrease with a rise of temp. if the process is exothermal. These deductions are quite independent of the mechanism of the process of dissolution.

According to T. Graham, iron at a red-heat is capable of taking up and holding when cold 0·46 vol. of hydrogen; and he added that it is difficult to impregnate malleable iron with more than one vol. of hydrogen under atm. press., but meteoric iron from Lenarto contains three times that amount. Hence he inferred that "the meteorite has been extruded from a dense atmosphere of hydrogen gas, for which we must look beyond the light, cometary matter floating about within the limits of the solar system." B. Neumann and F. Streintz observed that iron can occlude 9·3 to 19·17 times its vol. of hydrogen; and L. Troost and P. Hautefeuille found that charcoal iron heated for 48 hrs. in hydrogen at 800° absorbed 0·7 vol. of gas, whilst wrought iron absorbed 0·16 vol., and cast steel, 0·10 vol. G. P. Baxter observed no occlusion of hydrogen by iron obtained from the oxide by reducing it in hydrogen; and E. Heyn found that iron heated in hydrogen at 1000° absorbed 0·16 vol. of gas. H. Wedding and T. Fischer found that a gram of grey pig-iron at 800° absorbed 0·0079 mgrm. of hydrogen; iron from the converter, 0·0027 mgrm.; basic ingot iron, 0·0014 mgrm.; open-hearth ingots, 0·033 to 0·043 mgrm.; ingot when dulled, 0·12 to 0·17 mgrm.; wrought iron, 0·0018 to 0·017 mgrm.; and electrodeposited iron, 2·8 mgrm.—*vide* Table XLVII. T. C. Sutton and H. R. Ambler said that steel abruptly exposed to a high pressure and temp.—*e.g.* when cordite is exploded in a steel vessel—absorbs as much as 30 c.c. of gas per gram of metal, an amount which is larger than has been observed under other conditions. The gases are retained firmly below 600°, and are not all eliminated at 1000° under reduced press. The heat of absorption of the gas is estimated to be 0·75 cal. per c.c. of mixed gas. W. Frankenburger and co-workers studied

TABLE XLVII.—OCCLUDED GASES IN IRON AND STEEL.

the absorption of hydrogen by highly dispersed iron; and L. Baraduc-Muller, the absorption of gases by liquid steel.

A. Sieverts found that raising the *temperature* favours the absorption of hydrogen. Iron wire absorbs increasing amounts of hydrogen when it is heated in an atm. of that gas from 400°, upwards; but on cooling, the absorbed gas is evolved. Representing the amounts of hydrogen in mgrms. of gas per 100 grms. of iron, or in vols. of hydrogen per unit vol. of iron:

	Solid.								Liquid.	

The results are plotted in Fig. 318. There is a break in the curve corresponding with the $\alpha \rightleftharpoons \gamma$-transformation; and there is a marked increase in the solubility of the gas as the metal passes from the solid to the liquid state of aggregation between 850° and 900°; but no singularity was observed about the A_2-critical point. A. Skrabal also noted that hydrogen dissolves more readily in γ-iron than it does in α-iron. G. Tammann and J. Schneider observed that after α-iron has undergone the γ-transformation, it no longer absorbs hydrogen at 300°. K. Iwase observed that reduced iron absorbs hydrogen at different temp. in accord with the solubility curves shown in Fig. 319, and that the solubility, S c.c. of gas at n.p. θ per 100 grms. of metal, can be represented by the linear equations $S=1{\cdot}685+0{\cdot}016(\theta-200)$ for α-iron; and $S=13{\cdot}445+0{\cdot}1293(\theta-910)$ for γ-iron. G. Borelius, represented the solubility, S, of hydrogen in α-iron by $S=ae^{1720/T}$, and in γ-iron, by $S=ae^{1920/T}$, where a denotes a constant which varies with the temp., but has nearly the same value for all metals at high temp. H. S. Taylor and R. M. Burns, found that at 25°, one vol. of metal absorbs 0·05 vol. of hydrogen, and $<0{\cdot}05$ vol. at 110° and 218°; W. A. Dew and H. S. Taylor, that one gram of iron at 0°, 110°, 218°, and 305° absorbs respectively 0·0074, 0·0028, 0·0195, and 0·0116 c.c. of hydrogen. Observations were made by E. Martin, N. I. Nikitin, and A. Sieverts and E. Jurich. K. Iwase found that the solubility of hydrogen in cast iron is smaller, the higher is the proportion of *contained carbon*. The results with cast iron containing 3·5, 4·0, and 4·3 per cent. of carbon are shown in Fig. 320. Steel also dissolves more hydrogen than does cast iron. E. Martin's results agree better with those of A. Sieverts than with those of K. Iwase. C. J. Alexander examined the effect of liquid air temp.

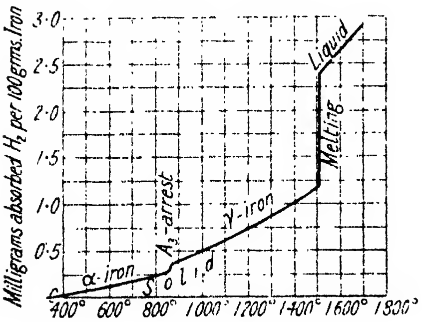

FIG. 318.—The Solubility of Hydrogen in Iron at Different Temperatures.

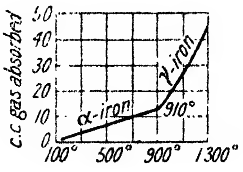

FIG. 319.—The Solubility of Hydrogen in Iron.

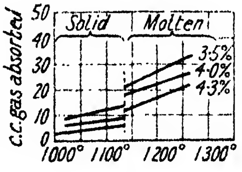

FIG. 320.—The Solubility of Hydrogen in Cast Iron.

G. Tammann and J. Schneider's observations show that the metal *hardened by* *cold-rolling* absorbs hydrogen at 300° more rapidly and to a greater extent than does the soft metal, but the reverse obtains with electrolytic hydrogen. The metal softened at 1100° absorbs electrolytic hydrogen much more rapidly than the hard metal. The octahedral planes of the crystals of the metal absorb hydrogen the fastest.

W. Heald, and W. Frankenburger and K. Mayrhofer studied the absorption of hydrogen by *thin films of iron.* L. Troost and P. Hautefeuille showed that *pyrophoric iron* reduced from the oxide by hydrogen at a low temp., decomposed water slowly at ordinary temp., and rapidly at 100°; the decomposition is more rapid the finer is the state of subdivision of the metal. The adsorbed hydrogen can be removed in vacuo without interfering with the pyrophoric character. According to T. W. Richards and G. E. Behr, finely-divided iron, obtained by reducing the oxide at a relatively low temp., 570°, has the power of absorbing hydrogen, but the potential of the metal is not appreciably affected thereby, unless the surface is fully charged with hydrogen when the potential is somewhat lowered. When iron which has been heated in an atm. of hydrogen or nitrogen is suddenly cooled by plunging it in water, it absorbs hydrogen from the water in a specially active form in virtue of which the potential is raised by about 0·15 volt. This hydrogen is not readily removed when the iron is kept in water or in a soln. of potassium sulphate, but it is rapidly expelled when the iron is placed in a soln. of ferrous sulphate, and the potential returns to its normal value.

According to N. I. Nikitin, the gas dissolved by pyrophoric iron at −185° represents a true surface adsorption, because it can be completely pumped off at ordinary temp., and it is in accord with the adsorption equation $a=kp^{1/n}$. He found pyrophoric iron is inert between −80° and 16°; and at higher temp. it absorbs the gas in increasing quantities. Pyrophoric iron reduced from the oxide at 515° to 525° absorbs v c.c. of hydrogen, reduced to n.p. θ per 5 grms. of metal when the press. is p mm.:

	−185°				380°				510°
p . . .	92·4	229·7	521·0	627·0	70·4	274·6	449·0	694·5	734·2 mm.
v . . .	3·2	5·3	7·7	8·3	3·5	4·4	4·9	5·2	6·10 c.c.

G. Tammann and J. Schneider found that the *rate of absorption* of hydrogen at different temp. can be represented by the slopes of the curves in Fig. 321, where the vol. of the gas is expressed in c.c. at n.p. θ per 100 grms. of metal. K. Iwase's results for solid and liquid cast iron are summarized in Fig. 322. G. Tammann and J. Schneider found that the velocity of absorption of hydrogen is greater, the larger is the number of icositetrahedral planes in the surface layer. The number of such planes decreases after heating the metal to a higher temp., and the rate of absorption shows a corresponding diminution. Observations on the rate of absorption were also made by G. Tammann and F. Laass.

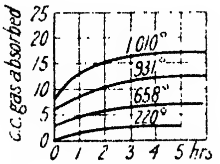

FIG. 321.—The Rate of Absorption of Hydrogen by Iron.

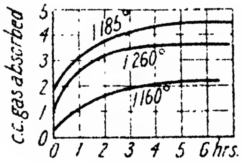

FIG. 322.—The Rate of Absorption of Hydrogen by Cast Iron.

A. Sieverts found that at a constant temp., the solubility, S, of hydrogen in iron is directly proportional to the *pressure*, p, of the gas, so that $S=kp^{\frac{1}{2}}$. G. Borelius and F. Gunneson added that this rule applies to iron, but, according to G. Borelius, not to steel. A. Sieverts found that with press. below 100 mm., the solubility of hydrogen in iron decreases more rapidly with falling pressures than corresponds with this relation. G. Tammann studied the effect of cold-work on the absorption of hydrogen; and H. Jellinek, the effect of the press. of the gas on the electrical resistance of the metal.

According to W. H. Johnson, and O. Reynolds, when pieces of iron or steel are immersed in sulphuric or hydrochloric acid, washed, and dried, there is an increase in weight of 0·0005 to 0·06 per cent. owing to the saturation of the metal with nascent hydrogen. On prolonged exposure to air, or more rapidly on heating, the hydrogen is evolved, and the metal regains its original physical properties. A. Ledebur found that the iron may absorb twenty times its vol. of hydrogen when placed in dil. sulphuric acid; and that cast iron behaves in a similar way. According to J. H. Andrew, the intercrystalline, amorphous cement between the ferrite crystals plays a part in conveying the gas into the interior of the solid metal. Thus, when a piece of wrought iron is immersed for some time in a sat. soln. of sodium hydroxide at 100°, the mass becomes brittle because the gas is absorbed more rapidly in the amorphous intercrystalline layers than by the crystals themselves, and the expansion of these layers forces the crystals apart and weakens their cohesion. After remaining longer in the soln. of sodium hydroxide, the iron loses its brittleness, because the hydrogen gradually diffuses into the crystals from the intercrystalline cement. Electrolytic iron, being already sat. with hydrogen, is unaffected by sodium hydroxide. M. Thoma said that iron is readily supersaturated with hydrogen when it comes in contact with nascent hydrogen either in the voltameter or that which is being generated on its own surface by the action of an acid. From the surface of the supersaturated iron, hydrogen is again spontaneously liberated, and the amount obtained is proportional to the extent of surface. J. H. Meidinger, and R. Lenz noticed that electrolytic iron may be contaminated with occluded hydrogen, and that at 100°, about a tenth of the total amount of occluded hydrogen is expelled, about two-thirds is given off at a dull red-heat, and only at 1000° is the metal freed from the gas. F. Haber discussed this question. R. Lenz found that when electrolytic iron is heated in a porcelain tube, the total amount of gas evolved varies from 20 to 96 vol. per cent. of gas per vol. of iron. The gas given off at 600° contained 58·5 vol. per cent. of hydrogen; 18·8, N; 11·3, CO; 10·1, CO_2; and 1·3, H_2O; whilst that evolved at a bright red-heat contained 43·2, H; 8·9, N; 22·7, CO; 17·8, CO_2; and 7·4, H_2O. It was thought that the steam and carbon monoxide were formed by the reaction between iron, carbon dioxide, and hydrogen. Observations were also made by L. Guillet, R. Hugues, H. O. von Samson-Himmelstjerna, A. Thiel and W. Hammerschmidt, M. Thoma, and R. A. Hadfield—*vide* Table XLVIII. F. Winteler gave, for deposits of electrolytic iron 0·08 mm. and 0·14 mm. in thickness, per 1 vol. of iron:

	H_2	N_2	CO	CO_2	H_2O-vapour	Total gas
0·08 mm. .	53·4	15·5	15·1	12·7	3·3	97·7 vol. per cent.
0·14 mm. .	60·3	5·6	26·7	4·3	3·0	21·2 ,, ,,

The presence of hydrogen in electrodeposited iron, in amounts varying from 0·0076 to 0·0262 per cent., was observed by S. Maximowitsch, C. F. Burgess and C. Hambuechen, W. M. Hicks and L. T. O'Shea, and A. Skrabal. The relations between the current density, concentration, acidity, and temp. of the soln. of ferrous sulphate on the proportion of occluded hydrogen, were studied by F. Förster, G. Coffetti and F. Förster, and W. A. MacFadyen. According to H. Lee, the hydrogen-content decreases with the duration of the electrolysis, with decreasing current density, with increasing acidity of bath, and with decreasing conc. of iron in the soln. The results of H. Lee are summarized in Fig. 324 for layers of iron of different thickness. According to R. Kremann and H. Breymesser, the hydrogen and iron are simultaneously liberated at the cathode, and the liberation of hydrogen can be prevented if the electrolysis be carried out under a high press. of hydrogen. Iron deposited under 20 atm. press. of hydrogen were composed of larger crystals than when deposited under 1 atm. press. of hydrogen. The metal obtained at the higher press. contained less occluded hydrogen, and it was also softer, and less brittle.

G. Borelius found that for iron, but not steel, the conc. of the occluded hydrogen is proportional to the sq. root of the current density. The press. eq. of the current density for a 2 per cent. soln. of sodium hydroxide at an ampère per sq. cm. is 17,000 atm.

T. W. and W. T. Richards observed that a magnetic field has no perceptible influence on the electrode potential of iron, but with iron having occluded hydrogen, the potential is definitely lowered; the change is roughly proportional to the strength of the magnetic field. With a given magnetic field, the decrease in the overvoltage is approximately proportional to the overvoltage itself, amounting, with a strong magnetic field, to about 5 per cent. of the value of the overvoltage. It is assumed that the magnetic field affects the potential not because of any change in the affinity between hydrogen and iron, but because of some change in the texture of the occluding metal due to magneto-striction. For the effect of the adsorbed hydrogen on the magnetic properties of iron, *vide supra*, the magnetic properties of iron. J. A. Kendall discussed the formation of a cell with one plate of iron through which hydrogen is passing.

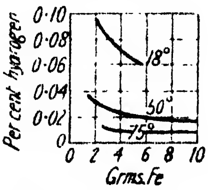

Fig. 323.—The Effect of Temperature on Occluded Hydrogen.

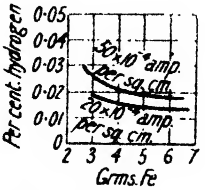

Fig. 324.—The Effect of Current Density on Occluded Hydrogen.

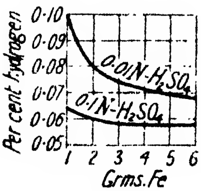

Fig. 325.—The Effect of Acidity on Occluded Hydrogen.

T. Graham discussed the **nature of the occluded hydrogen** in palladium, and he regarded it as a special form of hydrogen which he called *hydrogenium*—**1**. 7, 6. The occluded hydrogen is specially active chemically, and W. Ramsay attributed this activity to the presence of hydrogen in the monatomic condition. This inference is in harmony with the observations of T. W. Richards and G. E. Behr, T. W. and W. T. Richards, E. G. Mahin, S. Satoh, A. F. Penton and T. A. White, T. Franzini, T. S. Fuller, M. Thoma, G. Charpy and S. Bonnerot, W. H. Johnson, O. Reynolds, A. Coehn, and A. Winkelmann—*vide supra*. O. Faust's experiments on the chemistry of the iron electrode support this view; like T. W. Richards and G. E. Behr—*vide supra*—it was found that the electrode potential of spongy iron with occluded hydrogen is 0·39 volt, and without the hydrogen, 0·44 volt. A. Sieverts observed that for the occluded gas, $vp_{\frac{1}{2}}$ is constant; and for gaseous phase, vp is a constant. From the partition law, it follows that the hydrogen is occluded in the form of monatomic molecules. At very low temp., N. I. Nikitin's observations agree with the assumption that the adsorbed hydrogen is in the molecular state. A. Villachon and G. Chaudron believed that in liquid iron some hydrogen is present as a hydride; and W. Frankenburger and K. Mayrhofer found that when iron vapour condenses in an atm. of hydrogen, the film has Fe : H approximately as 1 : 2—*vide infra* for the hydrides. F. Duran and C. H. Teckentrup considered the absorption of hydrogen is a case of pure adsorption; L. Guillet and co-workers thought that a hydride is formed at the higher temp., and it dissociates below 250°.

The *permeability* of iron to hydrogen was observed by H. St. C. Deville and L. Troost, who found that the metal is permeable to ordinary hydrogen when it is heated to redness; and this fact was confirmed by T. Graham. L. Cailletet found that nascent hydrogen could pass through an iron vessel immersed in sulphuric acid at ordinary temp. H. M. Ryder's observations on the effect of temp. on the permeability of soft steel, and those of V. Lombard on electrolytic iron, are summarized in Fig. 326, and V. Lombard's observations on the effect of press. on the permeability of electrolytic iron are summarized in Fig. 327. M. Bodenstein, and M. Knobel and R. B. Norton expressed the rate of penetration of iron by hydrogen, D, as a function of the overvoltage, E. The subject was discussed by T. S. Fuller. E. Piwowarsky and H. Esser attributed the permeability of cast iron for gases to the presence of macroscopic flaws. B. Beer studied the subject. A. Winkelmann used an iron tube, closed below, as cathode in the electrolysis of a soln. of sodium hydroxide. The *rate of diffusion* of hydrogen formed on the exterior of the tube, into the interior, was found to be independent of the press. between 0 and 890 mm. of mercury. The rate of diffusion is not affected by reducing the external press. from 1 to 1·5 atm. It was accordingly inferred that the actual press. of the hydrogen on the outside of the iron tube is not of the same order as the internal press. and is not less than 58 atm. The independence of the internal press. agrees with the assumption that it is ionic or atomic, and not ordinary molecular hydrogen that is concerned in the process of diffusion. At a constant temp., the rate of diffusion increases more slowly than the current strength, and it is approximately proportional to the potential difference. The increase in the rate of diffusion, δ, with temp., $\theta°$, was rapid, and approximated to $\delta=\delta_0(1+0{\cdot}04550\theta)$ for a constant current, or to $\delta=\delta_0(1+0{\cdot}05610\theta)$ for a constant potential difference. G. Charpy and S. Bonnerot noted that the hydrogen as it diffuses through iron or steel at ordinary temp. acquires a special chemical activity. They showed that no diffusion occurs in steel tubes at ordinary atm. press. below 325°; the osmosis is perceptible at 350°; and it increases about 40-fold when the temp. is raised to 850°. The diffusion of gases in metals was studied by D. Alexejeff and L. Savinina, M. Bodenstein, A. H. W. Aten and P. C. Blokker, O. W. Richardson and co-workers, G. C. Schmidt and T. Lücke, C. A. Edwards, and by G. Borelius and F. Gunneson. W. E. Deming represented the rate of diffusion of hydrogen through iron by $d(p^{1/n})/dt=k/c\triangle^2p^{1/n}$, where p denotes the press. of the gas, and c the amount absorbed per unit vol. under unit press. For the steady state, the amount, dm, of hydrogen diffusing through an area, a, of thickness, dx, with press., p, and $p+dp$, in the time, dt, is: $dm=ka\triangle p^{1/n}dt$. A. Jaquerod and S. Gagnebin observed that the rate of diffusion of hydrogen in iron increases suddenly at about 200°, and other discontinuities occur at the Curie point, and at about 900°, when β-iron changes into γ-iron. A. H. W. Aten and M. Zieren, and T. S. Fuller discussed the penetration of iron by cathodic, nascent, or atomic hydrogen, and emphasized the difference between the behaviour of this form of hydrogen and ordinary gaseous hydrogen. A. Coehn considered that the experiments on the rate of diffusion of hydrogen in iron support the view that the absorbed hydrogen is in the form of electrons and protons. E. G. Mahin inferred that the hydrogen occluded by iron which has been pickled in acid diffuses in the metal in the atomic condition, and is liberated at the surface as molecular hydrogen.

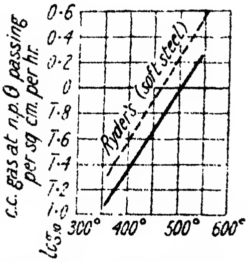

FIG. 326.—The Effect of Temperature on the Hydrogen Permeability of Iron.

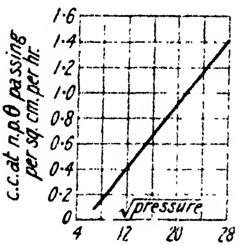

FIG. 327.—The Effect of Pressure on the Hydrogen Permeability of Iron.

N. B. Pilling observed that the *evolution of occluded hydrogen* from electrolytic hydrogen begins at about 100°, and attains a maximum at about 200°; H. Esser, J. Cournot, and C. F. Burgess and O. P. Watts, that the complete expulsion of the gas occurs above the a_3-point, —950° to 1050°; and O. W. Storey, that after heating to 910° to 1000°, electrolytic iron has the structure of ordinary iron; at 500° to 600° hydrogen is given off, but no change in structure is perceptible. B. Cazaud and

R. Hugues noted that there are discontinuities in the rate of evolution of the hydrogen attended by changes in the mechanical and magnetic properties of the metal; G. Borelius and F. Gunneson, that the variation in the rate of removal of occluded hydrogen and nitrogen from iron at different temp. shows a number of irregularities; and G. Tammann, and R. Hugues attributed some of the irregularities to the possible presence of hydrides. According to G. Belloc, the evolution of the occluded gas, when the metal is heated, is connected with the critical points of iron, and it may be divided into three stages: (i) the evolution begins at a variable, ill-defined temp. between 150° and 400°; the velocity, or dv/dt-curve (where v denotes volume), has a small minimum at 200°, and a small maximum at 300°, but the evolution of gas in the region of α-iron is very small, and tends to increase with temp. (ii) Between 500° and 600°, the dv/dt-curve exhibits a large maximum at the transition point of α- into β-iron, and then falls off to a minimum approaching zero at the end of the conversion. The transformation of cementation-carbon into temper-carbon has no marked influence on the result. (iii) The evolution of gas begins again with the transformation of β- into γ-iron, and after passing through a maximum, increases with temp. The gas first given off is nearly all carbon dioxide, and at about 550°, it disappears, and nitrogen makes its appearance and persists at all higher temp.; but the amount is small, not rising above the mean value of 10 per cent. Above 400°, carbon monoxide and hydrogen are alone evolved in proportions which may alter suddenly with temp. According to O. Boudouard, the results of heating iron in its various forms in vacuo at 1100°, with fifteen days' exposure to air between consecutive treatments, show that it is very difficult to extract the gases contained in iron and steel. Even after the third ignition at 1100°, the amount of gas retained by filings was 0·5 of the total vol., and 20 per cent. with sheet-iron and bar-iron. According to F. C. G. Müller, the gases sometimes regarded as occluded by iron are really mechanically held in the pores, for they are liberated on boring, and only a little additional gas is obtained when the borings are heated to redness in vacuo. The subject was also discussed by A. Pourcel, J. Parry and H. A. Brustlein, as well as by G. Alleman and C. J. Darlington, A. H. Allen, E. Améen and H. Willners, G. W. Austin, T. Baker, L. Baraduc-Muller, M. Barré, H. Bessemer, P. H. Brace and N. A. Ziegler, H. Braune, L. Cailletet, J. R. Cain, J. R. Cain and E. Pettijohn, H. Cassel and T. Erdey-Gruz, G. Charpy and S. Bonnerot, J. W. Donaldson, A. Friedmann, P. Goerens, P. Goerens and J. Paquet, E. Goutal, G. Hailstone, W. Herwig, W. Hessenbruch, W. Hessenbruch and P. Oberhoffer, P. Hird, L. Jordan and J. R. Eckman, E. Kahrs, O. von Keil, S. Kern, P. A. Klinger, W. Kusl, J. W. Langley, A. Ledebur, E. Liebreich, E. von Maltitz, E. Maurer, E. Münker, P. Oberhoffer and co-workers, A. S. de Osa, J. Paquet, N. Parravano and A. Scortecci, E. Piwowarsky, T. C. Poulter and L. Uffelman, F. Rapatz, P. Regnard, A. Ruhfuss, H. M. Ryder, O. Seth, J. E. Stead, J. E. Stead and S. Pattinson, G. Tammann, L. Troost and P. Hautefeuille, A. E. Tucker, U. le Verrier, A. Villachon and G. Chaudron, A. Vita, W. H. Walker and W. A. Patrick, H. Wedding, and A. Wüster and E. Piwowarsky. According to E. Améen and H. Willners, the gases: CO, CO_2, H_2, N_2, CH_4, and H_2O are dissolved by liquid steel, and when the steel hardens, these gases can react. The relation $CO_2 : CO$ is taken as a measure of the oxidation of the steel at a given temp. The CH_4 and H_2O content is a measure of the dissolved quantities of CO, CO_2, and H_2. Nitrogen is found chiefly in steels from the converter.

R. Hugues studied the rates of removal of hydrogen from about 20 c.c. of electrolytic iron, and L. Guillet and A. Roux, the vol. of gas removed from electrolytic iron at different temp. G. Hägg discussed the mol. vol. E. Heyn observed that the adsorption of hydrogen produces no perceptible effect on the microstructure, although it embrittles the metal. When cast iron is heated at 730° to 1000° in contact with hydrogen and then chilled, it becomes considerably more brittle than when similarly heated in air and chilled. If, however, the metal is allowed to cool slowly in hydrogen, it remains tough, and at temp. below 730° its properties are not affected by hydrogen. A cast iron containing 0·37 per cent. of carbon was found to behave in the same way as one containing only 0·05 of carbon and 0·01 of silicon. By heating the metal in nitrogen at a red-heat, the effect of the treatment with hydrogen is destroyed. In the case of iron containing very little carbon, the brittleness is partly removed by heating in boiling water, or even by long exposure to the air at the ordinary temp., and is completely destroyed by heating at 200° to 250°. Iron containing more carbon retains its properties much more obstinately. A superficial layer after treatment with hydrogen was found to show a greater flexibility, hence the hydrogen must penetrate below the surface. The density of the metal is not affected by the treatment with hydrogen. D. Alexejeff and M. Polukaroff studied the effect of hydrogen on the tensile properties of electrolytic iron. The results of A. Ledebur exposing wires of the metal to the action of acids are indicated in Table XLVIII. According to L. B. Pfeil, occluded hydrogen has a remarkable weakening effect on the intercrystalline boundary of iron—*vide supra*, hydrogenized iron. This applies not only to the boundaries between very large crystals, but also to the boundaries between the very minute crystals of which ordinary iron consists. The strength of the boundary between two single crystals has been shown to be about 8½ tons per sq. in., and of the boundary between very small crystals about 17 tons per sq. in. It is probable that this marked difference is due, not to any real variation in the strength per unit area, but to the difference in the ratio between the actual area of fracture and the cross-sectional area of the test-piece in the two cases. This ratio is much greater in the case of the aggregate than it is in the case of the two large crystals. In addition to its effect on the boundaries, hydrogen decreases the cohesion across the cubic cleavage planes, a pull of 5 tons per sq. in. applied at right-angles to the cleavage plane being sufficient to cause separation. Occluded hydrogen does not prevent deformation by slipping on the icositetrahedral planes of the iron crystal. Judging from the behaviour of the single crystals during these tests, it

TABLE XLVIII.—THE EFFECT OF OCCLUDED HYDROGEN ON THE MECHANICAL PROPERTIES OF IRON.

Metal	Tenacity (tons per sq. in.)		Elongation (per cent.)		Number of times metal could be bent	
	Normal	Hydrogenized	Normal	Hydrogenized	Normal	Hydrogenized
1. Uncleaned wires in 1 per cent. H_2SO_4, for 24 hrs. examined after 3 days .	54·54	54·66	3·5	2·8	10·2	8·0
2. Cleaned wires immersed 23 hrs. in 2·5 per cent. H_2SO_4, and examined immediately . .	54·09	56·00	3·4	2·7	7·4	3·0
3. Wires connected with a block of zinc and immersed 3 hrs. in 2·5 per cent. H_2SO_4, and examined immediately .	52·76	52·19	2·0	2·2	10·0	3·9
4. Wires treated as in 3, but examined 4 days later .	51·11	51·17	3·0	2·2	10·1	7·2
5. Wires treated as in 3, but heated to cherry redness for 15 mins. in an inert atm.	27·24	28·51	17·9	16·9	16·2	14·6

seems improbable that the hydrogen has even any important effect on the resistance to movement along the slip planes. The effect of hydrogen on the finely crystalline iron is very much less marked at temperatures a little above room temperature. Under these conditions the crystal boundaries are not so greatly weakened. Fracture takes place mainly *through* the crystals after they have been drawn down by slipping, but the point at which fracture occurs is determined by cracks which form as a result of a limited cleavage and intercrystalline failure. The cracks probably originate in those crystals so set at the surface of the test-piece as to present a cleavage plane at right-angles to the stress, these being particularly liable to fracture at low stresses. The minute notches so produced lead to large cracks which, decreasing the effective cross-section of the test-piece, cause a low value to be recorded for tensile strength. F. C. Lea observed that nascent hydrogen liberated at a cathode penetrates the crystal boundaries of mild steel, nickel, and stainless steel with 15 per cent. Cr, and 10 per cent. Ni. The penetration does not affect the tensile strength of these materials, but it lowers considerably the elongation of specimens of mild steel. The transverse cracks which develop indicate that the tearing of crystals apart at their boundaries occurs at fractures. The hydrogen interferes with the slip that takes place on certain crystal planes and which, under ordinary conditions, continues apparently across the crystal boundaries. Hydrogen escapes quickly after the current ceases, even at ordinary temperatures, and after heating at 100° the properties of the material are restored. Hydrogen in the cathode does not diminish the resistance to impact of mild steel and its effect on repeated stress seems of itself unimportant. The fractures under repeated stresses, however, show that the penetration of hydrogen has an important bearing upon the nature and form of fracture of a plastic material, which under repeated torsional stress, fails in a manner similar to quenched and tempered materials. Consequently the presence of the hydrogen at the crystal boundaries does not increase the concentration of stress in the repeated stress experiments, nor in the impact tests, but affects the continuity of slip and causes a crack to occur as in the quenched and tempered materials, and suggests that in all such materials the failure is at the boundaries, while the failure of plastic materials occurs by cracking within the crystal. Observations on the subject were made by J. H. Andrew, H. C. H. Carpenter and C. F. Elam, J. Coulson, C. A. Edwards and co-workers, C. F. Elam, T. S. Fuller, L. Jacque, S. C. Langdon and M. A. Grossman, P. Longmuir, F. Osmond and G. Cartaud, S. W. Parr, W. Rosenhain and D. Ewen, O. P. Watts and C. T. Fleckenstein, M. Majima, V. S. Meskin and Y. M. Margolin, M. Okochi, R. Hugues, L. Guillet and J. Cournot, B. Bogitch, and M. Guichard and co-workers.

According to W. C. Roberts-Austen, the heating curve of iron charged with occluded hydrogen shows breaks at 261° and 487°, and these breaks do not appear if the metal has been previously heated in vacuo. G. Borelius and F. Gunneson observed a number of irregularities in the thermoelectric force at approximately −5°, 150°, 220°, 300°, 460°, 530°, and 600°. There is also a marked increase in the absorption of hydrogen at the Curie point, 760°. It is thought that the phenomena may be due either to unknown modifications of iron, or to the existence of solid hydrides. G. Sirovich stated that there is an abrupt change in the rate of expansion of iron, and low-carbon steels at 370°; and he inferred that this represents a transformation point in addition to the usually-recognized critical points. H. S. Rawdon and co-workers also observed this irregularity, but said that it is not due to a polymorphic transformation, because the break in the curve is too irregular with different samples. The phenomenon is attributed to "some condition resulting from the presence of iron oxide in the iron"; and it may be due to the recrystallization of very fine grained metal resulting from the reduction of iron oxide by hydrogen at this low temp. N. B. Pilling noted the effect of hydrogen on the hardness of iron; R. S. Williams and V. O. Homerberg, on the ductility; and E. A. Harding and D. P. Smith, on the changes in length and the electrical resistance. R. Nübel discussed the thermal energy of hydrogenized iron. E. Rupp studied the optical properties of iron with a film of adsorbed hydrogen. A. Sieverts observed that the dissolution of hydrogen between 20° and 920° had no perceptible influence on the electrical resistance; but H. Kleine found that the resistance increased when the metal contained occluded gas. H. Gries and H. Esser examined the effect of occluded hydrogen on the magnetic properties of the metal.

G. Charpy and S. Bonnerot found that when iron at 600° to 900° is exposed for a long time to a current of hydrogen, no gas is absorbed but the physical properties of the metal are modified, it being softened by prolonged diffusion of the gas, which exercises a reducing action, removing such constituents as sulphur, phosphorus, and carbon in the form of their hydrides, the desulphurization being particularly rapid. The iron thus undergoes a process of purification by the passage of the hydrogen, and this may possibly explain certain of the anomalies in the metallurgy of iron and steel, when hydrogen is formed by the contact of water vapour with the hot metal. Observations on this subject were made by A. Johansson and R. von Seth, L. Jordan and F. E. Swindells, G. W. Austin, A. Bérard, F. Schmitz, F. Wüst and C. Geiger, F. Wüst and E. Sudhoff, G. Charpy, J. V. Emmons, H. S. Rawdon and co-workers, H. le Chatelier, J. H. Whiteley, E. D. Campbell and co-workers, O. E. Harder and co-workers, F. C. Langenberg and H. M. Boylston, V. Lombard, R. Schenck, and L. Forquignon. P. D. Merica noted the injurious effect of absorbed gases on the magnetic properties of iron (*q.v.*).

R. Schenck, and A. Johansson and R. von Seth represented the *decarburization of iron* by hydrogen by the reaction $Fe_3C+2H_2 \rightleftharpoons 3Fe+CH_4$ at 750°. The assumption is made that the carburization is effected by methane, but possibly other hydrocarbons are also concerned in the reactions. Fig. 328 represents qualitatively the equilibrium curves between carburized iron and hydrogen, when the dotted line represents the equilibrium conditions for the reaction $C+2H_2 \rightleftharpoons CH_4$. The ferrite-austenite line ends at a fixed point corresponding with 0 per cent. methane, and at the temp. of the A_3-arrest for iron alone. The intersection points of the curves are dependent only on the carbon press. of the different solid phases discussed in connection with the decarburization of cast iron. Small methane percentages at 900° to 1000° prevent the decarburization of hydrogen. R. Schenck found the intersection point between the carbon, hydrogen, and methane equilibrium curve and the ferrite-austenite line to be 720°. The relation between the percentage of carbon and the time of heating in the decarburization of steel by hydrogen at 1050° is shown in Fig. 329. G. W. Austin found that decarburization by dry hydrogen is much slower than by moist hydrogen. The subject was studied by J. Ciochina—*vide supra*, O. Schmidt, A. Korczynsky, R. Hocart, A. E. Mitchell and A. L. Marshall, and F. H. Constable. A. S. Ginsberg and A. P. Ivanoff, and O. Schmidt studied iron as a catalyst in the hydrogenation of various compounds; H. Remy and H. Gönningen, the $2H_2+O_2$ reaction; A. Quartaroli, the reducing action of the iron-copper couple; K. F. Bonhoeffer showed a correspondence between the adsorption of hydrogen and catalytic activity; and G. B. Kistiakowsky, the ionization potential of hydrogen adsorbed on iron. According to E. D. Campbell, the best temp. for the elimination of impurities by exposure to hydrogen is 950° to 1000°; a gas containing a small proportion of water-vapour is most efficient. The decarburization occupies on average four or five days. For example:

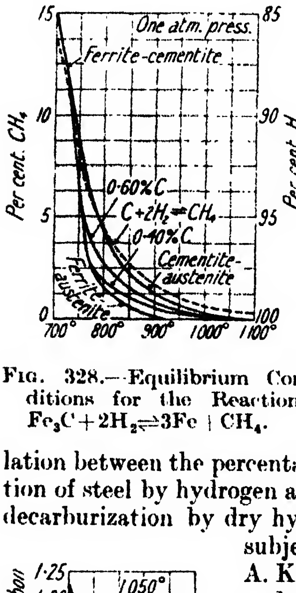

FIG. 328.—Equilibrium Conditions for the Reaction: $Fe_3C+2H_2 \rightleftharpoons 3Fe+CH_4$.

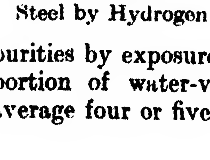

FIG. 329.—The Decarburization of Steel by Hydrogen.

Treatment	Per cent. carbon		Per cent. sulphur	
	Before	After	Before	After
4 days	0·094	0·076	0·025	0·017
5 days	0·354	0·017	0·026	0·014
8 days	1·184	0·005	0·018	0·006
12 days	1·150	0·133	0·023	0·026

T. Thomson[3] suggested that an **iron hydride,** or rather a *ferruretted hydrogen gas*, mixed with much hydrogen, is formed when iron is dissolved in dil. sulphuric acid. It was supposed that the ferruretted hydrogen was not removed from the gas by passing through four wash-bottles containing potash-lye, and a tube filled with asbestos. A. Dupasquier gave a long description of the supposed gas, but C. R. Fresenius and J. Schlossberger showed that the alleged properties of ferruretted hydrogen corresponded with those of hydrogen contaminated with hydrogen phosphide and sulphide, when no iron is present. Hence, the existence of ferruretted hydrogen is not established. H. Reinsch believed in the existence of such a gas; but E. Erlenmeyer, and C. A. Cameron could find no evidence to support the hypothesis. J. A. Wanklyn and L. Carius suggested that when ferrous iodide is treated with zinc ethyl, a **ferrous dihydride,** FeH_2, is formed: $FeI_2+Zn(C_2H_5)_2=ZnI_2+FeH_2+2C_2H_4$, but the evidence is not at all satisfactory. The alleged hydride may be iron with occluded hydrogen; A. Villachon and G. Chaudron were of the opinion that a hydride is possibly formed in liquid iron; W. Frankenburger and K. Mayrhofer, when iron vapour is condensed in an atm. of hydrogen; and G. Borelius and F. Gunneson, when hydrogen is occluded by iron. T. Weichselfelder and B. Thiede observed that when ferrous chloride is treated with an ethereal soln. of magnesium phenyl bromide, a black powder of iron dihydride, FeH_2, is formed; and if ferric chloride be employed, **iron hexahydride,** FeH_6, appears as a black, viscid oil. E. Piwowarsky observed no evidence of the existence of hydrides in hydrogenized iron; L. Guillet and co-workers thought that one is formed stable above 250°.

The effect of **air** and **oxygen** on iron is discussed elsewhere in connection with the corrosion and tarnishing of iron; with the reduction and formation of the various oxides of iron: and with the production of iron. In 1782, S. Rinman[4] reported that dry air does not corrode iron, but moist air does; and a few years later, W. Higgins stated that iron does not rust in dry oxygen, and explained the phenomenon by assuming that

> It is the oxygen of the water which unites to the iron, while the oxygen of the gas is condensed by the liberated hydrogen in the nascent state, so as to reproduce water. This is effected by a double influence which is so obvious as not to require an explanation.

P. A. von Bonsdorff made a similar observation—*vide infra*; S. U. Evans also noted that air dried by sulphuric acid did not corrode iron in a month under conditions where moist air corroded the metal; and E. Schröder and G. Tammann, and W. R. Dunstan and co-workers observed that iron showed no signs of change when kept for 3 months in dry oxygen at 34°; R. Ruer and J. Kuschmann observed that finely-divided iron, reduced by hydrogen from the oxide at 750°, does not absorb air, but there is a slight oxidation on exposure to dry air, for 100 grms. of iron increased 30 mgrms. in weight. Iron filings also oxidized slightly in dry air. G. Tammann estimated that at 15°, dry oxygen would produce a visible film on iron in 25×10^{17} years.

W. Hardy and M. Nottage found that a polished steel cylinder placed on a steel plate remained at a distance of 4μ above the plate in clean dry air. Pressure applied to the top cylinder made the two surfaces approach more closely, but on removing the pressure, the air film returned to 4μ. This thickness remained constant for glass to glass and steel to steel. The subject was studied by S. H. Bastow and F. P. Bowden, and H. E. Watson and A. S. Menon.

P. Gladky found from 0·021 to 0·974 per cent. of oxygen equivalent to 0·23 to 0·33 per cent. of ferrous oxide in various samples of iron and steel—*vide infra*.

ferrosic oxide, the corrosion of iron, and ferrous oxide. J. A. Pickard, A. Ledebur, A. H. Allen, A. K. Silin, J. E. Stead, L. Romanoff, M. A. Grossmann, J. Cournot and L. Halm, and S. Kern discussed the oxygen-content of iron and steel; and H. W. Gillet, the action of oxygen on the iron-carbon system. The oxygen-content of iron and steel is indicated in Table XLVII; the binary system iron-oxygen has been discussed by F. Schönert, F. Czopiwsky and S. Orzechowsky, and others in connection with ferrous oxide; and the ternary system Fe–O–H, and Fe–O–C, by H. Nishimara—*vide supra*, the blast-furnace reaction. W. R. Shimer and F. O. Kichline found a maximum of 0·074 per cent. oxygen in Bessemer steel when cooled quickly after a long after-blow. Oxygen leaves a bath of molten steel in a few minutes, so that few steels have much more than 0·03 per cent. oxygen. W. Austin found that the product obtained by melting a mixture of iron and iron oxide had 0·288 per cent. oxygen. F. Schmitz found 0·113 per cent. oxygen in Thomas-Gilchrist steel. E. A. Harding and D. P. Smith noted the occlusion of oxygen by iron electrodes.

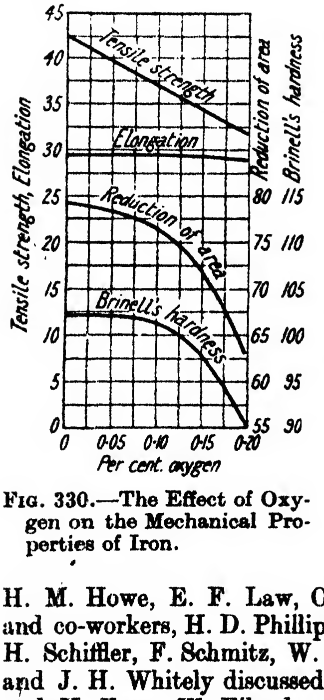

FIG. 330.—The Effect of Oxygen on the Mechanical Properties of Iron.

F. Durau and C. H. Teckentrup showed that the absorption of oxygen by electrolytic iron is a chemical process. A. Ledebur said that 0·1 per cent. of oxygen makes iron no longer forgeable, for it is then red-short; and the subject was discussed by F. Hatlanek. E. F. Law said that iron and manganese oxides can be detected as black spots under a magnification of 1000. F. R. Eichoff considers it to be doubtful if oxygen makes iron red-short, because of the high proportion in welded iron. It is assumed that the affinity of iron for oxygen, and of carbon for iron, increases with a rise of temp., while the affinity of carbon for oxygen increases relatively little under these conditions. Hence, carbon monoxide is formed at a certain temp. during the cooling of the iron, while above this temp. the oxygen and carbon are dissolved in the iron without acting on one another. F. Roll found that the presence of oxygen partly favours and partly hinders the decomposition of the carbide in cast iron. J. R. Cain, G. F. Comstock, H. Diergarten, J. R. Eckman and co-workers, W. Eilender and W. Oertel, E. W. Fell, W. Galbraith, J. D. Gat, P. Gladky, M. A. Grossmann, E. Gumlich and P. Goerens, F. Hatlanek, C. H. Herty and J. M. Gaines, H. D. Hibbard, H. Hochstein, A. Holtz, H. M. Howe, E. F. Law, O. Meyer, R. Moldenke, A. Niedenthal, P. Oberhoffer and co-workers, H. D. Phillips, F. Rapatz, J. Reschka and co-workers, H. Schenck, H. Schiffler, F. Schmitz, W. L. Stork, L. Treinen, A. E. White and J. S. Vanick, and J. H. Whitely discussed the presence of unreduced oxides in iron; H. Gries and H. Esser, W. Eilender and R. Wasmuth, and J. A. Lanigan, the effect of oxygen on the hardness—with 0·030 per cent. of oxygen, Brinell's hardness was 70·2, and with 0·141 per cent., 79·6; F. C. Thompson and R. Willows, the production of a banded structure in hot-worked, hypo-eutectoid steel; and E. W. Fell, J. R. Cain, and A. Niedenthal, the red-shortness produced by oxygen in iron. A. Wimmer's observations on the influence of oxygen on the mechanical properties of iron are summarized in Fig. 330, where the tensile strength is expressed in kilograms per sq. mm.; and the elongation and reduction of area in percentages. W. McA. Johnson made observations on the subject. H. Gries and H. Esser examined the effect of oxygen on the magnetic properties of iron. F. W. Lürmann, J. V. McCrae and R. L. Dowdell, F. Giolitti, F. C. Moorwood, C. H. Herty and co-workers, A. McCance, C. H. Desch, G. F. Comstock, P. Bardenheuer and K. L. Zeyen, L. Persoz, H. M. Boylston, and J. R. Cain investigated various deoxidizing agents for steel—*vide* aluminium, manganese, silicon, titanium, etc.; and E. R. Thews arranged possible deoxidizing agents in the order of their affinity for oxygen: Mg, Al, Si, Mn, Zn, P, Sn, and Cd; and in the order of their capacity for oxygen: Si, Al, P, Mg, Mn, Zn, Cd, and Sn. C. H. Herty and co-workers studied the deoxidation of steel by aluminium, and found that it proceeds more quickly than is the case with silicon—*vide* aluminium-iron alloys. A. K. Silin studied ferromanganese as a deoxidizer; P. Blum, and C. H. Herty and co-workers, silicon; E. Diepschlag and H. Schürmann, phosphorus; W. Zieler, zirconium; P. Blum, and E. Lemaire, calcium; E. Lemaire, magnesium; P. Blum, boron; J. R. Cain, manganese, silicon, titanium, and aluminium; C. H. Herty and G. R. Fitterer, manganosilicon; J. H. Whitely, hydrogen at 950°; and A. Glazunoff, and A. Hiorth, sodium. *Vide supra*, the growth of iron.

In the sixteenth century, Paracelsus said that "when iron is fused in the furnace, it sends forth limpid, clear sparks which rise to a height, and that as soon as these appear, unless the iron be at once removed from the fire, it will be burnt up like straw." G. C. Lichtenberg, and J. Ingenhousz found that when iron is heated to whiteness in air or oxygen, it burns with vivid sparking, forming ferrosic oxide. In air, the combustion soon ceases, but in oxygen, combustion continues if the piece of iron be thin, and the high temp. produced may volatilize some of the iron which is then oxidized to ferric oxide. According to L. F. Bley, and G. Magnus, finely-divided iron suspended from a magnet burns when placed in a flame, and when the flame is removed, the ferrosic oxide which remains is also ferromagnetic. The early experiments on the combustion of iron were discussed by E. von Lippmann, and E. Cohen. S. S. Sakowsky and E. W. Butzker showed that with oxygen under a high pressure, iron and steel burn readily and completely, and if once ignited propagate a flame with explosive velocity. According to R. Phillips, R. Adams, S. Stratingh, and F. d'Arcet, if a bar of iron be heated until it emits sparks—welding-point—it will burn even in the air if the blast of the bellows be strongly directed upon it, or if it be swung rapidly round—by tying a rod to a piece of cord at one end, and heating the other end white-hot; when the cord is swung rapidly round, a brilliant circle of sparks, resembling fireworks, is produced by the combustion of the metal. J. Percy mentions that the old nailmakers availed themselves of the combustibility of iron at a high temp. to keep their nails hot during the process of forging. "There is a little blowpipe connected by a tube with a small pair of bellows and a jet of air is thrown on the iron when it is becoming too cold, and immediately the temp. is much raised." When a piece of flint is struck by a piece of steel, fine particles of the metal are detached by the stone, and brought to such a temp. that they fire in air, and ignite tinder. Hence, as found by H. Davy, a flint and steel in vacuo gives but very feeble sparks. W. G. Hildorf and C. H. McCollain, C. M. Bigger, P. K. von Engelmeyer, G. M. Enos, A. K. West, M. Bermann, E. Pitois, and L. Demozay studied the nature of the sparks removed by the attrition of different kinds of steel against a grindstone, and proposed that the results be used as a test of the nature and quality of steel. According to A. Pourcel, the method was suggested in 1804 by J. C. de Manson. M. Fink and U. Hofmann observed the oxidation produced by rolling friction in dry air. H. P. Walmsley studied the nature of the smoke of aerosol obtained by burning iron between electrodes.

According to H. Moissan and C. Moureu, iron powder, prepared by the reduction of ferrous or ferric salts, is chemically more reactive than compact iron; and the powder obtained by reducing the oxide, carbonate, or oxalate in hydrogen at 440° is pyrophoric, for it becomes incandescent when exposed to moist air. If the pyrophoric iron be kept at 310° to 320° for about 48 hrs., A. Smits and co-workers observed that it is no longer pyrophoric, and the change is accompanied by an increase in vol. It is said that pyrophoric iron consists of a mixture of different kinds of iron molecules which are not in a state of equilibrium. C. G. Fink and C. L. Mantell discussed the pyrophoric qualities of commercial ferrum reductum, of freshly reduced iron. C. Johns said that in growing molten steel, the surface remains optically clean for a short time, and the period is longer the higher is the temp. The surface is protected from oxidation by a barrage of metal vapour. As the temp. falls, the vap. press. is reduced until finally the oxygen penetrates to the metal and oxidation begins.

The attack of iron by oxygen or air was studied by J. Keir, C. Becker, J. B. Trommsdorff, C. F. Bucholz, J. L. Gay Lussac, J. H. Hassenfratz, N. J. Conté, J. B. Guyton de Morveau, N. J. B. Guibourt, M. M. Hall, J. R. Bréant, K. Inamura, J. Zumstein, S. Clegg and J. Farey, L. J. Thénard, J. L. Proust, M. Darso, M. Delaville, J. Cuthbertson, E. Jordis and W. Rosenhaupt, K. Hoffmann, G. Tammann and co-workers, S. Tour, and N. B. Pilling and R. E. Bedworth—*vide infra*, the tarnishing, and scaling of iron. J. V. Emmons, H. Scott, E. H. Schulz and P. Niemeyer, and A. Johannson and R. von Seth, the surface decarburization of iron when it is heated in air or oxygen; and H. C. Greenwood, by heating it in a bath of lead dioxide.

C. Dufraisse and R. Horclois said that the wide distribution of iron in nature and in the respiratory pigments of the higher animals makes a study of its catalytic activity of importance. Iron is usually but not exclusively a positive catalyst for autoxidation. It can act both as an anti-oxygenic and as a pro-oxygenic catalyst. Ferrous oxide is anti-oxygenic towards furfural; ferric hydroxide, towards alkaline soln. of sodium sulphite; ferric chloride, for benzaldehyde, and for furfural; ferrous iodide, for benzaldehyde and acrolein; ferric acetylacetonate, for sodium sulphite in feebly acidic soln., and for furfural; oxyhæmoglobin carboxylhæmoglobin, and methæmoglobin, for furfural; acrolein, and sodium sulphite; α-chlorohæmin, for furfural; β-chlorohæmin, hæmatin, dimethylester of α-chlorohæmin, and β-bromohæmin, for furfural, acrolein, sodium sulphite and benzaldehyde.

W. Manchot found that iron reacts with oxygen at a temp. only slightly higher than that at which it reacts with **ozone.** Iron rendered passive by immersion in nitric acid, or by being used as anode in dil. sulphuric acid, reacts almost instantly in the cold with 3 per cent. ozone, whereas active iron shows no such sensitiveness towards ozone.

The rusting of iron in moist air at ordinary temp. has been discussed elsewhere. C. Girtanner, in 1788, communicated a paper: *Ueber die Auflösbarkeit des Eisens in reinem Wasser.* According to M. M. Hall, N. J. B. Guibourt, E. Ramann, S. Birnie, A. Job and R. Reich, and J. A. N. Friend, pyrophoric iron decomposes **water** at ordinary temp., and, according to S. Birnie, some hydrogen is evolved. W. van Rijn said that mercury accelerates the reaction with pyrophoric iron. J. A. Wanklyn and L. Carius found that iron does not decompose water at 50° but does so at 100°, giving off hydrogen; E. Ramann also found that iron decomposes boiling water; J. R. Baylis obtained a little hydrogen even at ordinary temp.; and L. T. Alexander and H. G. Byers found that hydrogen is developed from the action of water on iron at ordinary temp. when felspar is ground in a steel ball mill. S. Micewicz found that at 100°, the rate of evolution of hydrogen from water on contact with powdered iron is diminished in the presence of sodium and potassium chlorides, it is slightly increased by calcium chloride, and very much increased by magnesium chloride. E. Berl and co-workers found that the attack of iron by distilled water increases with the temp. and with the pressure; thus, with 10 grms. of powdered iron, during 16 hrs., and at 100 and 200 atm. press., the vols. of hydrogen developed were respectively 160 c.c. and 480 c.c.; and the percentages of iron in the product were 98·21 and 94·45, and of ferrous oxide, 0·87 and 5·51, respectively. L. Troost and P. Hautefeuille observed that aluminium, if present, accelerates the reaction. Boiling soln. of alkali hydroxides behaved similarly. H. V. Regnault observed that iron is decomposed by steam, and the action of steam on iron has been discussed in connection with the iron oxides, and the reactions in the blast-furnace—*vide infra,* ferrosic oxide. P. P. Fedotéeff and T. N. Petrenko represented the reaction with steam at 1000° to 1100°, $Fe \rightarrow FeO \rightarrow Fe_3O_4$, and with mixtures of steam and air, $Fe \rightarrow FeO \rightarrow Fe_3O_4 \rightarrow Fe_2O_3$. The action of steam on iron was also studied by J. A. N. Friend and co-workers, A. G. Christie, A. Fry, F. Körber and A. Pomp, F. G. Straub, E. Piwowarsky, G. Dessus and co-workers, W. H. Hatfield, J. K. Rummel, W. L. Denman and E. Bartow, and R. Kattwinkel. W. Kraus studied the kinetics of the reaction; and J. Chipman, the state of equilibrium in the oxidation of liquid iron by steam over the range from 1550° to 1770°. Ferrous oxide is said to be formed, and the free energy of the reaction $Fe+\frac{1}{2}O_2=FeO$ is $-31200-1{\cdot}0T$. K. Murata found that the partial press. of hydrogen corresponding with the reaction: $3Fe+8H_2O \rightleftharpoons Fe^{\cdot\cdot}+2Fe^{\cdot\cdot\cdot}+8OH'+4H_2$ is 566 atm.

The wearing away of metal plates by the action of steam was examined by J. Walter; A. A. Cary, and F. Westhoff studied the corrosion of wrought and cast iron by dry steam; W. Campbell and J. Glassford, the corrosion of cast iron by superheated steam; T. S. Fuller, the effect of steam on the endurance tests; and C. B. Marson and J. W. Cobb, and H. T. Angus and J. W. Cobb, the scaling of steel in atmospheres of steam. J. K. Rummel found that the corrosion of steel by superheated steam at press. up to 3450 lbs. per sq. in., is negligible up to about 430°; and in some cases up to 650°. The presence of oxygen in the steam favours the attack. The subject was studied by W. H. Hatfield, G. Dessus and co-workers, I. N. Hollis, A. A. Cary, A. S. Mann, E. F. Miller, R. G. C. Batson, J. A. N. Friend and co-workers, W. Campbell and J. Glassford, F. N. Bushnell, W. Krauss, P. Askenasy, R. G. Edwards, B. Houghton and D. C. Weeks, and A. B. Williams and C. W. Welsh. The action of water on iron has been studied by G. Schikorr—*vide infra*, the corrosion of iron. The decomposition of steam by iron powder at about 250° is a convenient and rapid method of preparing hydrogen of a high degree of purity. S. S. Bhatnagar and S. L. Bhatia studied the rate of evaporation of adsorbed water from iron. J. V. Emmons found that steel heated in steam was decarburized more than when heated in hydrogen, carbon dioxide, or in air. H. Remy discussed the catalytic activity of iron on detonating gas; I. Moscicki and J. Broder, the spheroidal state of water on iron; and A. Sellerio, the force necessary to remove brass frozen on to iron and other metals by an intermediate film of water.

L. J. Thénard, and G. T. Moody found that dil. soln. of **hydrogen dioxide** has no visible action on iron, though it is catalytically decomposed by the metal; the converse result, by W. R. Dunstan and co-workers, is attributed to the use of impure hydrogen dioxide. Cast iron is rapidly attacked by hydrogen dioxide, and it is assumed that the sulphur, and phosphorus which it contains as impurities are oxidized by the hydrogen dioxide to form acids. Hydrogen dioxide in alkaline soln., say, $0{\cdot}2N$-NaOH or NH_4OH, does not attack iron of a high degree of purity, although oxygen is set free from the dioxide. Under similar conditions, cast iron acquires a thin film of a bronze-coloured oxide. W. R. E. Hodgkinson and A. H. Coote, H. Tatu, N. Floresco, R. Kuhn and A. Wassermann, and H. Wieland and W. Franke studied the action of hydrogen dioxide on iron, and the last-named found that with conc. soln., 0·5 to $5{\cdot}0N$-H_2O_2, there is no perceptible action, but with dil. soln. the iron rusts. E. Pietsch and co-workers also observed that if the surface of the metal is homogeneous there is no action, but if, by incomplete polishing, etc., the surface is heterogeneous, rusting occurs. A. von Kiss and E. Lederer studied the catalytic decomposition of hydrogen dioxide in the presence of iron-ions. As indicated below, the rate of dissolution of iron in acids is hastened if hydrogen dioxide be present. W. L. Dudley observed that when iron is treated with fused **sodium dioxide,** red crystals of $Fe_2O_3.H_2O$ are formed; and T. Wallace and A. Fleck observed the attack with a fused mixture of sodium hydroxide and dioxide. W. Guertler and T. Liepus observed that iron is attacked in less than 8 days by chlorine water, sea-water, sea-water and air, rain-water and air, and a soln. of magnesium chloride; it is attacked in less than 8 hrs. by 10 and 50 per cent. soln. of sodium hydroxide; and it is stable for 48 hrs. in an alkaline soln. of hydrogen dioxide. Observations on the action of sodium dioxide on iron were made by W. G. Mixter, W. H. Hatfield, C. Zenghelis and St. Horsch, and E. Leidié and L. Quennessen. J. L. Gay Lussac, and L. J. Thénard found that when iron powder is heated with **potassium peroxide,** K_2O_4, potassium is formed; and St. Meunier found that when iron is fused with the peroxide, a ferrate is formed.

According to H. Moissan,[5] **fluorine** slowly attacks compact iron at ordinary temp.; but when the metal is warmed, it burns with sparks; and at a red-heat, the absorption of fluorine is rapid, and much heat is evolved. Powdered iron reacts with fluorine below redness with incandescence; and iron reduced by hydrogen combines with great energy in the cold. H. Moissan and J. Dewar observed that the reaction proceeds quietly at −185°; and C. A. Crommelin, likewise, at −253°. T. Andrews noted that dry **chlorine** does not attack iron, although the moist gas quickly corrodes the metal. A. Lange observed that liquid chlorine when dry does not attack compact iron at ordinary temp., and this enables liquid chlorine to be preserved in iron reservoirs. Analogous observations were made by A. Fürth, and W. A. Masel, whilst H. Gautier and G. Charpy noted that at ordinary temp. liquid chlorine attacks iron very slowly. Iron is readily corroded by moist chlorine at ordinary temp.; P. A. von Bonsdorff noticed that air containing traces of chlorine quickly corrodes the metal. G. Tammann and W. Köster studied the rate of attack of iron by chlorine. The corrosion of iron by chlorinated water was examined by G. L. Clark and R. B. Iseley, M. L. Hamlin and F. M. Turner, C. G. Gillespie, and N. V. Lothian and A. R. Ward. When iron is heated in the dry gas it volatilizes and condenses in what H. Davy called " beautiful minute crystals of extraordinary splendour "; which J. Davy showed were ferric chloride. According to O. Ohmann, if a small ball of steel-wool be sprinkled with antimony, or, according to R. Böttger, with Dutch metal, and then plunged into chlorine, it is ignited at ordinary temp. Observations were also made by M. Rosenfeld. G. Tammann and co-workers examined the rate of attack of iron by the halogens. W. Guertler and T. Liepus found that iron is attacked in less than eight days by chlorine water. H. E. Fierz-David discussed iron and iodine as chlorine carriers in the chlorination of benzene derivatives. T. Andrews observed that dry **bromine,** like dry chlorine, does not attack iron. J. B. Berthemot found that, as in the case of chlorine, bromine does not act on iron in the cold, but when the vapour of bromine is passed over heated iron wire or turnings, J. B. Berthemot, A. Scheufelen, and J. von Liebig observed that combination, accompanied by a vivid glow, occurs. The reaction was studied by H. Gautier and G. Charpy, P. Höfer, L. Mathesius, L. Schneider, F. Wüst and N. Kirpach, and A. Fürth, G. Tammann and W. Köster studied the rate of attack. J. Nicklès observed that iron is attacked by an ethereal soln. of bromine; J. B. Berthemot also observed that iron dissolves in bromine-water; and P. Berthier found that a mass of graphite, iron carbides, etc., remains when cast iron or steel is digested with bromine-water. According to L. Carius and J. A. Wanklyn, S. de Luca, F. Fischer, L. B. Parsons, I. L. Bell, G. Tammann, C. L. Jackson and I. H. Derby, when iron is heated with an excess of **iodine,** ferrous iodide, not ferric iodide, is formed. N. Floresco, B. L. Meredith and W. G. Christiansen, and G. Tammann and W. Köster studied the rate of attack of iron by iodine. G. C. Fleury found that iron and iodine, in the presence of water, interact to form ferrous iodide. The reaction is supposed to occur in stages first forming ferric iodide which decomposes into ferric oxide and hydrogen iodide, and the latter, acting on free iron, forms ferrous iodide; and J. J. Berzelius, and P. Berthier noted that a mass of graphite, iron carbides, etc., remains when cast iron or steel is digested with iodine-water. V. A. Kistyakovsky and I. V. Krotoff studied the corrosion of iron by iodine vapours. L. B. Parsons observed no reaction with iron and iodine in the presence of carbon tetrachloride, carbon disulphide, chloroform, quinoline, pyridine, heptane, ethyl benzene, and benzene in which ferrous iodide is insoluble, but a slow reaction occurs in alcohol, ether, and acetone in which the ferrous iodide is slightly soluble. H. E. Fierz-David observed that iron associated with iodine is a powerful catalyst in the chlorination of benzene derivatives. A. Schükareff, and R. G. van Name and co-workers studied the rate of dissolution of iron in an aq. soln. of iodine and potassium iodide. J. T. Dunn showed that glycerol retards the reaction. W. Engelhardt studied the action of an aq. soln. of iodine on the hydrosol of iron. L. B. Parsons found that whilst an alcoholic, ethereal, or acetone soln. of iodine reacts with iron, the metal is not perceptibly attacked by soln. of iodine in carbon tetrachloride chloroform, carbon disulphide, quinoline, or pyridine.

O. Ruff and H. Krug observed that **chlorine trifluoride** reacts with iron with incandescence. G. Gore observed that reduced iron develops no hydrogen in dry liquid **hydrogen fluoride** at −7° to −18°. According to C. Poulenc, hydrogen fluoride slowly attacks reduced iron at a red-heat, forming ferrous fluoride ; a soln. of the same salt was obtained by C. W. Scheele, J. J. Berzelius, and O. Ruff and E. Ascher by dissolving iron in a soln. of **hydrofluoric acid**—hydrogen is at the same time evolved. G. Gore found that dry, liquid **hydrogen chloride** does not attack iron. F. Durau and C. H. Teckentrup showed that the absorption of hydrogen chloride is a chemical process. According to F. Wöhler and J. von Liebig, and P. Junius, ferrous chloride is formed when hydrogen chloride is passed over red-hot iron filings. R. E. Wilson and W. H. Balke, K. A. Hofmann and F. Hartmann, and C. Matignon examined the action of hydrogen chloride and oxygen on the metals. P. A. von Bonsdorff noticed that air containing traces of hydrogen chloride quickly corrodes iron. C. H. Desch, and A. de Waele discussed the action of hydrogen chloride in flue gases derived from the combination of coal containing chlorides. U. R. Evans observed that in air containing traces of carbon dioxide and hydrogen sulphide, the metal remained " dry " in the ordinary sense of the term ; in hydrogen chloride, the specimens lost their lustre, and acquired a whitish-grey, frosted appearance, and they remained " dry," but on exposure to damp air, water was absorbed and the surface became covered with a damp, brown rust. Hence, so long as hydrogen chloride is in excess, ferrous chloride is formed, but on exposure to air, this is oxidized to hydrated ferric oxide, and ferric chloride which attracts moisture making the surface appear " damp."

When iron is dissolved in **hydrochloric acid,** a soln. of ferrous chloride is formed and hydrogen is evolved : $Fe+2HCl=FeCl_2+H_2$—a reaction studied by F. Isambert, etc. Measurements of the speed of the reaction were made by C. M. Guldberg and P. Waage in 1867. H. Kreusler observed that iron reduced from the oxalate and then melted in vacuo is not perceptibly attacked by boiling hydrochloric acid ; but B. Lambert and J. C. Thomson found that the hydrogen is liberated briskly even when electrolytic iron of a high degree of purity is employed ; T. Ericson-Auren and W. Palmaer, and M. Centnerszwer and co-workers stated that pure metals do not dissolve in acids, and H. Moissan found that finely-divided pure iron dissolves in acids without residue. A. Thiel and J. Eckell showed that with non-homogeneous metal, the parts where the homogeneity is interrupted are the centres of attack. W. Palmaer found that electrolytic iron dissolves more slowly at 25° than does grey cast iron ; the respective velocities are 0·0145 and 1·5 ; P. Nicolardot, that a soln. of hydrogen chloride in absolute alcohol dissolves iron without the evolution of hydrogen. A. de Hemptinne observed that the heat of dissolution is modified a little in the presence of a magnetic field. G. Tammann and K. Bochoff found that when dil. sulphuric acid or hydrochloric acid acts on iron, in a closed vessel, the reaction comes to an end before all the metal is dissolved. The potential of the metal becomes electronegative owing to the dissolution of hydrogen by the metal ; the hydrogen also becomes more electronegative. The embrittling of iron by the absorption of some of the hydrogen during the action was indicated above. The action of **hydrobromic acid** was studied by A. J. Balard, and it resembles that of hydrochloric acid ; and likewise also with **hydriodic acid.** W. Palmaer found that there is a well-defined period of induction which, at 25°, varies with the conc. of the acid, thus :

	N-	0·5N-	0·4N-	0·2N-	0·1N-HCl
Period of induction . .	100	150	230	260	330 minutes

F. J. R. Carulla, and E. Prost showed that hydrochloric acid is particularly active in its attack on cast iron. J. M. Weeren made similar observations with respect to the action of acids on iron as were made with respect to zinc. T. Turner observed that cast irons containing large flakes of graphite are more susceptible to attack by acids than is the case with close-grained, white cast iron. Hence, white cast iron is better for use in acid-resisting plant. Cast irons low in phosphorus, and close-grained, withstand acids very well. It is assumed that ferrite is more readily attacked by acids than are the carbides, so that the resistance of white cast irons is attributed to the carbides. Grey cast irons are more porous, and O. Kröhnke observed that when white cast iron is immersed in acids, the ferrite is dissolved, whilst the graphite, cementite, and phosphide remain *in statu* without disturbing the original, outward shape of the mass. The carbides are more readily attacked by alkalies than is ferrite. The subject was studied by M. Ballay, and W. Palmaer. H. Endo observed that 5 hrs'. exposure of iron, at 25°, to the action of hydrochloric acid of different conc. resulted in the following losses—Fig. 331—expressed in grams per sq. cm. :

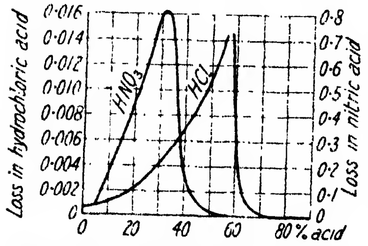

FIG. 331.—The Action of Hydrochloric and Nitric Acids on Iron.

HCl.	5	20	40	50	55	65	75	90 per cent.
Loss	0·000950	0·002313	0·007156	0·010348	0·014150	0·000825	0·000377	*nil*

Y. Utida and M. Saito, W. Guertler and B. Blumenthal, Y. Yamamoto, H. Edwards, and H. Endo and K. Nakawaga also studied this subject. W. H. Hatfield measured the solubilities of different forms of iron, and of iron alloys in conc. hydrochloric acid of sp. gr. 1·18. Cylinders of the metal approximately 0·5 in. diam., and weighing 50 grms., were immersed in about 85 c.c. of acid, at 15°. The losses stated in grms. per sq. cm. in 24 hrs., were :

		N-HCl	5 per cent.	25 per cent.	50 per cent.	Conc. HCl
Electrolytic iron . .		0·0085	—	- -	—	0·0860
Armco iron . . .		0·0116	- -	—	- -	0·1385
English wrought iron .		0·1416	...	—	—	0·2217
Steel, 0·29 per cent. C	15°		0·0490	0·1367	0·1842	—
	40°		0·0866	0·4088	0·6107	...
	60°		0·0879	0·4042	0·8341	-
	80°		0·0928	0·4112	0·7356	—

G. Tammann and F. Neubert's results with steel containing different proportions of carbon are summarized in Fig. 332. 3·6N-HCl was employed. The results are taken to support the theory of local elements.

W. Palmaer studied the action of hydrochloric acid on grey pig-iron, and obtained the results indicated in Fig. 333, at 25°. The velocities are expressed in terms of the changes in the e.m.f. of the metal. There is a well-marked period of induction; and it was found that the presence of potassium, ammonium, or magnesium chloride had very little influence on the results. With zinc, the addition of zinc salts depresses the speed of the reaction in a marked way, but with grey pig-iron, the effect of ferrous salts is insignificant. W. Bauhuis found that both polished and rough electrolytic iron are active in hydrochloric acid, and that the metal dissolves at characteristic rates in acids of different concentrations, and there is a well-defined period of induction. The addition of halides retard the rate of dissolution, and this the more, the higher the at. wt. of the halogen; oxidizing agents accelerate the speed of dissolution in the acid. H. O. Forrest and co-workers studied the initial rate of corrosion. H. Endo observed that the presence of oxygen dissolved in 0·05 per cent. hydrochloric acid raises the rate of dissolution of iron over seventy times what it is in the absence of oxygen, and with 5·0 per cent. acid, over fifteen times. The subject is further discussed in connection with the corrosion of iron. J. A. N. Friend reported that specimens of cast iron and mild steel, measuring 4·5×0·8×0·65 cm., and weighing about 22 grms., were immersed in 500 c.c. of hydrochloric acid for 8 hrs. at 17°, under comparable conditions, and that the losses were:

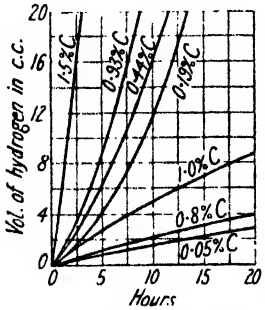

FIG. 332.—The Effect of Carbon on the Solubility of Iron in Hydrochloric Acid.

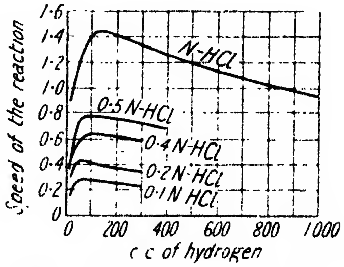

FIG. 333.—The Action of Hydrochloric Acid on Grey Pig-Iron.

HCl	0	N-	$2N$-	$4N$-	$6N$-	$7N$-	$8N$-	$9N$-	$10N$-
Cast iron	0·009	10·67	14·61	19·45	19·36	17·22	15·78	14·29	9·03
Mild steel	0·0053	0·612	0·786	0·968	1·957	3·31	5·38	9·94	13·27

As in the case of sulphuric acid (*q.v.*), the rate of dissolution of cast iron rises to a maximum and increasing concentrations of acid, and then falls. With mild steel, the rate of dissolution rises steadily as the concentration of the acid increases. F. Schmitz found that with pieces of steel containing 0·06, 0·42, and 0·92 per cent. of carbon and 20×20×10 mm. with a 4 mm. hole, lost respectively, 1·130, 1·140, and 0·511 per cent. in 180 hrs. in dil. hydrochloric acid (1 : 10), and in conc. acid, respectively, 23·070, 19·750, and 14·340 per cent.

J. T. Conroy measured the effect of varying the *concentration* of hydrochloric acid, and found that with soln. containing [HCl] grms. per litre, the rates of evolution of hydrogen in c.c. per hour were:

[HCl]	25	50	150	200	250	300	350 grms. per litre
H_2	5	8·5	15	30	85	250	470 c.c. per hour

As the conc. of the acid increases in arithmetical progression, the rate of action over a considerable range increases in a geometrical progression, so that the rate of dissolution is doubled for each increase of 30 grms. of HCl per litre in the acidity of the soln. Observations on the action of acids on iron were made by C. F. Burgess and S. G. Engle, K. Daeves and co-workers, V. Duffek, M. Faraday, J. A. N. Friend, R. Gans and co-workers, A. Geissel, L. F. Girardet and T. R. Kou, H. G. Haase, W. H. Hatfield, E. Heyn and O. Bauer, W. H. Johnson, G. B. Jones, J. Keir, P. Kötzschke and E. Piwowarsky, J. Priestley, F. W. Richardson, W. D. Richardson, J. Sauvageot and L. Lauprète, J. W. Shipley and co-workers, J. B. Trommsdorff, G. Walpert, H. W. Webb, W. G. Whitman and R. P. Russell, and R. E. Wilson. R. Girard found that with soln. of sulphuric, hydrochloric, carbonic, and carbolic acids with a concentration less than 0·1N, polished steel and cast-iron plates are similarly attacked. W. G. Whitman and co-workers observed that with carbonic and hydrochloric acids, the results were somewhat similar, as illustrated by Fig. 334, for with a H'-ion conc. less than 0·000001, or $p_H=6$, the curves of attack coincide. G. Tammann noted that cold-work increased the speed of dissolution of iron in dil. acids. L. McCulloch found that if a rubber band be wrapped tightly round a piece of soft iron, and the whole left in dil. hydrochloric acid for a few weeks, the pitting is greatest beneath the rubber, showing that the acid attacks the metal in the capillary spaces between the metal and rubber more vigorously than it does on the exposed surfaces—*vide infra*, the corrosion of iron. U. R. Evans and J. Stockdale showed that if a small cathodic current be applied to iron whilst the metal is immersed in a pickling acid, the attack is reduced.

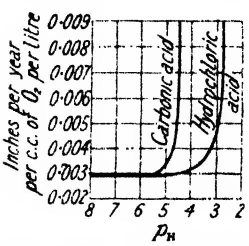

FIG. 334.—The Attack of Iron by Acids.

The effect of *temperature* is such that the rate of dissolution is nearly doubled for each 10° rise of temp. with acids having between 25 and 216 grms. HCl per litre. A. Sieverts and P. Lueg found that the dissolution of iron in hydrochloric acid at 78° is approximately proportional to the cube of the conc. of the acid. The temp. coeff. of the rate of dissolution is 2·0 to 2·3 per 10° between 50° and 78°. W. S. Calcott and J. C. Whetzel, and J. T. Conroy found that the logarithm of the rate of dissolution of iron in acids is a linear function of the temp. Observations were also made by J. R. Baylis. W. Palmaer found that there is a maximum in the effect of temp. of the speed of dissolution of grey cast iron in hydrochloric acid of various concentrations. There is no complication by the formation of a passive film. The high temp. coeff. of the reaction is due to the change in the viscosity of the soln. which permits the rapid removal of ferrous chloride soln. from the surface of the metal. The temp. coeff. increases with increasing conc. of acid; and the addition of ferrous chloride scarcely affects the velocity of the reaction. According to A. Thiel and W. Ernst, the difference observed between the quantity of gas evolved during the spontaneous dissolution of a metal in acids, and the quantity evolved when the metal is in combination with another metal serving as cathode, depends entirely upon the resistance of the liquid medium.

According to O. P. Watts and N. D. Whipple, a reduction of *pressure* favours the dissolution of iron and zinc in acids, and E. W. Greene and O. P. Watts found that a reduction of press. lowered the rate of corrosion in amalgamated zinc by removing depolarizing oxygen, and with unamalgamated zinc in the absence of oxygen, or amalgamated zinc, a reduction of press. accelerated the action by facilitating the escape of hydrogen gas. W. Rohn found that in 10 per cent., cold hydrochloric acid, purified, unannealed iron lost 0·12 grm. per sq. dm. in 1 hr. and 0·5 grm. in 24 hrs.; and 33·8 grms. per sq. dm. in 1 hr. in the hot acid. The action was less vigorous with annealed iron. Observations were made by W. Guertler and T. Liepus, and B. Kindt. C. Barus showed that the rate of dissolution of steel wire hardened by drawing is greater than is the case with soft metal. M. A. Rozenberg and V. A. Yuza, and L. V. Pisarzhevsky found that a *magnetic field* retards the action of the acid on iron.

O. P. Watts and N. D. Whipple found that the addition of hydrogen dioxide quickens the attack of hydrochloric acid. J. T. Conroy observed that the presence of arsenic in the acid retards its activity, and if the quantity is large enough to cover all the iron with a film of arsenic, the reaction, at ordinary temp., may be stopped. According to O. P. Watts and co-workers, the protective effect of arsenic is due to polarization by hydrogen, and this is in accord with the observation that the corrosion of the protected iron is stimulated by oxidizing agents—*e.g.* hydrogen dioxide observed by E. Salkowsky, A. Quartaroli, and O. P. Watts and N. D. Whipple; and that the arsenic does not protect the iron from corrosive agents—*e.g.* ferrous salt soln.—which do not evolve hydrogen by their action. A. S. Dwight mentions a case of acid corrosion by water containing sulphuric acid derived from the oxidation of smelter fumes, which was stopped by the addition of arsenic to the water. E. Heyn and O. Bauer, and C. F. Burgess and S. G. Engle showed that although arsenic in the acid retards the attack by sulphuric and hydrochloric acids, arsenic in the iron favours the attack. According to H. H. Gray and M. B. Thompson, the nitrogenization of iron increases its resistance to attack by hydrochloric acid, and this the more with low-carbon than with high-carbon steels. G. Batta, and R. C. Griffin observed that the rate of attack of hydrochloric acid on wrought iron, cast iron, and steel is greatly retarded if 1 per cent. of formaldehyde be present. H. J. Prins found that the presence of a reducible substance like nitrobenzene or benzaldehyde accelerates the rate of dissolution of iron in acids; and M. B. Rane and M. Prasad found that alkaloids—narcotine, nicotine, and brucine—retard the action of hydrochloric acid. A. Sieverts and co-workers found that in the action of sulphuric and hydrochloric acids on iron, ferrous sulphate, methyl sulphate, ammonium chloride, tetramethylammonium chloride, choline hydrochloride, and taurine have no inhibiting effect. Potassium cyanide, caffeine, theobromine, coniine, pyramidone, pyridine, atropine, quinoline, *iso*quinoline, and codeine had a slight inhibiting effect. Nicotine, veratrine, cocaine, and cinchonine were more effective, whilst α- and β-naphthaquinolines, strychnine, brucine, narcotine, and quinine were very effective. The most effective inhibitant was an "extract" consisting of the ether-soluble basic constituents of crude anthracene. It was found that the amount of inhibition was much the same in both acids, but with theobromine, nicotine, cinchonine, narcotine, and quinine, the inhibiting effect was more marked in hydrochloric acid. The authors conclude that all compounds containing pyridine nitrogen are more or less effective inhibitants. For slight amounts of poisoning, an increase of temp. reduces the inhibition: for larger amounts, it has no effect. O. Vogel said that nitrogen ring compounds generally retarded the reaction. A. Sieverts and P. Lueg proposed the empirical formula: $(K_0-K_c)/K=ac^b$, where K_0 is the rate of soln. with no poisoning; K_c is the rate of soln. at poison conc. c, and a and b are constants depending on the nature of the poison. The formula breaks down if more than about 75 per cent. of the inhibiting agents is present—*vide infra*, sulphuric acid. G. Walpert attributed the inhibition to adsorption by the metal.

In agreement with A. Sieverts and P. Lueg, A. Krieger found that the rate of dissolution of iron in $6N$-HCl at 78° is proportional to the surface of the metal. If the metal has been annealed at a red-heat, the rate of dissolution is depressed. If l denotes the length of the wire; k_2, the velocity constant; and N, the normality of the acid:

HCl . . .	$3N$-	$4N$-	$5N$-	$5{\cdot}25N$-	$5{\cdot}50N$-	$5{\cdot}75N$-	$6N$-
$k_2\times 100$ . .	13·1	17·7	28·3	36·7	47·7	58·7	67·5
$k_2\times 100/\sqrt{l}$ . .	3·99	5·39	8·61	11·2	14·5	17·9	20·5
$k_2\times 100/N^5\sqrt{l}$.	1·18	0·46	2·68	2·74	2·60	2·58	2·47

The rate of dissolution of the iron in acid increases approximately with the fifth power, N^5, of the concentration. The retardation in the rate of dissolution by α-naphthaquinoline and α-chrysidine is in agreement with A. Sieverts and P. Lueg's formula. The retardation is dependent on the mol. wt. and on the constitution of the "poison." Amongst substances of the same mol. wt. but of different constitution, some—*e.g.* α-naphthaquinoline—are very poisonous; whilst other isomeric forms—*e.g.* acridine—are non-poisonous even with conc. of 2 millimols per litre. Increasing the size of the molecule with substances of like chemical constitution greatly reduces the toxicity—*e.g.* chrysidine is less poisonous than naphthaquinoline. Very small additions of α-naphthaquinoline and of α- and β-chrysidine accelerate the dissolution of iron in $6N$-HCl—*e.g.* with up to a millimol of chrysidine per litre; consequently, the concentration-velocity curves show a maximum for small concentrations. On increasing the "toxic dose," the curves show a decline and afterwards a remarkable rise for a short stretch. Thus, with α-chrysidine and 6N-HCl at 78·2°:

α-Chrysidine .	0	0·125	0·25	0·50	1·0	2·0 millimol per litre.
$100k_1$ . .	61·9	63·5	62·6	62·5	63·3	58·4

There is a very marked induction period with chrysidine. According to J. A. Aupperle, the presence of antimony chloride inhibits the action of hydrochloric acid on iron; and, according to C. F. Burgess, arsenic acts similarly; whilst W. D. Richardson observed no accelerating influence was produced in the action of hydrochloric acid, though O. P. Watts and H. C. Knapp observed that corrosion is stimulated by the presence of these salts. C. Moureau and C. Dufraisse showed that the tendency of various easily oxidized substances to combine with oxygen may be reduced or multiplied by the addition of a third substance in very small proportion. W. Palmaer, and J. G. A. Rhodin discussed the application of the facts to the corrosion of iron and steel.

H. H. Gray and M. B. Thompson found that the greater the carbon-content of steel, the less is its resistance towards hydrochloric acid—*vide infra*, nitrogen. The subject was studied by K. K. Jarvinen, F. Schmitz, and L. Aitchison. T. Turner observed that when cast iron is attacked by dil. acids, the iron is first dissolved, the carbides and phosphides being more resistant; with alkaline corrosion, however, the impurities are first dissolved, and iron is dissolved last. A. J. Hale and H. S. Foster found that at temp. between 17° and 20°, plates of cast iron and wrought iron having 1 sq. dm. of area exposed, lost respectively 3·0 and 0·17 grm. with a litre of 0·2N-HCl for 4 hrs.; respectively 18·2 and 19·0 grms. with half a litre of the same acid per day for 7 days; and respectively 2·9 and 3·3 grms. during 28 days' exposure in half a litre of acid. U. R. Evans observed that iron in contact with 1·3N-HCl slowly gave off hydrogen, but if a piece of nickel was in contact with the iron, the gas came off more quickly, but copper and tin did not have any appreciable effect. W. D. Richardson found that grey cast iron containing graphite is attacked by N-HCl much more quickly than open-hearth iron of a higher degree of purity, but the corrosive action of the acid on the latter is greatly increased if a trace of a platinum salt be added so as to produce metallic platinum in contact with the iron. This treatment had no accelerating influence on the corrosion of cast iron. Thus, with plates 15 sq. cm., open-hearth iron and cast iron lost respectively 0·12 and 8·7 grms. per hr. in N-HCl, and respectively 10·5 and 8·8 grms. per hr. in N-HCl along with a trace of platinum salt. C. F. Burgess and S. G. Engle found that the loss in grams per sq. inch per hour, at 22°, on a 17-hr. run, with N-HCl, was 0·2146 grm. with electrolytic iron; 0·0083 grm. with electrolytic iron heated to 1000° and slowly cooled; 0·0095 with soft sheet iron, low in carbon, used for transformer plates; 0·0026 grm. for tempered steel used in the manufacture of knife-blades; and 0·1058 grm. for ordinary cast iron. E. L. Nichols, and H. A. Rowland and L. Bell investigated the action of a magnetic field on the dissolution of iron in acids. G. Berndt, and S. S. Bhatnagar and co-workers found that the dissolution of iron in hydrochloric acid is reduced by a magnetic field, and F. K. Bell and W. A. Patrick found that copper in contact with iron decreases the speed of soln. in acids, but not so with platinum or silver.

The early observations on the peculiar nature of the gases evolved when cast iron, or steel is treated with hydrochloric acid or sulphuric acid, have been indicated in connection with iron carbide—**5**. 39, 20. The hydrogen which is evolved is accompanied by the vapour of a malodorous oil or oils, as by arseniuretted, phosphuretted, and sulphuretted hydrogen, and possibly also methane. F. A. Abel and W. A. Deering showed that the combined carbon of steel furnished hydrocarbon gases when dissolved in hydrochloric acid, and the reaction was studied by S. Cloëz, H. Moissan, F. Mylius and co-workers, H. Hahn, E. Heyn and co-workers, etc. R. Schenck and co-workers found that with

	Cast iron (2·5 per cent. C.)	Steel	
	Cementite, Pearlite	Hardened at 1150°. Cementite, Austenite, Martensite	Hardened at 780°. Cementite, Martensite
Methane	1·02	3·53	3·19
Ethane	0·10	0·50	0·45
Ethylene	0·27	0·50	0·47
Propylene	7·08	24·37	25·21
Butylene	4·00	10·25	9·08
Amylene	1·25	3·36	4·20
Hexene	1·15	4·37	5·21
Octene	0·80	3·02	3·36
Carbon	78·04	38·82	42·10
Loss	6·29	11·28	6·37

L. G. Knowlton said that the presence of depolarizers—potassium permanganate, nitric acid, chlorine, etc., prevent this reaction. F. Osmond and J. Werth found that in the anodic dissolution of annealed steel in dil. hydrochloric acid, a skeleton of graphite is formed. According to V. Tantin, the phosphorus in iron slowly forms phosphine during the action of the dil. acid; and, according to G. Craig, and H. Rocholl, part of the sulphur forms hydrogen sulphide. J. L. Proust passed the gases through alcohol, and separated the oil which was arrested by diluting the alcohol with water; A. Schrötter collected the oil by passing the gas through dil. sulphuric acid. The solid residue which remained undissolved consisted of a mixture of graphite, iron carbides, amorphous carbon, and also silicon, etc. This residue has been examined by A. E. Jordan and T. Turner, W. A. Tilden, B. Sandrock, C. J. B. Karsten, J. Hull, J. Percy, E. Prost, J. J. Berzelius, B. Kosmann, C. E. Schafhäutl, J. F. Daniell, and F. Kohn, and it appears to be related with the product which is obtained when cast iron has been exposed for many years to the action of sea-water—*vide infra.*

A. D. White found that aq. **hypochlorous acid** slowly attacks iron with the evolution of both hydrogen and chlorine; whilst a soln. of **bleaching powder** attacks iron with the evolution of oxygen; and G. N. Quam, H. P. Pearson, O. F. Hunziker and co-workers, and H. W. Young and A. W. Peake examined the corrosive action of soln. of bleaching powder. H. P. Pearson found that iron is energetically attacked by a soln. of **sodium hypochlorite.** W. S. Hendrixson observed that dil. and conc. soln. of **chloric acid** attack iron—the metal is dissolved without the evolution of hydrogen, and the chloric acid is reduced. W. S. Hendrixson found that **perchloric acid** is not reduced by iron. G. Lunge and A. Deggeler examined the corrosion of iron by aq. soln. of **potassium chlorate.** R. Böttger observed that finely-divided iron burns vigorously in heated potassium chlorate; and M. Hönig, that it likewise burns in heated **potassium perchlorate**—the violence of the reaction can be reduced by diluting the chlorate with sodium carbonate. The reaction was studied by E. Berger. According to A. Connell, iron dissolves in a boiling soln. of **iodic acid,** forming a ferrous iodate.

Iron has a strong affinity for **sulphur,** and the two elements readily combine with incandescence when heated to redness—*vide infra,* iron sulphides. The affinity of the two elements was studied by E. Schürmann,[6] O. Schumann, E. F. Anthon, R. Winderlich, K. Jellinek and J. Zakowsky, J. Zakowsky, E. V. Britzke and A. F. Kapustinsky, and W. Guertler. Manganese had the greatest affinity for sulphur, then followed Cu, Ni, Co, Pb, Ag, and Sb. Iron comes between copper and lead. C. Frick compared the heats of formation of the metal sulphides, and found that aluminium and magnesium come before iron. According to J. G. Gahn, J. L. Proust, J. J. Berzelius, and A. Evain, when sulphur is in contact with a red-hot bar of iron, the elements unite to form a fusible iron sulphide. R. Hare found that if sulphur be heated to redness in the gun-barrel of a muzzle-loader, closed at one end, the vapour of sulphur escapes at the nipple, and a piece of iron wire held in the vapour burns with a bright light to form the sulphide; according to G. C. Winkelblech, if a small piece of potassium or sodium be placed at the end of a piece of iron wire, ignited, and plunged into the vapour of sulphur, the metal burns, forming iron sulphide. N. Lemery observed that if a paste be made with water and a mixture of equal parts of iron filings and sulphur, the mixture becomes so hot that it can be scarcely held in the hand. If several pounds of the mixture be buried in the ground, the earth is raised and burst asunder—*Lemery's volcano*—as the iron is sulphurized. N. Lemery based a theory of volcanoes on this reaction. O. Ohmann observed that iron powder reduced at a low temp. ignited spontaneously in sulphur vapour. G. Tammann and K. Schaarwächter found that the attack of iron by sulphur begins at about 210°, and increases rapidly up to 500°. W. P. Jorissen and C. Groeneveld discussed the velocity of propagation of the reaction in mixtures of iron and sulphur; and W. P. Jorissen and B. L. Ongkiehong added that the upper limit of the reaction with mixtures of iron, aluminium, and sulphur is approximately 43 per cent. of iron and 57 per cent. of a mixture of 62·5 per cent. aluminium, and 39·5 per cent. of sulphur. The action of sulphur on metals was also examined by E. Priwoznik, A. Colson, and O. Bauer and H. Arndt. H. Schmidt, and A. E. Wood and co-workers studied the corrosion effects of sulphuric acid sulphur compounds—mercaptans, alkyl sulphides and sulphites, sulphonic acids, sulphoxides, sulphones, and thiophene —dissolved in naphtha.

The binary system: Fe–S, and the ternary system: Fe–S–C, have been studied by H. Hanemann and A. Schildkötter, G. Ritzau, R. Vogel and G. Ritzau, and others—*vide infra*, iron sulphides. There is a ternary eutectic in the system: Fe–FeS–Fe_3C at 975°. There are three kinds of crystals—binary solid soln. of iron with carbon, cementite, and iron sulphide. W. F. Holbrook and co-workers studied the diffusion of sulphur in molten iron.

According to C. J. B. Karsten, the action of sulphur on iron is very detrimental, so that proportions which can scarcely be determined by analysis make the metal red-short. The presence of 0·03375 per cent., for example, made the metal red-short, and prevented its being welded. C. J. B. Karsten also said that sulphur expels carbon from iron at a high temp., so that spiegeleisen, sat. with carbon, and melted with sulphur in a crucible, caused a separation of carbon as a sooty deposit on the under-surface of the resulting ferrous sulphide. Sulphur also turns grey cast iron white. This phenomenon interested J. Percy, who concluded that when the sulphur in cast iron exceeds 2·5 per cent., the co-existence of graphite is impossible, and the metal is necessarily white. W. J. Keep questioned if the evil effects attributed to sulphur are all deserved, but T. D. West, and J. Roberts did not agree. The former found that 0·2 per cent. of sulphur is enough to ruin any casting; and the latter stated that in some cases 0·214 per cent. greatly affected the strength. If manganese is absent, the sulphur helps to keep the carbon as carbide producing hard iron, while if a high proportion of manganese be present, manganese sulphide will be formed, and the hardening effect will be neutralized. F. Wüst, and W. J. Keep showed that the presence of other elements may affect the action of sulphur; thus, silicon may correct to some extent the deleterious action of sulphur. H. I. Coe showed that silicon neutralizes the action of the sulphur by forming a silicon sulphide. The subject was discussed by A. Hayes and H. E. Flanders, J. Mehrtens, H. S. Rawdon, and J. O. Arnold and G. R. Bolsover. F. Wüst and J. Miny observed that the formation of graphite is affected by sulphur according to the proportion of manganese present; with sufficient manganese, the effect of the sulphur is neutralized—thus, the presence of 0·30 per cent. of manganese will prevent the hardening effect of 0·20 per cent. of sulphur. M. Hamasumi noted that with a low proportion of manganese, Brinell's hardness steadily rose as the proportion of sulphur increased from 0·019 to 0·196 per cent. E. Piwowarsky found that with a low proportion of manganese, the sulphur should not exceed 0·08 to 0·10 per cent; and M. Hamasumi said that up to 0·1 per cent. did no harm.

The subject was studied by E. Adamson, S. G. Afanaseff, A. Allison, J. O. Arnold and G. B. Waterhouse, F. E. Bachman, A. A. Blair and P. W. Shimer, G. K. Burgess, J. B. Cabot,

J. R. Cain, A. Carnot and E. Goutal, F. J. R. Carulla, J. Ciochina, H. I. Coe, C. Diegel, G. Dillner, E. W. Fell, H. E. Field, G. A. Forsberg, N. J. Gebert, R. C. Good, W. Guertler, G. Hailstone, F. W. Harbord and A. E. Tucker, K. Hasegawa, C. R. Hayward, J. Henderson, C. H. Herty and co-workers, H. D. Hibbard, K. Hilgenstock, W. N. Hindley, A. H. Hiorns, T. E. Holgate, A. L. Holley, H. M. Howe, J. E. Hurst, M. Janoyer, G. R. Johnson, J. E. Johnson, W. J. Keep, K. Köhler, B. Kosmann, A. Lissner, A. Lodin, P. Longmuir, J. Massenez, T. Mauland, E. Maurer and W. Haufe, A. Messerschmidt, R. Moldenke, A. Niedenthal, P. Oberhoffer, R. H. Palmer, L. Piedbœuf and J. R. Marechal, W. J. Priestley, E. W. Rettew and L. A. Lanning, J. Roberts, H. Schenck, J. Shaw, O. Simmersbach, A. E. M. Smith, E. K. Smith and F. B. Riggan, R. H. Smith, G. J. Snelus, J. E. Stead, F. Stille, B. Stoughton, E. R. Taylor, B. Thomas, F. E. Thomson, E. E. Thum, T. Turner, O. Wedemeyer, F. Wüst, and F. Wüst and F. Schüller.

A. Fry discussed the diffusion of sulphur in iron. The system: iron-sulphur has been discussed elsewhere; it was studied by W. Treitschke and G. Tammann, K. Friedrich, F. Sauerwald and W. Hummitzsch, and E. Becker. E. Becker observed that virtually no solid soln. are formed with α-, β-, or γ-iron. The transformation points of iron are not changed, so that the γ-iron passes to β-iron at 898°, and β-iron passes to α-iron at 768°; but W. Treitschke and G. Tammann observed that the first of these points is lowered more than the second by the presence of ferrous sulphide, and with less than 92 per cent. of iron, there is only one break in the cooling curve at 800°, and this is probably connected with the soln. of ferrous sulphide in γ-iron. The deleterious effects produced by, say, 0·02 per cent. of sulphur are attributed to the brittle character of the solid soln. rich in iron; and when over 2 per cent. of sulphur is present, to the presence of a readily fusible layer of sulphide between the particles of iron. This explanation was also given by J. E. Stead. The effect of sulphur on the carbon-iron system was investigated by D. M. Levy, J. E. Stead, and T. Liesching, but the data are not sufficient to form the ternary diagram. T. Liesching prepared alloys with over 2 per cent. of sulphur, and found that when the proportion of carbon was high the material separated into two layers—one containing 26 to 28 per cent. of sulphur and 0·22 to 0·32 per cent. of carbon; and the other 2·05 to 2·25 per cent. of sulphur and 3·04 to 3·43 per cent. of carbon. D. M. Levy, and T. Liesching observed that sulphur lowers the m.p. of the iron-carbon alloy from 50° to 75° for 1 per cent. of sulphur. Even with a high proportion of sulphur, the pearlitic transformation remains unchanged at 695° to 706°. D. M. Levy showed that with up to 1·0 per cent. of sulphur, the surface of sections of the metal is bright and even, but marked all over by the pattern of the pearlite; and with over 1 per cent. of sulphur, the sections were pitted all over by the excess of sulphide in the alloy. The saturation point for sulphur in iron-carbon alloys with 2·73 per cent. of carbon is rather less than 0·9 per cent. In this case the sulphur remains uniformly diffused throughout the mass, but with higher proportions, more sulphide occurs in the upper than in the lower part. The following arrests were observed in the cooling curve of iron with 2·7 per cent. carbon and

Sulphur .	0·005	0·081	0·23	0·43	0·85	1·14	1·31	1·25	34·8 per cent.
Arrests .	.	.	.	. .	---	. .	1204°	1204°	1206°
	1279°	1277°	1239°	1247°	1236°	1189°	1189°	1190°	—
	1138°	1133°	1132°	1128°	1128°	1122°	1133°	1127°	—
	887°	887°	856°	863°	865°	870°	872°	866°	–
	—	—	—	—	—	972°	892°	980°	977°
	695°	696°	695°	696°	698°	692°	697°	695°	—

The arrest at 1279° is due to the solidification of iron holding carbon to the extent of 1·5 per cent.—that is, austenite; and as the temp. falls below 1000°, the carbide falls out of solid soln. W. H. Hatfield suggested that the action is continuous, not abrupt. D. M. Levy said that the arrest at 1138° is due to the splitting up of the eutectic with 4·3 per cent. of carbon into cementite and austenite. The arrest at 887° is attributed to the separation of cementite from austenite, but this was questioned by W. H. Hatfield on the ground that the separation of cementite is continuous, not abrupt. The arrest at about 950° occurs with samples containing free sulphide. The pearlite arrest is at 695°. J. E. Stead investigated the cooling curve of iron with 2·98 per cent. combined carbon, no graphite, 0·29 per cent. of manganese, 1·89 per cent. silicon, 0·27 per cent. sulphur, and 1·62 per cent. phosphorus. The arrest at 1149° is the primary f.p. where the separation of austenite begins; that at 1074° is due to the breaking up of the iron-carbon eutectic into cementite and austenite; that at 945° is due to the freezing of the ternary eutectic of Fe–P–C; and that at 773° is due to the formation of pearlite. G. Tammann and W. Salge studied the residues left after treating the metal with an acidified soln. of ammonium persulphate. H. Sawamura, and F. Roll observed that sulphur partly favours and partly hinders the separation of graphite in cast iron.

With less than 0·8 per cent. of sulphur, D. M. Levy found no sulphide in the pearlite areas representing primary austenite, but it is found in the eutectic separating between 1120° and 1130°, and J. E. Stead also observed the $Fe(Fe_3C)$–$Fe(FeS)$ eutectic. D. M. Levy thought the films of sulphide help to preserve the carbide from dissociation. J. E. Stead showed that in the absence of manganese some sulphur crystallizes with the carbide, and that it is that portion of sulphur which crystallizes with the carbide which is mainly responsible in preventing the separation of graphite and in making the carbide stable. The nature of the sulphide constituents of iron were discussed by E. Heyn, R. Baumann, G. J. Ward and A. H. Longden, H. Schottky, E. Blanchi, P. Oberhoffer, and P. Oberhoffer and A. Knipping. J. H. Andrew and D. Binnie found that sulphur may be retained in soln. by iron when a molten iron-sulphur alloy is rapidly chilled, and the deposition of iron sulphide occurs on re-heating the alloy above 900°. If manganese sulphide is soluble in iron, the solubility is very small. In the case of oxygen associated with sulphur, J. J. Porter, E. D. Campbell, and H. le Chatelier and M. Ziegler attributed the red-shortness to the presence of an iron oxysulphide. F. Osmond, A. Carnot and E. Goutal, J. O. Arnold and G. B. Waterhouse, J. O. Arnold and G. R. Bolsover, W. Heicke, and G. Röhl studied the system: FeS–MnS, and observed the formation of a manganese iron sulphide $Fe_3Mn_2S_5$. J. E. Stead, D. M. Levy, J. E. Hurst, W. H. Hatfield, and H. I. Coe showed that if manganese is present it combines with the sulphur to form manganese sulphide, and thus neutralizes its effects. W. H. Hatfield concluded that sulphur increases the stability of iron carbide at high temp., and thus hinders the breaking down of the carbides during the cooling of the metal. It is probable that the small percentage of sulphide associated with the carbide crystals accomplishes this action. H. I. Coe's inference that the sulphur separates as sulphide at the f.p. is not strictly correct, since a certain proportion is retained by the cementite carbide. The action is chemical, not mechanical, as suggested by D. M. Levy. E. D. Campbell, J. O. Arnold, and H. le Chatelier and A. Ziegler made observations on the diffusion of sulphur in solid iron. J. O. Arnold demonstrated the presence of ferrous sulphide in a mild steel free from manganese; and he also demonstrated the presence of manganous sulphide in manganiferous steels. The pale brown ferrous sulphide exists mainly in the form of sectional meshes, but sometimes occurs in the globular form. Manganous sulphide has a dove-grey colour, and exists almost exclusively as globules. J. O. Arnold and G. B. Waterhouse found that manganous sulphide is plastic at a yellow-heat. J. E. Stead doubted if the alleged manganous sulphide is really such; and J. O. Arnold and G. R. Bolsover indicated the probable existence in liquid commercial steels of an eutectic of ferrite and manganous sulphide which has a high f.p. J. O. Arnold found that the sp. gr. of steel is reduced from 7·8478 to 7·6903 as the proportion of sulphur increases from 0·03 to 0·97 per cent.

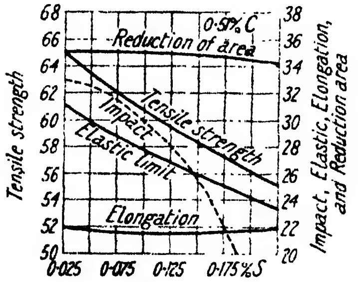

Fig. 335.—The Effect of Sulphur on the Mechanical Properties of Iron.

E. Piwowarsky showed that sulphur definitely tends to harden iron, and the effect increases with the rapidity with which the iron is cooled. J. S. Unger measured the mechanical properties of iron with 0·09, 0·32, and 0·51 per cent. sulphur, and the results for 0·51 per cent. of carbon are summarized in Fig. 335. The tensile strength and elastic limit are expressed in kilograms per sq. mm.; the elongation and reduction in area in percentages; and the impact test by the number of impacts required for fracture by a weight of 990 kgrms. falling 4·8 metres. A. Wimmer, and K. Taniguchi also made observations on this subject.

A. Holtz found that sulphur has very little influence on the magnetic properties of iron; but F. Goltze, and H. F. Parshall said that it reduces the magnetic properties of cast iron. According to H. von Jüptner, the sulphur in iron and steel may occur in different forms: (i) A compound which is decomposed by dil. acids, liberating hydrogen sulphide—J. O. Arnold and H. J. Hardy, F. H. Williams, L. Schneider, G. Hattensauer, etc., add that if proper precautions are taken, all the sulphur may be converted into hydrogen sulphide even when copper is present. (ii) A compound which on treatment with dil. acids liberates volatile methyl sulphide, $(CH_3)_2S$—F. C. Phillips, E. Prost, E. Franke, W. Schulte and L. Campredon, A. Barraud, D. M. Levy, O. Herting, T. Naske, F. Bischoff, G. T. Dougherty, etc. (iii) In a form which under certain conditions remains behind in the undissolved residue as an organic compound. The two latter forms may represent decomposition products of ore. The sulphurous residue was examined by L. L. de Koninck, C. R. Fresenius, E. Prost, H. Rocholl, etc. Its presence has been attributed to three causes: (*a*) the presence of cuprous sulphide insoluble in hydrochloric acid—F. Bischoff; (*b*) a graphitic residue—T. Turner; and (*c*) an organic compound which volatilizes with difficulty, and which may be distilled off by prolonged boiling with hydrochloric acid—F. C. Phillips. G. N. Huntley discussed sulphur as a cause of the corrosion of steel.

K. Oma observed that sulphur in electrolytic iron may be derived from the electrolyte or anode—*vide supra*. J. H. Nead, and C. H. Herty noted that molten iron absorbs sulphur from furnace gases containing sulphur dioxide. H. Caron observed that when manganese is added to cast iron containing sulphur, some sulphur is eliminated, and J. Massenez based a process for the desulphurization of iron by this reaction. The iron sulphide forms manganese sulphide which rises through the metal and joins the slag. E. H. Saniter showed that iron is desulphurized by adding calcium chloride or fluoride; E. Wilke-Dörfurt and H. Buchholz, by fluorides;. W. Zieler, by zirconium; and B. Bogitsch, and J. E. Stead demonstrated that sulphur is removed during the puddling process by the highly basic iron-slag. P. P. Berg and M. S. Pshonik, G. Tammann and H. O. von Samson-Himmelstjerna studied the desulphurization of steel with the alkaline earth oxides, and with the oxides of lead, zinc, manganese and iron. In molten cast iron, part of the sulphide may float on the surface as scum. H. H. Beeny, C. Bettendorf and N. J. Wark, E. Blanchi, J. Ciochina, E. W. Colbeck and N. L. Evans, W. Denecke and T. Meierling, E. Wilke-Dörfurt and co-workers, G. A. Drysdale, H. H. Ebert, L. F. Girardet and co-workers, K. Hilgenstock, E. J. Lowry, J. Mehrtens, R. T. Rolfe, L. Scharlibbe, and A. de Vathaire studied the desulphurization of iron by fluorspar, calcium chloride, soda-ash, lime, and rock salt; and A. Possenti, by acidic and basic slags. According to T. Turner, the small percentage of sulphur, rarely over 0·08, in foundry iron, is due to the conditions governing the blast-furnace operations. These conditions—temp., composition of burden and slags—are conducive to the retention of silicon, but not to the absorption of sulphur by the iron. Only a very small proportion of the sulphur in the charge is found in the molten iron. J. E. Stead confirmed T. Turner's observations on this subject. J. Ciochina discussed the effect of hydrogen in the process of desulphurization.

J. E. Stead pressed smooth bromide paper soaked with 3 per cent. sulphuric acid over the polished metal, washed the print to remove acid, then immersed it in a soln. of sodium thiosulphate to remove the excess of silver; and then washed and dried the paper. Brown stains showed the presence of manganese sulphide. This *auto-sulphur printing*, as it is called, was devised by R. Baumann for determining the distribution of the sulphide constituents. L. E. Benson, J. Durand, E. Heyn, D. M. Levy, S. Maeda, M. Niessner, P. Oberhoffer and A. Knipping, H. Patsch, F. Rogers, H. J. van Royen and E. Ammermann, and H. Schottky studied the process. The presence of sulphur in iron and steel is generally regarded as favourable to corrosion, as in S. Weinwurm's experiments with steel plates containing 1·08 per cent. of sulphur and 0·2 per cent. of manganese. According to A. L. Baikoff, the sulphur in good steel is present as manganese sulphide, and in S. Weinwurm's specimen there was not sufficient manganese to unite with all the sulphur.

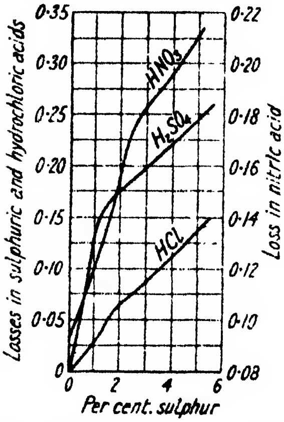

FIG. 336.—The Corrosion of Iron-Sulphur Alloys by Acids.

If the steel contains sulphides which have segregated, the heterogeneous metal may favour the development of local galvanic currents which stimulate corrosion, a subject studied by J. W. Cobb, G. Gallo, K. P. Grigorowitch, H. G. Haase, G. N. Huntley, V. V. Kendall and E. S. Taylerson, R. Stumper, and S. Weinwurm. Sulphur may be oxidized to sulphuric acid, and this favours corrosion. G. N. Huntley mentioned a case of the abnormal corrosion of boiler-plates through the oxidation of manganese sulphide in the steel; R. Stumper also found that the rate of corrosion of iron is accelerated by contact with iron sulphide; and G. R. Woodvine and A. L. Roberts noted that steel with segregated sulphur is more quickly corroded than steel free from these aggregates. H. Endo, Fig. 336, found the losses in grams per sq. cm., during 5 hrs'. attack at ordinary temp., with iron containing 0·34 to 0·42 per cent. of carbon, and

	Sulphur .	0·106	0·313	0·544	0·730	1·001	1·60	3·28	5·38 per cent.

	HCl .	0·01107	0·01252	0·01668	0·02080	0·03061	0·06559	0·09149	0·13657
	HNO_3	0·03491	0·04949	0·06108	0·07792	0·08025	0·13332	0·18383	0·20657

A. E. Wood and co-workers, L Tronstad and J. Sejersted, and H. Schmidt studied the corrosion of steel by soln. of sulphur, and of sulphur compounds in naphtha. W. Guertler and T. Liepus observed that iron is attacked by soln. of **sodium sulphide** in less than 24 hrs. C. van Brunt found that **sodium xanthate** forms a protective film of ferrous sulphide.

According to L. N. Vauquelin, iron in an aq. soln. of **hydrogen sulphide** in contact with air liberates hydrogen and turns black. Iron decomposes dry hydrogen sulphide. J. B. Fournier and F. Lang observed that liquid hydrogen sulphide had no perceptible action on iron at ordinary temp. for 11 years, or in 15 days at temp. up to 60°. J. B. Peel and P. L. Robinson found that hydrogen sulphide reacts with iron above 350°, forming ferrous sulphide. S. C. Britton and co-workers, J. M. Devine and co-workers, E. Dittrich, U. R. Evans, H. J. French, H. Gruber, W. P. Jorissen and B. L. Ongkiehong, F. J. Kayser, H. Schmidt,. A. Schulze, R. Stumper, G. Tammann and W. Köster, A. White and L. F. Marek, and R. E. Wilson and W. H. Balke studied the rate of attack of iron by hydrogen sulphide. P. A. von Bonsdorff, F. Hanaman, and U. R. Evans found that air containing traces of hydrogen sulphide rapidly corrodes iron. L. Biener, and F. Eisenstecken and L. Biener studied the mechanism of the sulphurization of iron by hydrogen sulphide. L. W. Vollmer and B. B. Westcott attributed the embrittlement of steel wire-rope, by hydrogen sulphide, to the absorption of hydrogen developed by the reaction $H_2S+Fe=FeS+2H_{nascent}$—*vide infra.* C. Menzel noted that a pump dealing with natural brine was much corroded by the hydrogen sulphide in soln.; and C. van Brunt found a pump dealing with a sulphide soln. was protected from corrosion by the formation of a film of sulphide—*vide infra*, and also the action of coal-gas on iron. J. Jahn observed that with iron in contact with hydrogen sulphide, at

	100°	154°	203°	259°	313°	414°	
Iron	588·5	582·4	591·2	580·7	591·2	735·8	mgrms.
Gain in weight . .	0·3	0·4	0·9	1·7	4·8	13·8	,,

and H. Gruber observed with pieces of iron 60×12×13 mm.,

	700°	800°	900°	1000°
Gain in weight . .	0·76	5·5	10·0	destroyed

A. E. Wood and co-workers studied the action of soln. of hydrogen sulphide in naphtha; and E. Rupp, the optical properties of films formed by hydrogen sulphide on iron. E. Beutel and A. Kutzelnigg studied the surface films produced by heating the metal in contact with the sulphides of copper, silver, mercury, and lead.

According to A. Lange, and A. Harpf, **sulphur dioxide** when dry has no action on iron, even at 100°, but in the presence of moisture the metal is slightly attacked. The action of sulphurous acid was examined by F. Schmitz, and B. Neumann and E. Goebel. F. Durau and C. H. Teckentrup found that the absorption of sulphur dioxide by electrolytic iron is a chemical process. According to U. R. Evans, when iron and steel are exposed over water sat. with sulphur dioxide, the metals become dark, and in 24 hrs., black. The filter-paper on which the samples rested acquired a rust-brown stain. The metal is soon covered with a yellowish-brown hydrated ferric oxide. H. Schiff, T. N. Morris, M. T. Burton, W. H. Hatfield, and F. Hanaman also studied the action of sulphur dioxide. L. Losana and G. Reggiani found that a mixture of $10CO_2+4CO_2+2O_2+48N_2+$traces of SO_2 +traces of hydrocarbons, saturated with water vapour at 16° to 20°, is more corrosive than air. J. Jahn observed that iron in contact with sulphur dioxide, at

	100°	150°	200°	250°	300°	400°	
Iron . . .	748·5	745·5	744·6	749·2	750·1	742·4	mgrms.

Iron . . .	754·0	758·5	758·4	757·9	756·9	728·0	,,
Gain in weight .	0·1	0·1	0·1	0·3	0·4	10·7	,,

P. Chirvinsky said that the reaction $3Fe+SO_2=FeS+2FeO$ is exothermal and proceeds from left to right at fairly low temp. A. C. Halferdahl calculated the free energy of the reaction $3Fe+2SO_2=Fe_3O_4+S_2$ to be −61,000 cals. at 600°, and −26,700 cals. at 1400°; and for $4Fe+3SO_2=2Fe_2O_3+1\frac{1}{2}S_2$, −76,200 cals. at 600° and −18,100 cals. at 1400°. F. Schmitz found that the losses with **sulphurous acid** by 0·06, 0·42, and 0·92 per cent. carbon steel, 20×20×10 mm. with a 4 mm. hole, were respectively 20·630, 2·580, and 1·940 per cent. during 180 hrs'. attack. J. Rothe and F. W. Hinrichsen studied the action of sulphurous acid on iron. A. Lange found that liquid sulphur dioxide has little action on iron at ordinary temp., but under compression, or in the presence of moisture, the corrosion is appreciable. The corrosive action of town air, the air of railway tunnels, and smoke, all contaminated with sulphur dioxide, was discussed by R. C. Brenner, A. W. Carpenter, A. S. Cushman, S. L. Foster, L. de Gaetani, S. W. Griffin and W. W. Skinner, O. Haehnel, P. Longmuir, D. Meneghini, E. A. and L. T. Richardson, S. Rideal, J. Rothe and F. W. Hinrichsen, P. Siedler, and W. H. J. Vernon. The corrosive action of sulphurous acid on metals was studied by J. Uhl, and P. Schweitzer. P. Nicolardot studied the action of the acid on iron. H. J. Braun observed that wrought iron is sufficiently resistant to the action of **fluosulphonic acid** at 0°, 130°, and 150° that it can be employed for the retorts in manufacturing the acid. H. Moissan and P. Lebeau found that **sulphuryl fluoride** has no action on iron even at a red-heat. F. Wöhler said that liquid **sulphur monochloride** acts slowly on iron, but H. E. Patten observed no reaction; the subject was discussed by R. Dittmar, P. Nicolardot, B. W. Dunn, and

E. H. Harvey. E. Baudrimont found that boiling sulphur monochloride slowly attacks iron reduced by hydrogen, forming ferric chloride. P. Nicolardot said that the presence of nickel, silicon, chromium, or tungsten makes the iron more resistant to the attack. N. Domanicky found that the presence of ether accelerates the attack of iron by sulphur monochloride. H. B. North found that **sulphuryl chloride** acts on iron at an elevated temp., forming crystals of ferric chloride; and E. Fromm observed that a soln. of sulphuryl chloride in absolute ether does not act on iron. H. E. Patten observed that with **thionyl chloride**, iron is coated black. H. B. North and A. M. Hageman found that in sealed tubes at 150° to 200°, with thionyl chloride in excess, the reaction can be symbolized: $2Fe+4SOCl_2=2FeCl_3+2SO_2+S_2Cl_2$: and if the metal is in excess: $3Fe+2SOCl_2=2FeCl_2+FeS+SO_2$. K. Oma gave $2Fe+2SOCl_2=2FeCl_2+S+SO_2$.

The action of **sulphuric acid** on iron resembles in many respects the action of hydrochloric acid—*vide supra*, hydrochloric acid. It was discussed by J. W. Priestley at the beginning of the nineteenth century, and later by C. J. B. Karsten, and others—*vide* **5**. 39, 20. Sulphuric acid in all stages of dilution attacks iron; and in the case of the dil. acid, hot or cold, hydrogen is evolved; but, according to M. Berthelot, the conc. acid furnishes hydrogen in the cold, and at temp. exceeding 160° sulphur dioxide is the main product. R. H. Adie said that sulphur dioxide appears at 220°, and that no hydrogen sulphide is formed. P. Hart found that the finely-divided metal at 200° yields sulphur dioxide with sulphuric acid of sp. gr. 1·75. A. Ditte studied the products of the reaction with the conc. acid. C. W. R. Powell observed that the slow action of the conc. acid on iron at 25° to 30° furnishes ferrous sulphate—mostly anhydrous—sulphur dioxide, hydrogen, and water; and C. E. Fawsitt and C. W. R. Powell found that at 180° the sulphur dioxide which is evolved contains a small proportion of hydrogen sulphide, but no hydrogen. In general, cold or hot 61 per cent. acid furnishes hydrogen; but at higher concentrations sulphur dioxide, hydrogen sulphide and sulphur are formed. The 92 per cent. acid has very little action on iron: the action increases with increasing dilution; at 130° to 150° the 92 per cent. acid furnishes hydrogen and sulphur dioxide: the proportion of hydrogen decreases as the temp. rises to 250°. Sulphur begins to separate at about 210°. H. Endo found that the effect of oxygen dissolved in the acid is practically negligible with 95 per cent. sulphuric acid, but with decreasing concentration of the acid the effect increases until, with a 5 per cent. acid, the rate of corrosion is over fourteen times as fast as it is with a soln. free from dissolved oxygen. Observations were made by M. Ballay, S. C. Bate, C. F. Burgess and S. G. Engle, W. H. Creutzfeldt, G. Delbart, A. Ditte, V. Duffek, J. A. N. Friend and J. H. Dennett, R. Girard, L. F. Girardet and T. R. Kou, M. Centnerszwer and M. Straumanis, J. J. Healy, Y. N. Kojhevnikoff, J. Zamaron, W. Guertler and T. Liepus, W. H. Hatfield, G. W. Heise and A. Clemente, A. d'Heureuse, A. Larsson, B. Sandrock, J. Sauvageot and L. Lauprète, F. E. Thomson, W. M. Thornton and J. A. Harle, Y. Utida and M. Saito, G. W. Whitman and co-workers, M. Schunkert, and Y. Yamamoto. The speed of the dissolution of iron in dil. sulphuric acid was studied by C. M. Guldberg and P. Waage, G. Tammann and F. Neubert, and A. de Hemptinne. H. Bablik compared the speeds of attack by sulphuric and hydrochloric acids. C. Bizio discussed the action of fuming sulphuric acid on iron. H. Endo found the loss in grams per sq. cm. during 5 hrs'. action, at 25°, to be:

H_2SO_4 .	5	10	15	20	25	30 per cent.
Loss .	0·000699	0·000807	0·001250	0·008857	0·016840	0·036048

C. G. Fink and C. M. Decroly found that the loss of electrolytic iron in milligrams per sq. dm. per 24 hrs., with sulphuric acid of the percentage concentration:

H_2SO_4 .	5	10	25	50	75	90 per cent.
Loss .	3300	4020	15,200	2300	350	1120

J. I. Crabtree and G. E. Matthews observed a loss of 11·4 grms. per 100 sq. in. per day in 5 per cent. sulphuric acid. W. Bauhuis observed that electrolytic iron dissolves in sulphuric acid of different concentrations with characteristic velocities; there is a well-defined period of induction, which is more marked than is the case with hydrochloric acid. Both the smooth and rough metal dissolve actively; cathodic polarization makes no appreciable difference to the rate of dissolution, but anodic polarization passivates the metal. The addition of hydrochloric acid to sulphuric acid lowers the speed of the reaction, and the addition of halides to the sulphuric acid lowers the speed of dissolution of the metal, as is also the case with hydrochloric acid. The addition of oxidizing agents accelerates the speed of dissolution of the metal. W. Palmaer found that the period of induction is longer the slower the speed of dissolution of the metal. The subject is further discussed in connection with the corrosion of iron. G. Tammann and co-workers observed the effect of the hydrogen press. on the rate of dissolution of iron in sulphuric acid.

F. Schmitz found that the losses with 0·06, 0·42, and 0·92 per cent. carbon steel, 20×20×10 mm. with a 4 mm. hole, in sulphuric acid (1 : 10), were, respectively, 1·560, 2·740, and 54·920 per cent. during 180 hrs., and with conc. acid, respectively, 0·130, 0·145, and 0·110 per cent. B. Garre studied the effect of cold-work—torsion or tension—on the solubility of iron in dil. sulphuric acid, and some of his results are summarized in Fig. 337. W. Köster represented the influence of quenching and annealing on the solubility of iron with 0·1 per cent. of carbon in dil. sulphuric acid by Fig. 338. According to A. J. Hale and H. S. Foster, with a sq. dm. of cast iron and wrought iron, at 17° to 20°, and 0·2N-H_2SO_4, the losses were respectively 2·8 and 0·35 grms. with a litre of acid in 4 hrs.; respectively 16·0 and 17·0 grms. with half a litre of acid per day for 7 days; and 3·2 and 3·3 grms. with half a litre of acid in 28 days.

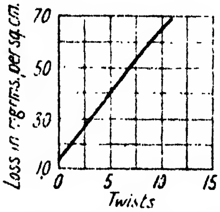

FIG. 337.—The Effect of Torsion on the Solubility of Iron in Dilute Sulphuric Acid.

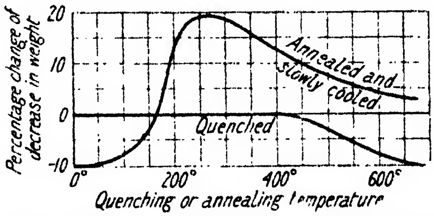

FIG. 338.—The Effect of Heat-treatment on the Solubility of Iron in Dilute Sulphuric Acid.

B. Lambert and J. C. Thomson found that the purified metal is very little affected by cold, dil. sulphuric acid, but dissolution readily occurs when the acid is warm. Conc. sulphuric acid has very little action on cast iron, hot or cold, provided access of air is excluded, for the moisture absorbed would dilute the acid and make it act more strongly. G. Lunge investigated the subject, and found with various samples of cast iron at 20°, 100°, and 295°, the average losses, grams per sq. cm. per hour, were respectively 0·021, 0·095, and 0·113 with an acid of sp. gr. 1·840; at 20°, 100°, and 200°, with an acid of sp. gr. 1·710, 0·018, 0·149, and 2·096 grms.; and at 20°, 100°, and 147°, with an acid of sp. gr. 1·530, 0·026, 0·300, and 1·564 grms. The general results showed that all acids down to sp. gr. 1·530 have very little action on cast iron at ordinary temp.; the action is stronger at 100°, and still more pronounced at the b.p. of the acid. With monohydrated sulphuric acid the losses in grams per sq. cm. with cast iron and wrought iron were 0·062 and 0·056 respectively in 6 days at 20°, and respectively 0·015 and 0·095 in 2 hrs. at 100°. Wrought iron is more susceptible to attack than cast iron, but at ordinary temp. it resists conc. sulphuric acid down to a little below a sp. gr. of 1·7000. If moisture be absorbed from the air the acid may become more dilute, and a strong corrosive action may occur. R. Knietsch obtained the following losses, in grms. per sq. metre per hour, during 72 hrs'. action at 18° to 20°, with the exclusion of air:

Per cent. H_2SO_4	Cast iron	Mild steel	Puddled iron
48·8	0·2177	—	—
61·2	0·1510	—	0·3032
67·7	0·0847	—	0·0789
73·4	0·0662	—	0·0623
79·7	0·1560	—	0·1159
83·7	0·1388	—	0·1052
85·1	0·1306		0·1034
88·2	0·1636	—	0·1417
90·6	0·1760	—	0·1339
92·0	0·0983	—	0·1040
93·0	0·0736	0·0987	0·0856
94·3	0·0723	0·0987	0·0708
95·4	0·1274	0·0933	0·1209
96·8	0·1013	0·0815	0·0988
98·4	0·0681	0·0533	0·0655
98·7	0·0589	0·0509	0·0570
99·2	0·0568	0·0418	0·0504
99·30	0·057	0·042	0·050
99·50	0·060	0·038	0·049
99·77	0·066	0·042	0·049
100·00	0·087	0·088	0·076

This shows that whilst dil. sulphuric acid readily attacks cast iron, the conc. acid does not attack it to any great extent until the acid exceeds the conc. represented by H_2SO_4. Thus, R. O. Davis found that the acid of sp. gr. 1·45 is very corrosive; the metal is but little attacked by an acid of sp. gr. 1·49, and the action is inappreciable with an acid of sp. gr. 1·50 to 1·55. With wrought iron, however, all concentrations are active until the conc. exceeds that required by the formula H_2SO_4 by some 27 per cent. Hence, added R. Knietsch, whilst cast-iron vessels are suitable for the preparation of hydrated sulphuric acid, it is dangerous to employ them for the fuming acid. W. H. Hatfield treated cylinders of iron, approximately 0·5 in. diam. and weighing about 50 grms., with about 85 c.c. of acid at 15°, and expressed the losses in grms. per sq. cm. per 24 hrs.; he found:

		N-H_2SO_4	5	10	25	50 per cent. H_2SO_4
Electrolytic iron		0·0057	—	0·0068	—	—
Armco iron		0·0099	—	0·0152	—	—
English wrought iron		0·1452	—	0·3610	—	—
Steel, 0·29 per cent. C	15°		0·1353	—	0·2027	0·0020
	40°		0·4004	—	0·8226	0·0060
	60°		0·4495	—	1·2552	0·0105
	80°		0·4958	—	1·2741	0·0112

Many other observations have been made on the relative resistance of cast iron, wrought iron, and steel to sulphuric acid—*e.g.* by J. Aston and C. F. Burgess, G. Delbart, H. Edwards, U. R. Evans, J. A. N. Friend, J. A. N. Friend and C. W. Marshall, L. Gruner, E. Heyn and O. Bauer, and J. Sauvageot and L. Lauprète—*vide infra*, corrosion. L. Aitchison, T. Andrews, P. Bardenheuer and K. L. Zeyen, O. Bauer, R. A. Hadfield and J. A. N. Friend, P. Kötzschke and E. Piwowarsky, E. Piwowarsky, W. Schreck, and T. Turner studied the influence of carbon. H. Endo showed that with steel having from 0·1 to 1·3 per cent. of carbon, the rate of action increases almost linearly with increasing proportions of carbon. F. Robin found that the solubility of steel in dil. sulphuric acid increases with the temp. of forging. For high-carbon steels, the maximum is at 300°; and with soft steels, 100° to 200°. The solubility diminishes rapidly with steels forged between 400° to 600°, and attains a minimum at 700° with soft steels, and at 800° with hard steels. For the effect of cold-work—twisting or bending—on the rate of dissolution of the metal, *vide infra.*

F. J. Daniell, and W. H. Johnson found that both iron and steel frequently become brittle after exposure for a short time to acid attack, and D. Sevoz, and

O. Reynolds attributed this to the presence of occluded hydrogen; and J. H. Andrew added that the hydrogen is absorbed by the intercrystalline cement and the resulting expansion forces the crystals apart and reduces their cohesion—*vide infra.* A. Ledebur observed that cast iron is not so sensitive as wrought iron, possibly owing to the altered solubility of hydrogen; when the container is in contact with fuming sulphuric acid, it is liable to burst or disintegrate, often with a loud noise. It is assumed that the acid penetrates the pores of the metal, liberating sulphur dioxide, hydrogen sulphide, and even carbon dioxide, which remain in the metal under high press., ultimately leading to rupture. The sulphur dioxide and hydrogen sulphide can be detected in the fractured metal by their odour. A. C. Cumming also noted a similar disruption with cast-iron vessels containing a mixture of sulphuric and nitric acids. It was concluded that crystals of salts forming in the interior of the iron were responsible for the disruption. T. F. Banigan found that cast-iron pipes and malleable castings frequently crack, without corrosion, after long exposure to sulphur trioxide fumes. Amorphous silicon alloyed with iron is rapidly oxidized by 15 per cent. oleum, but not by 96 per cent. sulphuric acid. Silicon carbide is not affected. The cracking is attributed to the effect of internal strains due to the increase in vol. of the particles of silicon when oxidized to silica.

J. A. N. Friend gave the following results for the effect of increasing concentrations of sulphuric acid on mild steel and grey cast iron under comparable conditions. The specimens measured 4·5×0·8×0·65 cms., they weighed 22 grms., and were in contact with 500 c.c. of acid for 8 hrs. at 15°, when the losses were

H_2SO_4 . .	0	0·5*N*-	*N*-	2*N*-	3*N*-	4*N*-	5*N*-
Cast iron .	0·0245	7·597	9·463	10·77	10·47	9·90	9·5
Mild steel .	0·0083	0·334	0·524	0·765	0·994	1·241	1·566

The attack on cast iron rises to a maximum and then falls; the conc. of the acid producing the maximum effect varies with different varieties of cast iron. The rate of dissolution of steel rises steadily with the conc. of the acid, and shows no maximum in the range examined. J. E. Stead attributed the fall in the rate of dissolution of the cast iron to the formation of a protective layer of sulphate which is not dissolved by the conc. acid. This agrees with the results of A. Larsson, but it does not explain why the same phenomenon does not occur with steel. M. P. Applebey and S. H. Wilkes, and L. McCulloch also attributed the passivity of iron in sulphuric acid to a film of sparingly-soluble sulphate. M. Mugdan said that the resistance of iron to conc. sulphuric acid is due to its assuming the passive state (*q.v.*). G. W. Heise and A. Clemente observed that iron becomes passive in sulphuric acid when 10 grms. potassium dichromate per litre are present in 0·5*N*-H_2SO_4; 50 grms. per litre in *N*-H_2SO_4; and in 2*N*-H_2SO_4 a passive state was not attained.

L. Aitchison found that the effect of carbon in steel exposed to 1 per cent. sulphuric acid is such that the losses in grams per 100 sq. cm. in 77 days in the dark are as follow, and similarly with 10 per cent. sulphuric acid during 45 days' action in the dark:

Carbon . . .	0·07	0·19	0·50	0·68	0·89	1·25	1·46 per cent.
H_2SO_4 1 per cent. .	2·88	3·48	3·34	4·15	4·25	4·38	6·65
H_2SO_4 10 per cent. .	7·02	7·15	4·57	6·90	10·82	3·57	4·90

A. Sieverts and P. Lueg observed that the inhibitory agents discussed above in connection with hydrochloric acid act similarly with sulphuric acid. Recommendations have been made at various times to retard the evolution of hydrogen—acid mist—in the pickling of iron by an acid, and prevent the embrittlement of the metal by hydrogen. Thus, S. E. Grove recommended nitre-cake, sumac, and water; S. W. Griffin, 1 per cent. of formaldehyde and hydrochloric acid; T. L. Bailey, glue, dextrin, glucose, and jelly; O. Vogel, 1 to 2 per cent. of anthracene residues, waste sulphite lye, crude anthracene, products obtained in the dry distillation of coal, and quinolinic derivatives; H. N. Holmes, 0·2 per cent. of formaldehyde, benzaldehyde, furfural, and acetaldehyde; and J. G. Schmidt and H. R. Lee, thiourea and substituted ureas. O. P. Watts found that with 19 per cent. sulphuric acid, at 30°, HCl, HBr, HF, Na_3AsO_4, $As_2(SO_4)_3$, KF, KBr, KI, NH_4Cl, NaCl, $HgCl_2$, $HgSO_4$, $SnCl_2$, Na_2SnO_3, $Cr_2(SO_4)_3$, $MnCl_2$, hydroquinone, and resorcin acted as retarding agents; KNO_3, $KClO_3$, $CuSO_4$, $AgNO_3$, Ag_2SO_4, $HgNO_3$, CrO_3, $CrCl_3$, K_2CrO_4, $K_2Cr_2O_7$, $Bi_2(SO_4)_3$, $KMnO_4$, and $PtCl_4$ acted as accelerating agents; whilst K_2SO_4, $(NH_4)_2SO_4$, H_3BO_3, $Sb_2(SO_4)_3$, and citric acid had no perceptible effect. W. H. Creutzfeldt noted the retarding action of various organic substances, tar, oil, etc.; and W. S. Calcott and I. E. Lee, of thiophenol, thio-β-naphthol, benzylmercaptan, isoamylmercaptan, or isopropylmercaptan in proportions of the order of 0·03 per cent. The subject was discussed by I. Apati, H. Bablik, G. Batta and E. Leclerc, E. L. Chappell and P. C. Ely, G. W. Emlen, J. E. Hansen and G. S. Lindsay, M. Omerz, H. Pirak and W. Wenzel, F. H. Rhodes and W. E. Kuhn, A. Sieverts and P. Lueg, F. N. Speller and E. L. Chappell, H. Staley, H. Sutton, K. Taussig, A. D. Turnbull, and J. C. Warner. According to A. D. Turnbull, carbohydrates like sugar or starch have a good influence on retarding the action of dil. sulphuric acid on iron. With cellulose, there is a reaction between water: $C_6H_{10}O_5+H_2O=C_6H_{12}O_6$; and the cellulose acts as an inhibitor. J. G. Schmidt and H. R. Lee observed that thiourea acts as an inhibitor of the action of sulphuric acid on iron. The Newport Co. found that 1 per cent. or less of thiourea or its substitution derivatives prevents or retards the action. J. C. Warner found that the rate of dissolution of iron in an aq. soln. may be diminished not only by substances which produce passivity at anodic areas, but also by substances which increase the hydrogen overvoltage at cathodic areas. This inference is supported by observations on the effect of gelatin, petroleum bases, and coal-tar bases on the rate of dissolution of a low-carbon iron in dil. sulphuric acid and on the hydrogen overvoltage at the metal surface in this soln.; but aniline and quinoline, which definitely retard dissolution, actually lower the hydrogen overvoltage measured at 10 milliamps. per sq. cm. Overvoltage measurements at lower current densities might remove this anomaly. O. Vogel found many nitrogen ring compounds act as retarders. F. H. Rhodes and W. E. Kuhn examined the inhibitory action of some heterocyclic compounds of nitrogen on the attack of iron by sulphuric acid:

Toluidine, triethanolamine, aniline, pyridine, picoline, piperidine, lutidine, collidine, 8-hydroxyquinoline, quinoline, phenylquinoline, 2-methylquinoline (quinaldine), crude quinaldine, 6-methylquinoline, 2,4-dimethylquinoline, pyrrole, acridine, diquinolyl, diquinolylmethane, dimethyldiquinolyl, β-naphthoquinoline, methylacridine, 3,6-diaminoacridine, phenylacridine, 3,6-dimethyl-2, 7-diaminoacridine ethyl chloride, 3,6-dimethyl-2,7-diethyldiaminoacridine hydrochloride, benzidine, α-naphthylamine, phenyldinaphthacridine, α, β-dinaphthacridine, fluorenenaphthacridine, β,β-dinaphthacridine, α,α-dinaphthacridine, and diphenanthracridine.

They concluded that the inhibitory effect increased with the mol. wt. and also with the introduction of a methyl, phenyl, or amino-group. Thus, in such a series as pyridine-quinoline-acridine the increase in the number of rings in the molecule was accompanied by a regular increase in effect, and in the series pyridine-lutidine-picoline-collidine the introduction of a single additional methyl group increased the inhibiting action of the compound by nearly 25 per cent. Hydroxyl groups decreased the inhibiting action, and the most efficient of all the compounds studied were those containing several alkyl and amino-groups substituted in an acridine nucleus; thus, 3:7-diamino-2:8-dimethyl-acridinum ethochloride and hydrochloride. The addition of a specific inhibitor to an acid electrolyte increased the film resistance, and it is indicated that the protective action is due to some specific property of the observed film and not solely to the increased resistance offered. L. Heilbronn used an inhibitor, a peptone and formol; J. H. Gravell and A. Douty, a thiocyanate; J. H. Gravell, anhydroformaldehydeaniline, thiocarbonilide, or thionex; L. J. Christmann, tetramethyldiaminodiphenyl disulphide; J. G. Vignos, sulphated arylthiazole compounds; and E. I. du Pont de Nemours, a product of the action of an aldehyde and an amine, and carbon disulphide, *e.g.* $CH_3.CO.H$, or $C_6H_5NH_2$ and CS_2. M. Hartmann and W. Klarer used as inhibitors of the reaction the products obtained by condensing aldehydes, ketones, and suitable acid chlorides like phosgene with aromatic amino- or nitro-compounds with subsequent reduction, *e.g.* diaminodiphenylmethane, diaminoditolylmethane, and diaminonaphthylmethane, or the corresponding symmetrical and unsymmetrical, primary or secondary nitrogen-substitution products, *e.g.* 4, 4′-tetramethyldiaminodiphenylmethane. Further, they employed the corresponding products which may be obtained with acetaldehyde, or acetone instead of with formaldehyde; ketones such as 4, 4′-tetramethyldiaminobenzophenone, also the triphenylmethane, or, quite generally, the leuco-compounds of the triarylmethane dyes containing amino-groups, such as leuco-crystal-violet, or leuco-malachite-green, or the corresponding quaternary ammonium bases of all these compounds. T. W. Bartram and D. H. Tomkins, and J. G. Schmidt used a complex aldehyde; L. B. Sebrell, trithioformaldehyde.

G. Walpert found that the rate of dissolution of iron and the electrode in $8N$-H_2SO_4 was depressed by the addition of hydrochloric acid, and the period of induction is augmented. The rate of dissolution of the iron in conc. sulphuric acid is depressed more by the addition of iodides than with bromides, and with bromides more than with chlorides. The effect with dil. sulphuric acid is small. The addition of the aliphatic acids also retards the rate of dissolution, and this in the order: formic acid, acetic acid, propionic acid, and butyric acid. Substances with a high mol. wt., like gelatin and methyl violet, also reduce the speed of the reaction. The phenomena are attributed to the adsorption of the foreign substance on the surface of the metal being dissolved.

The effect of the inhibitor quinoline ethiodide on the evolution of hydrogen from various kinds of iron, and also the cathode potential was studied by E. L. Chappell and co-workers. The results on the evolution of hydrogen from steel in N-H_2SO_4 with different proportions of quinoline ethiodide, at 60°, are indicated in Fig. 339, and the effect on the cathode potential of Armco iron at 25°, in Fig. 340.

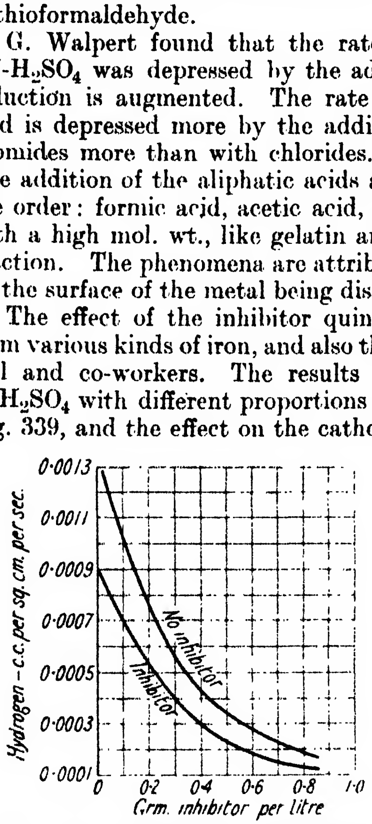

FIG. 339.—The Effect of Inhibitors on the Evolution of Hydrogen.

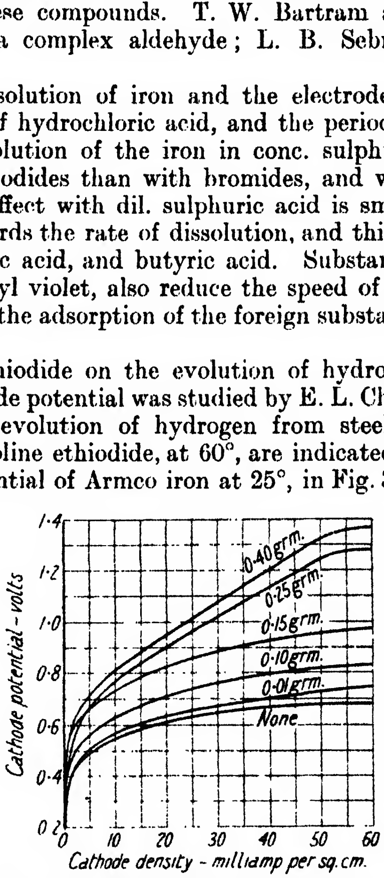

FIG. 340.—The Effect of Inhibitors on the Cathode Potential.

The inhibitor has little effect on the anode potential, and a marked effect on the hydrogen overvoltage. It is therefore concluded that the effect produced is the result of cathode reactions. With a constant density of 10 milliamperes per sq. cm., N-H_2SO_4, and soln. with 0·0 and 0·4 grm. quinoline ethiodide per litre at 25°, the following cathode potentials, E volt, and increases in the overvoltages were observed:

	Armco iron	Rough steel	Polished steel	White cast iron	Annealed malleable	Wrought iron
E { 0·0 . .	0·56	0·38	0·60	0·41	0·46	0·52 volt
E { 0·4 . .	0·80	0·55	0·77	0·57	0·58	0·60 ,,
Increase o.v. .	0·24	0·17	0·17	0·16	0·12	0·08 ,,

E. L. Chappell and co-workers also observed the effect of various inhibitors, 0·70 grm. per litre, on the evolution of hydrogen -*v* c.c. per sq. cm. per minute—with N-H_2SO_4 and steel; as well as the cathode potential, *E* volt, with a current density of 9·1 milliamperes per sq. cm., at 60°.

	None	Sodium cyanide	Picric acid	Bismarck brown	Sodium arsenate	Quinoline ethiodide
E . .	0·388	0·408	0·304	0·428	0·395	0·454
v . .	0·091	0·064	0·061	0·029	0·020	0·020

The effect of alkaloids like brucine on the overvoltage of metals was indicated by J. I. Crabtree, and M. le Blanc; organic quinine and quinoline bases, by A. Mazzucchelli; colloids like gum and gelatine, by N. Isgarisheff and S. Berkmann, and C. Marie and R. Audibert; and arsenious acid, potassium cyanide, hydrogen sulphide, brucine, and quinine, by N. Isgarisheff and E. Koldaeva.

W. Rohn showed that with 10 per cent. cold sulphuric acid, purified, unannealed iron loses 0·06 grm. per sq. dm. in 1 hr., and 1·1 grm. in 24 hrs.; and 21·7 grms. per sq. dm. are lost in 1 hr. in the hot acid. The attack on annealed iron is less vigorous. According to G. J. Burch and J. W. Dodgson, iron in contact with silicon in sulphuric acid of sp. gr. 1·84 hastens the dissolution. The resistance to sulphuric acid offered by iron containing silicon, etc., was discussed by A. Ricevuto, R. Irmann, D. F. McFarland and O. E. Harder, F. Schmitz, L. Aitchison, etc.—*vide* the corrosion of iron and steel. C. E. Fawsitt and A. A. Pain observed that with 5 grms. of steel exposing a surface of 36 sq. cm., at 30°, for 28 days, the average vol. of gas evolved in c.c. per hr. per sq. dcm. of steel surface, and the loss of weight in grams in 28 days, were:

H_2SO_4 . .	97·4	94·0	90·9	89·3	87·9	85·0	80·0 per cent.
Vol. gas no shaking	—	0·27	0·31	0·06	0·28	0·30	2·5 c.c.
Vol. gas shaking .	0·17	1·46	2·07	0·24	0·89	0·89	4·94 c.c.
Loss wt. shaking.	0·099	0·861	1·222	0·140	0·523	0·526	2·915 grms.

According to W. D. Richardson, grey cast iron, containing graphite, is more readily attacked by N-H_2SO_4 than open-hearth iron, but the corrosion of the latter is greatly accelerated if a trace of platinum salt be added so as to produce a little platinum in contact with the iron. The losses in grams per hour, from plates 15 cm. square, at 16°, with open-hearth iron and cast iron, were respectively 0·76 and 8·9 grms. without platinum, and 15·5 and 9·6 grms. with platinum. W. D. Richardson observed that with normal acids at about 16°, the average attack per hour:

	H_2SO_4 (First 20 hrs.)	H_2SO_4 (Second 20 hrs.)	HNO_3 (2 hrs.)
Copper steel (0·1 per cent. Cu) .	0·09 to 0·23	0·00 to 0·03	1·90 to 19·8
Open-hearth iron . . .	0·30 to 0·08	0·02 to 0·05	15·2 to 20·7
Bessemer steel	0·27 to 0·34	0·01 to 0·09	14·7 to 20·5
Puddled iron	0·39 to 1·03	0·06 to 0·86	18·2 to 20·0
Grey cast iron	4·82 to 4·87	3·99 to 5·02	5·0 to 8·8
White cast iron . . .	2·03 to 2·12	1·77 to 2·33	6·5 to 9·9
Malleable iron	1·56 to 2·91	0·98 to 1·36	5·4 to 6·0
Semi-steel	4·06 to 4·18	4·26 to 5·15	5·4 to 7·2
Cast steel	0·66 to 1·03	0·30 to 0·77	1·60 to 16·5

He also found that the action was not stimulated by the presence of copper or silver salts, although O. P. Watts and H. C. Knapp observed that the action of the acid is accelerated by the presence of these salts. O. P. Watts and N. D. Whipple found that the presence of arsenic in dil. sulphuric acid greatly reduces the corrosion for the same reason as that indicated in connection with hydrochloric acid; whilst the presence of hydrogen dioxide hastened the rate of attack. H. Anthes discussed the evolution of arsine under these conditions. For E. Heyn and O. Bauer's observations on the effect of carbon in steel on the corrosion by dil. sulphuric acid, *vide infra*, Fig. 394. C. E. Fawsitt and C. W. R. Powell, from a study of the action of sulphuric acid on iron and steel, concluded that conc. sulphuric acid acts at the ordinary temp. on steel and on some kinds of cast iron, the products being ferrous sulphate and hydrogen with a small quantity of sulphur dioxide. The reaction proceeds more rapidly with rise of temp., and the gaseous products at 180° are sulphur dioxide with occasional small quantities of sulphuretted hydrogen, but no hydrogen. The rate is increased, on the average, about three times for each 10° rise of temp. The rate of reaction depends on the conc. of the acid, but for small dilutions the ratio of hydrogen to sulphur dioxide in the mixture of gases evolved remains almost unchanged. Although the rate of reaction depends to a certain extent on the composition of the sample of iron, as indicated by the large difference between steel wire and pig-iron, an important factor governing the reaction with any one sample appears to be the condition of the surface of the iron. C. E. Fawsitt found that at 30° with 91·5 per cent. acid, steel lost in 4 days 0·068 grm., and if mercury was in contact with the steel, 0·061 grm.; at 25° and with 91·5 per cent. acid, in 11 days the loss was 0·134 grm., and with platinum and aluminium respectively in contact with the steel, the losses were 0·123 and 0·071 grm.; and with 96·3 per cent. acid, at 250°, the loss was 0·048 grm. in 27 days; and if platinum and aluminium were in contact with the steel, the losses were respectively 0·048 and 0·055 grm. C. E. Fawsitt and A. A. Pain found that the differences in the electrochemical behaviour show that no real similarity exists between iron which is slowly dissolving in conc. sulphuric acid and iron rendered "passive" by dipping into nitric acid. The action of the acid produces a form of ferrous sulphate monohydrate on the surface of the iron, which causes the slowing down or cessation of the reaction. In general, increasing dilution of the acid with water results in greater reactivity, but certain anomalies were observed in this respect, notably that 89·3 per cent. acid had considerably less action on the metal than 94 per cent., 90·9 per cent., 87·9 per cent., or 85 per cent. acid. The solvent effect is in all cases noticeably increased by shaking the vessel containing the acid and the metal. F. J. R. Carulla reported that cast-iron nitre-pots withstand the action of sulphuric acid and nitrous and nitric acids in a glowing furnace for months, and sometimes years: J. E. Stead attributed this to the formation of a protecting layer of ferrous sulphate insoluble in the hot, conc. acid. The resistance offered by the silicon-iron and other alloys (*q.v.*) to the action of sulphuric acid was discussed by J. W. Parkes.

J. W. Turrentine, and M. G. Levi and co-workers found that iron dissolves in a soln. of **ammonium persulphate**, forming ferrous sulphate, a portion of which undergoes further oxidation. The reaction was studied by G. Tammann and F. Neubert. O. Aschan and G. V. Petrelius found that with soln. of ammonium, **potassium and sodium persulphates** iron dissolves, forming the complex salts $(NH_4)_2Fe(S_2O_8).6H_2O$, $K_2Fe(S_2O_8).6H_2O$, and $Na_2Fe(S_2O_8).4H_2O$, respectively. J. I. Crabtree and G. E. Matthews observed that iron is attacked by **sodium thiosulphate,** and the photographic fixing-bath is discoloured. E. Beutel and A. Kutzelnigg observed that with a boiling soln. of sodium thiosulphate and lead acetate, iron acquires a sequence of colours from yellow to steel-blue owing to the formation of a film of lead sulphide.

C. F. Burgess and J. Aston found that the presence of 0·017 per cent. of **selenium** in iron reduced the attack by 20 per cent. sulphuric acid, but increased its tendency to atmospheric corrosion. A. E. H. Tutton found that **selenic acid** dissolves iron, forming ferrous selenate and a deposit of selenium which hinders the action of the acid on the metal; no hydrogen is evolved, and the selenium is presumably formed by the reaction: $3H_2+H_2SeO_4=4H_2O+Se$; so that the resultant equation is $3Fe+4H_2SeO_4=3FeSeO_4+Se+4H_2O$. For the action of selenium, *vide* the selenides—**10**. 58, 7. G. Tammann and K. Schaarwächter found that the attack of iron by selenium begins about 200°, and quickly attains a maximum speed. The alloys were studied by H. Fleek, and A. L. Norbury; and the effect of iron on the photoelectric properties, by F. H. Constable and A. F. H. Ward. For the action of **tellurium**, see the tellurides—**11**. 59, 7. G. Tammann and

K. Schaarwächter observed that tellurium begins to attack iron at about 446°, and the action becomes very rapid soon afterwards. N. Ageeff and M. Zamotorin studied the diffusion of tellurium in iron. G. B. Waterhouse and I. N. Zavarine observed that steel with 0·12 per cent. of tellurium has a lower ductility than normal steel. C. F. Burgess and J. Aston discussed the working properties of iron with a small proportion of selenium. Iron decomposes dry **hydrogen selenide,** as well as **hydrogen telluride.** J. B. Peel and P. L. Robinson found that hydrogen selenide reacts with iron at 750°, forming ferrous selenide. V. Lenher found that iron when heated in a sealed tube with **selenium oxybromide** is attacked, forming iron bromide and **selenium monobromide ;** and V. Lenher and C. H. Kao found that the metal is attacked by **selenium monochloride.**

The absorption of **nitrogen** by iron has been discussed in connection with Table XLVII, and also from the point of view of the nitrides—**8.** 49, 12. F. Durau and C. H. Teckentrup [7] showed that the absorption of nitrogen by electrolytic iron is a process of adsorption. T. Graham, and A. Wehrle obtained the gas from iron. One group of observers—E. Baur and G. L. Voerman, G. Charpy and S. Bonnerot, G. J. Fowler, W. Frankenburger and K. Mayrhofer, A. Mittasch and W. Frankenburger, H. Hardtung, W. Herwig, A. Ledebur, E. B. Maxted, P. Oberhoffer and A. Beutell, I. I. Shukoff, J. K. Smith, C. Stahlschmidt, and N. Tschischewsky—could not detect any marked adsorption of molecular nitrogen by iron at temp. ranging up to 800°, and at a press. up to 205 atm.; another group—F. Briegler and A. Geuther, C. Despretz, W. A. Dew and H. S. Taylor, E. Frémy, K. Iwase, E. Martin, E. Jurisch, A. F. Benton and co-workers, E. B. Maxted, W. Moldenhauer and F. Groebe, A. Sieverts, A. Sieverts and P. Beckmann, E. W. R. Steacie and F. M. G. Johnson, H. S. Taylor and R. M. Burns, J. G. Thompson and E. H. Hamilton, H. Wolfram, and F. Wüst and J. Duhr—found that nitrogen is absorbed under these conditions. E. Jurisch inclined to the opinion that the discordant conclusions are due to the iron absorbing nitrogen only at a temp. exceeding 850° ; G. Tammann, to the formation of an impervious film of nitride on the surface of the metal ; and W. Frankenburger and co-workers, to the absorption with pure iron being dependent on its structure, which, in turn, depends on its mode of preparation ; it is further supposed that the nitrogen is absorbed only at particularly active parts of the surface and is thence able to pass to the interior—with commercial iron, the impurities present can take up nitrogen directly, and then deliver it up to the iron. E. Martin's results agree with those of A. Sieverts, Fig. 343, and not with those of K. Iwase. A. Fry's results are shown in Fig. 342. There is another difference in the case of the results of E. Jurisch, and K. Iwase. As indicated previously, **8.** 49, 12, the percentage amount of nitrogen taken up by the metal at different temp. is, according to E. Jurisch :

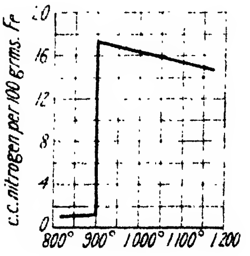

FIG. 341.—The Solubility of Nitrogen in α-Iron.

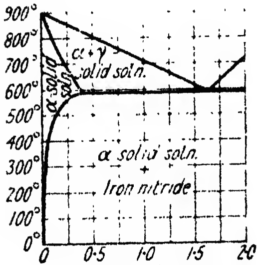

FIG. 342.—The Solubility of Nitrogen in Iron.

	878°	930°	981°	1033°	1084°	1136°
Nitrogen	0·00158	0·02165	0·02103	0·02022	0·01973	0·01885 per cent.

whilst K. Iwase gave :

	620°	722°	852°	940°	980°	1030°
Nitrogen	0·00128	0·00207	0·00220	0·00285	0·00477	0·00687 per cent.

so that in both cases the nitrogen absorbed increases with a rise of temperature up to about 900°, and in the former case the amount taken up beyond 900° decreases with a rise of temp., and increases in the latter case. K. Iwase represented his results by the curve shown in Fig. 343, when the solubility of nitrogen in iron is represented as c.c. of gas at n.p. θ per 100 grms. of metal. The rates of absorption of the gas at 850° and 980° are shown in Fig. 344. The presence of increasing quantities of carbon lowers progressively the solubility of the nitrogen. The corresponding data for the soln. of nitrogen in cast iron are summarized in Figs. 345 and 346. The rate of absorption of nitrogen by iron was also studied by H. Braune, P. Oberhoffer and A. Heger, G. Tammann, and W. Watson; the absorption of the gas was also investigated by L. Cailletet, G. M. Eaton, A. Grabe, L. Jordan and J. R. Eckman, E. Martin, F. Rapatz, A. Sieverts, J. K. Smith, C. E. Stromeyer, B. Tazawa, N. Tschischewsky, G. Valensi, and A. Villachon and G. Chaudron; the absorption of nitrogen by alloy steels, by N. Parravano and A. Scortecci; the absorption of nitrogen in the electric arc between iron electrodes in nitrogen was observed by L. Arons, J. H. Paterson, J. H. Paterson and H. Blair, H. S. Rawdon and co-workers, W. E. Ruder, and E. J. B. Willey; and the absorption of nitrogen during the cathodic spluttering of iron in nitrogen, by W. Frankenburger and K. Mayrhofer, V. Kohlschütter and T. Goldschmidt, V. Kohlschütter and R. Müller, M. Pawloff, and R. Ruer and J. Kuschmann.

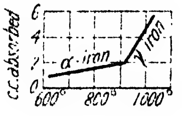

FIG. 343.—The Solubility of Nitrogen in Iron.

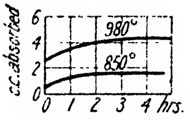

FIG. 344.—The Rate of Absorption of Nitrogen by Iron.

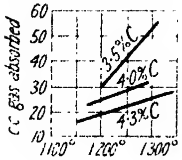

FIG. 345.—The Solubility of Nitrogen in Cast Iron.

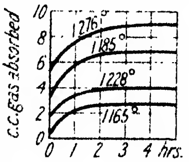

FIG. 346.—The Rate of Absorption of Nitrogen by Cast Iron.

A. Sieverts, and E. Jurisch observed that the quantity of nitrogen, S, absorbed by the metal is proportional to the sq. root of the press., p mm., so that with press. up to 1·5 atm., $S=kp^{\frac{1}{2}}$, where k denotes the coeff. of solubility. C. B. Sawyer, and J. H. Andrew also found the rule to be valid for steel up to 200 atm. press. Molten iron absorbs nitrogen more readily than does the solid, since, according to C. B. Sawyer, when iron is melted in nitrogen under a press. of 1 to 3 atm., the molten metal "spits" during solidification. B. Strauss found that after the solidification of iron which has been melted for half an hour in nitrogen under a press. of 1 atm., the metal retains 0·03 to 0·04 per cent. of nitrogen; F. Adcock observed that iron melted for half an hour in nitrogen at atm. press., and cooled under a press. of 1 to 2 mm., retains 0·02 per cent. nitrogen; C. B. Sawyer, that armco iron, with 1 per cent. of carbon melted and cooled in nitrogen at 1 to 3 atm. press., retains 0·014 to 0·036 per cent. of nitrogen; and J. H. Andrew, molten iron, with 0·16 to 0·6 per cent. of carbon, solidified in nitrogen at 200 atm. press., retains 0·25 to 0·30 per cent. of that gas. K. Jellinek also studied the effect of the press. of the gas on the electrical resistance of the metal; and G. B. Kistiakowsky, the ionization potential of adsorbed nitrogen.

L. Kaul found that when nitrogen acts on heated iron, a state is reached at the γ-point at which nitrogen is fixed by the release of at. energy. Further heating alters the conditions so that the then highly active nitrogen is no longer fixed, and on cooling below the γ-point, the freed energy is again required for cohesion and nitrogen is given up. R. Lenz, and F. Haber did not consider that the nitrogen in electrodeposited iron was derived from the air dissolved in the electrolyte. The subject was discussed by S. Epstein and co-workers. The absorption of nitrogen from air in the manufacture of steel by the Bessemer, or the open-hearth processes was discussed by W. Köster, P. Oberhoffer and co-workers, E. H. Schulz and R. Frerich, C. E. Stromeyer, and H. E. Tholander. The nitriding or nitrogenization of steel, and the case-hardening of steel by nitrogenization were discussed by C. R. Aldon, C. F. Bason, E. Baur and G. L. Voerman, L. E. Benson, H. Braune and C. Bolin, F. Brühl, J. H. Cates, F. L. Coonan, R. J. Cowan, M. Daubois, R. O. E. Davis, G. M. Eaton, J. J. Egan, W. Eilender and O. Meyer, P. H. Emmett and co-workers, S. Epstein, H. A. de Fries, A. Fry, L. Guillet, H. M. Gustafson, O. E. Harder and co-workers, J. H. Higgins, R. H. Hobrock, V. O. Homerberg and co-workers, H. A. de Fries, J. E. Hurst, M. Ishizawa, B. Jones and co-workers, A. B. Kinzel and co-workers, A. B. Kinzel and J. J. Egan, W. Köster, E. Lehrer, H. W. McQuaid and co-workers, H. W. McQuaid and W. J. Ketcham, V. T. Malcolm, W. J. Merten, J. T. Norton, E. Oehman and E. S. Engberg, C. F. Olmstead, A. Osawa and S. Iwaizumi, F. Rapatz, R. G. Roshong, F. W. Rowe, D. Saito and H. Okawa, S. Sato, C. B. Sawyer, F. Schmitz, L. W. Schuster, R. Sergeson, A. Sieverts and F. Krüll, E. A. Sjöstet, J. W. Urquhart, A. E. White and J. S. Vanick, and E. J. B. Willey. T. Nakayama studied the effect of various elements on the nitrogenization of steel.

A. Müller, and H. Krämer thought that the occluded nitrogen in iron is present as nitride, and this view is supported by the X-radiograms of nitrogenized steel by R. Brill, O. Eisenhut and E. Kaupp, G. Hägg, L. R. Ingersoll, A. Osawa and S. Iwaizumi, and A. Pourcel. G. Charpy and S. Bonnerot, W. Frankenburger and co-workers, and N. Tschischewsky have suggested that the nitrogen is combined with the foreign elements associated with the iron. S. Sato said that the nitrogen is present as atomic nitrogen or iron nitride. H. E. Tholander discussed the assumption that the iron is combined with the carbon as iron cyanide; but H. Braune favoured the nitride and rejected the cyanide hypothesis (i) because of the behaviour of nitridized iron towards hydrochloric acid; (ii) A. H. Allen could detect no definite relation between the nitrogen and carbon-content of steel; and (iii) H. Braune, and W. Giesen found that in nitridized steel the cementite is free from nitrogen. In favour of the cyanide hypothesis, there are the observations of J. Kirner, B. Strauss, S. W. Miller, and W. E. Ruder that nitrogen is associated with the carbon of steel. H. Nishimura studied the system: $Fe-N_2-H_2$. For the effect of foreign elements on the absorptions of nitrogen—*vide infra,* the action of ammonia. J. Duhr discussed the absorption of nitrogen by ferroaluminium, ferrotitanium, ferrovanadium, ferrochromium, ferrotungsten, ferromanganese, and phosphor iron. F. Schmitz found that in molten iron, the foreign elements are neutral towards nitrogen. E. J. B. Willey discussed the action of activated nitrogen on iron.

The effect of nitrogen on the equilibrium diagram of iron was discussed by J. H. Andrew, S. Brunauer and co-workers, O. Eisenhut and E. Kaupp, A. Fry, R. F. Mehl and C. S. Barrett, J. Rieber, S. Sato, C. B. Sawyer, L. W. Schuster, B. Strauss, and C. Wagner and W. Schottky—*vide* **8**. 49, 12. The microstructure of nitrogenized iron was discussed by A. Fry, F. Hanaman, O. A. Knight and H. B. Northrup, W. E. Ruder and G. R. Brophy, C. B. Sawyer, B. Strauss, and N. Tschischewsky. H. Braune observed that the effect of nitrogen is to decrease the grain-size of the crystals, and when the nitrogen-content has attained 0·2 per cent., the cellular structure disappears. A system of linear markings is developed and dark pointed needles appear—*vide* iron nitride. H. le Chatelier, and B. Strauss suggested that the needles are Neumann's lines. G. S. Scott observed that twinning occurred in iron carburized with nitrogenous cements, and that nitrogen in steel favoured the γ-state. J. H. Andrew agreed with this and said that Neumann's lines are characteristic of nitrogenized iron. J. Kirner, and B. Strauss observed a constituent resembling pearlite in nitrogenized steel; J. Kirner called it *flavite*—*vide* cementation—and B. Strauss showed that it could be distinguished by heat-tinting, and J. Kirner, by etching with picric acid. S. W. Miller considered that the needles in welded steel were cementite, but G. F. Comstock showed that they are produced by nitrogen, and he recommended the use of an alkaline soln. of potassium ferrocyanide to distinguish nitride from pearlite; W. E. Ruder and

G. R. Brophy used Stead's phosphorus reagent; and A. Fry an alkaline soln. of sodium picrate. The acicular constituent of steel was also studied by J. H. Andrew, W. R. Bean and co-workers, A. A. Blue, H. M. Boylston, H. Braune, H. le Chatelier, E. Colver-Glauert, G. F. Comstock, G. F. Comstock and M. E. Ruder, R. A. Hadfield, F. Hanaman, Z. Jeffries, O. A. Knight and H. B. Northrup, W. Köster, E. F. Law and co-workers, S. W. Miller, H. S. Rawdon and co-workers, W. E. Ruder, W. E. Ruder and G. R. Brophy, C. B. Sawyer, B. Strauss, and N. Tschischewsky. The X-radiograms, and the lattice structure of nitrogenized steel were studied by G. Hägg, S. Epstein and co-workers, S. B. Hendricks and P. R. Kosting, P. D. Merica, S. Epstein, A. Osawa and S. Iwaizumi, E. Lehrer, O. Eisenhut and E. Kaupp, A. Sieverts and co-workers, and R. Brill. W. A. Wood observed that in the case-hardening of steels by nitridization, a surface layer of nitrides is formed with distorted lattices. The sp. gr. was studied by A. Sieverts and co-workers, F. Krüll, and O. Eisenhut and E. Kaupp. The effects of nitrogen on the mechanical properties of iron, observed by N. Tschischewsky and co-workers, were summarized in Fig. 16, **8**. 49, 12; and the subject was discussed by H. L. Buff, T. P. Campbell and H. Fay, A. W. Coffman, R. S. Dean, R. S. Dean and co-workers, C. Despretz, W. Eilender and R. Wasmuht, H. Fay, G. J. Fowler, H. G. Freeland, A. Fry, T. S. Fuller, B. Getzov, A. Grabe, W. T. Griffiths, F. Hanaman, I. E. Kontorovich, O. E. Harder and G. B. Todd, O. Hengstenberg and R. Mailänder, E. C. Herbert, W. Herwig, J. H. Higgins, V. O. Homerberg and J. P. Walstead, J. E. Hurst, J. E. Johnson, W. Köster, R. Mailänder, O. Meyer and R. Hobrock, N. L. Mochel, H. A. Pearson, J. Petren and A. Grabe, F. Savart, F. W. Scott, A. Sieverts and F. Krüll, O. Silvestri, V. N. Svechnikoff, G. Tammann, O. I. Ver and co-workers, and T. Yosiki. A. A. Noyes and L. B. Smith measured the dissociation press. E. Rupp studied the optical properties of the film of adsorbed nitrogen. H. Braune observed that there is an increase of 14·6 microhms per cm. cube in the electrical resistance for 1 per cent. of nitrogen adsorbed by iron. The subject was also studied by F. Hanaman, and E. B. Maxted. The effect of nitrogen on the magnetic properties of iron was discussed by H. Gries and H. Esser, C. Despretz, G. J. Fowler, E. Frémy, W. Köster, E. Lehrer, E. B. Maxted, P. D. Merica, and A. W. F. Rogstadius. The decarburization of iron by heating it in nitrogen was studied by A. Bramley and co-workers, L. Forquignon, H. M. Howe, A. Johansson and R. von Seth, H. von Jüptner, E. Jurisch, J. Kirner, P. Oberhoffer and A. Heger, F. Schmitz, B. Strauss, H. E. Tholander, H. Wolfram, F. Wüst and C. Geiger, and F. Wüst and E. Sudhoff—*vide infra*, cementation. No decarburization occurs at 1050° other than that depending on other gases occluded in steel, and no cyanogen was formed. W. Eilender and R. Wasmuht said that as little as 0·01 per cent. of nitrogen in steel will raise the hardness 15 per cent. S. Sato studied the occlusion of hydrogen by iron nitride; and N. P. Inglis and G. F. Lake, the corrosion of nitrided steel.

The effect of nitrogen on the corrosion of iron by dil. acids was studied by L. Guillet and M. Ballay, who observed that the nitrogenization of steels increased their corrodibility by 5 per cent. (by vol.) sulphuric or hydrochloric acid, with the exception of a steel containing 4·08 per cent. Ni, and 0·91 per cent. Cr, the resistance of which towards the former acid was increased. For the chromium-aluminium steels, cementation had the same effect. O. Hengstenberg observed that the nitrogenization of the alloy steels made them more resistant to corrosion by air and steam, and soln. of copper sulphate. H. H. Gray and co-workers found that the nitrogenization of mild steel rendered it almost insoluble in dil. hydrochloric acid. The resistance to attack by sea-water containing 5 per cent. of 12-vol. hydrogen dioxide, and to a mist from 20 per cent. sodium chloride soln., was increased by nitridation more than by cementation, followed by tempering, especially in the cases of the chromium and aluminium steels. This effect was even more marked with rain-water, especially for nickel steels. Cementation slightly increased the resistance towards 10 per cent. copper sulphate soln., but the nitride steels were scarcely attacked. H. H. Gray and M. B. Thompson found that the higher the initial proportion of carbon in a steel, the greater the loss of carbon during nitrogenization; and the higher the temp. of nitrogenization, the greater the subsequent resistance of the metal towards hydrochloric acid. O. Niezoldi observed that copper is deposited on nitrided steel from soln. of copper sulphate more slowly than it is on ordinary steel. O. Meyer found crucibles of **titanium nitride** attack iron slightly at about 1600°.

According to F. Hatton, nitrogenous organic matter dissolved in water is reduced by spongy iron to form elemental nitrogen. The action of **ammonia** gas on heated iron was considered in connection with the nitride—**8**. 49, 12. F. Durau and C. H. Teckentrup showed that the absorption of ammonia by electrolytic iron is a chemical process. Iron takes up nitrogen from ammonia far more readily than it does directly from nitrogen. G. Gore observed that liquid ammonia does not attack electrolytic iron. W. A. Dew and H. S. Taylor observed that iron at 0°, 110°, 218°, and 305° absorbs respectively 0·175, 0·0669, 0·036, and 0·0084 c.c. of ammonia per gram of metal. N. I. Nikitin and W. I. Sharkoff observed that between −18° and 100°, powdered iron readily absorbs ammonia in accord with the formula $a=kp'/n$. Near the beginning of the nineteenth century, A. B. Berthollet, and L. J. Thénard reported that they could detect no increase in weight when iron is heated in ammonia gas, but C. Stahlschmidt explained this result by assuming that the temp. was too high. J. S. Vanick and co-workers noted the deterioration of steel and wrought-iron pipes in hot gaseous ammonia; and R. Coustal and H. Spindler found that iron anodes are slightly attacked by liquid ammonia. L. J. Thénard, and C. Despretz showed that the presence of iron favours catalytically the thermal decomposition of ammonia. J. A. Almquist and E. D. Crittenden, M. P. Applebey, A. K. Brewer, J. K. Dixon and W. Steiner, A. B. F. Duncan and D. A. Wilson, E. Elöd and W. Banholzer, P. H. Emmett, W. Gluud and co-workers, C. H. Kunsman and co-workers, A. T. Larson and A. P. Brooks, J. S. Vanick and co-workers, E. Winter, P. H. Emmett and S. Brunauer, H. H. Gray, E. Tiede and E. Hay, F. Czopinsky and M. Wojcik, and J. Zawadzky and B. Modrzejewsky discussed iron as a catalyst in the synthesis of ammonia; and P. H. Emmett and S. Brunauer, the poisonous action of water vapour on the iron catalyst. Quite a number of observers—G. T. Beilby and G. G. Henderson, H. L. Buff, G. Charpy and S. Bonnerot, C. Despretz, T. G. Finzel, G. J. Fowler, E. Frémy, F. Hanaman, H. Hardtung, G. G. Henderson and J. C. Galletly, H. Herzer, E. B. Maxted, A. Mittasch and co-workers, H. V. Regnault, F. Savart, C. B. Sawyer, C. Stahlschmidt, A. E. White, and H. Wolfram—noted that when iron is heated in ammonia, nitrogen is absorbed; and N. Tschischewsky gave for the percentage increase in weight at different temp.:

	200°	300°	400°	450°	500°	600°	700°	750°	850°	
N_2 .	0·11	3·09	10·705	11·11	10·36	8·905	4·76	0·535	0·290	per cent.

showing that with finely-divided iron, the optimum temp. is about 450°—Fig. 17, **8**. 49, 12. T. Nakayama obtained analogous results. A. Mittasch and co-workers found that the reaction begins near 200°, and at 300° iron nitride is readily formed. Observations with compact iron were made by G. T. Beilby and G. G. Henderson, G. Charpy and S. Bonnerot, P. H. Emmett and S. Brunauer, F. Hanaman, O. A. Knight and H. B. Northrup, A. Mittasch and co-workers, E. Müller and K. Schwabe, B. Strauss, B. Tazawa, N. Tschischewsky, J. P. Walsted, and H. E. Wheeler. E. Lehrer's observations on the equilibrium conditions in the system: iron–ammonia–hydrogen are summarized in Fig. 347. The α-phase is a solid soln. of nitrogen in α-iron; the γ-phase, a solid soln. of nitrogen in γ-iron; and the γ'-phase, a solid soln., the ϵ-phase, containing iron tetritanitride. J. G. Thompson discussed the best type of steel for resisting attack in plants synthesizing ammonia. R. H. Hobrock, etc., discussed the surface hardening of steels by nitridizing them in ammonia at a suitable temp., and pressure. B. Strauss observed no absorption of nitrogen when ammonia is passed over molten iron. C. Stahlschmidt observed the formation of hydrogen in the reaction between ammonia and iron. J. H. Andrew showed that a large proportion of hydrogen is formed; but E. Colver-Glauert observed only a trace; and G. J. Fowler, F. Hanaman, and E. B. Maxted observed none. The rate of absorption, or diffusion of the nitrogen from ammonia by heated iron, was studied by H. Braune, E. Colver-Glauert, J. Duhr, A. Fry, L. Guillet, E. B. Maxted, T. Nakayama, C. B. Sawyer, G. Engelhardt and C. Wagner, and H. E. Wheeler. C. B. Sawyer showed that the presence of phosphorus in iron affects the nitrogenization of iron; L. Guillet found that the presence of aluminium, silicon, chromium, and molybdenum accelerates the absorption, and they form, along with the iron, stable nitrides, but H. E. Wheeler doubted if these elements form nitrides under these conditions. F. W. Harbord and T. Twyham discussed the action of manganese, but they found no relation between the nitrogen and manganese-content of iron. N. Tschischewsky considered that in addition to manganese, silicon and aluminium may be regarded as carriers of nitrogen, because in nitrogenized ferromanganese, ferroaluminium, and considerable proportions of the nitrides of manganese, aluminium, and silicon are present. W. Frankenburger and co-workers considered that carbon, manganese, chromium, and hydrogen, and B. Strauss, that silicon and chromium, play an important part in the adsorption of nitrogen; T. Nakayama also showed that the presence of aluminium, silicon, titanium, and chromium accelerates the absorption of nitrogen, but copper, manganese, cobalt, and nickel do not favour the absorption. A. Bramely and co-workers found that the presence of carbon retards the action of ammonia so that the amount of nitride formed decreases as the initial conc. of the carbide increases– *vide supra*. A. Fry observed that when heated to 680° in ammonia, the carbon of cementite is all displaced by nitrogen.

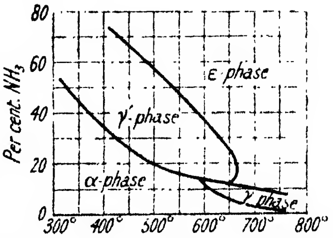

FIG. 347.—The Solid Phases in the System: $Fe–NH_3–H_2$.

P. A. von Bonsdorff observed that air containing traces of ammonia does not favour the rusting of iron. U. R. Evans observed no corrosion of iron over conc. aq. ammonia for 8 days. C. Matignon and G. Desplantes studied the oxidation of metals in the presence of ammonia. The corrosive action of aq. soln. of ammonia on iron is discussed below. W. R. Hodgkinson and N. E. Bellairs studied the action of aq. ammonia; and F. N. Speller, the action of ammonia in refrigerators. F. Schmitz showed that with pieces of 0·06, 0·42, and 0·92 per cent. carbon steel, 20×20×10 mm. with a 4 mm. hole, the losses in conc. aq. ammonia were respectively 0·000, 0·173, and 0·059 per cent. during 180 hrs. J. D. Pennock and D. A. Morton found that conc. aq. ammonia does not rust clean iron, but actually prevents rusting, even in the presence of oxygen or of ammonium carbonate. W. Guertler and T. Liepus observed that iron is not corroded by aq. ammonia in 24 hrs. The action of ammoniacal feed-water for boilers was discussed by M. Tilgner. A. H. White and L. Kirschbraun studied the electrolytic dissolution of nitrogenized iron. K. A. Hofmann and co-workers compared the action of dry hydrogen chloride and **ammonium chloride** vapour on metals at 250° to 350°, and found that the sequence with the former is Fe>Ni>Cu>Ag>Hg, and with the latter Fe>Cu>Ni>Ag>Hg. For the action of soln. of ammonium salts, *vide infra*. F. W. Bergstrom found that a soln. of **ammonium bromide** in liquid ammonia acts on iron in a few months to form $FeBr_2.6NH_3$. A. d'Heureuse observed that molten **ammonium sulphate** and iron yield ammonia, and at a higher temp. sulphur dioxide and ferrous sulphide are formed. M. Lachaud and C. Lepierre noted that a series of complex ferric or ferrosic ammonium sulphates is formed when iron acts on the molten salt; and F. W. Bergstrom said that a soln. of ammonium sulphate in liquid ammonia acts very slowly on iron. F. W. Dafert and R. Miklauz observed a vigorous reaction between iron and molten **lithium nitride.** H. and F. Hanaman found that the effect of heating iron in **hydrazines** is similar to that which occurs with ammonia; and likewise also with **amines,** and **imides.** F. W. Bergstrom found that the action of **potassamide** on iron, if it occurs at all, is extremely slow. F. Ephraim observed no reaction when iron is heated with **sodamide.** T. Curtius and J. Rissom observed that iron dissolves in **hydrazoic acid,** N_3H, forming ferrous azide with the brisk evolution of hydrogen. A. W. Browne and co-workers observed the nitridization of iron when it is used as anode in a soln. of **ammonium azide,** with liquid ammonia as solvent; ferric azide is formed. J. W. Turrentine found that a soln. of **sodium azide** on electrolysis with iron as anode furnishes initially ferric azide; if the soln. is agitated the iron becomes passive. J. T. Nance examined the action of soln. of ammonium chloride; and P. Junius, the vapour of that salt; W. R. Hodgkinson and A. H. Coote, F. Hatton, E. Heyn and O. Bauer, G. Tammann, E. Ramann, E. Weitz and H. Müller, and E. B. R. Prideaux and R. M. Caven, the action of iron on soln. of **ammonium nitrate**—*vide infra* for the effect of soln. of these salts; and the effects of pressure, by E. Berl and F. van Taack, F. Haber, H. Ehrig, A. Kaufmann, L. G. Knowlton, and E. Weitz and H. Müller; and W. R. Hodgkinson and A. H. Coote, the action of fused ammonium nitrate and **ammonium nitrite,** as well as of their aq. soln. O. Baudisch discussed the reduction of nitrites by iron. E. Divers found that iron is not attacked by a soln. of ammonium nitrate in liquid ammonia, but F. W. Bergstrom found that with powdered iron some ferric oxide is formed as well as $Fe(NO_3)_2.4NH_3$ and $Fe(NO_3)_2.6NH_3$. E. Priwoznik observed that iron gradually acquires a black film when immersed in a soln. of **ammonium polysulphide.**

P. Sabatier and J. B. Senderens found that **nitrous oxide** is reduced by iron powder at 170° to form ferrous oxide. F. Durau and C. H. Teckentrup showed that the absorption of nitrous oxide by electrolytic iron is purely adsorption. P. Oberhoffer observed that iron can be nitrogenized by heating it to 200° or 300° in an atm. of nitrous oxide. The rate of attack was studied by E. Schröder and G. Tammann. P. Sabatier and J. B. Senderens found that **nitric oxide** behaves like nitrous oxide at 200°; and F. Emich found iron is nitrogenized by heating it in nitric oxide. F. Durau and C. H. Teckentrup observed that the absorption of nitric oxide by electrolytic iron is a chemical process. According to B. B. Adhicary, when a mixture of nitric oxide and hydrogen is passed over the heated metal, ammonia begins to form at 300°, and the action is rapid at 350°. E. Müller and H. Barck found that decomposition is complete at 500°. The rate of attack was studied by E. Schröder and G. Tammann, and G. Tammann and W. Köster. E. Davy, and J. J. Sudborough found that iron is attacked by **nitrosyl chloride.** P. L. Dulong, and P. Sabatier and J. B. Senderens found that reduced iron decomposes **nitrogen peroxide** at ordinary temp. The metal becomes incandescent and yields ferric oxide. J. A. Almquist and co-workers found steel to be stable in contact with the liquid peroxide. There is also formed nitro-iron, Fe_2NO_2—**8.** 49, 39.

B. Lambert and J. C. Thomson found that cold dil. **nitric acid** has very little action on the purified metal, but when warm, the metal is dissolved. According to H. Gautier and G. Charpy, iron dissolves in 34 per cent. nitric acid at ordinary temp., giving off gas rapidly; the rate of evolution of gas then slackens, until finally only traces of ammonia and nitrogen peroxide are evolved, and ferric nitrate is formed. No gas is evolved with 61 per cent. acid in the cold, but at temp. exceeding 60°, gas is evolved. V. H. Veley and J. J. Manley said that purified nitric acid, freed from nitrous acid and dissolved nitrogen oxides, is without action on purified iron, even at the b.p. According to B. C. Banerji and N. R. Dhar, ferrous salts accelerate the dissolution by forming nitrous acid, which acts as a catalyst, and ferric salts also favour the reaction since they are reduced to ferrous salts. Oxidizing agents retard the reaction by preventing the formation of nitrous acid. C. C. Palit and N. R. Dhar also discussed the action of nitric acid on metals. A. Quartaroli showed that oxidation is a necessary antecedent for the dissolution of metals in nitric acid, and that nitric acid is not an oxidizing agent if no nitrous acid be present, or if substances like carbamide, an amino-acid, or an amide, which destroy the nitrous acid, be present. J. G. Brown studied the rate of the reaction. H. Endo observed that the weights lost by iron, expressed in grams per sq. cm., during 5 hrs'. action at 25°, are:

HNO_3 .	5	10	25	30	35	45	50	55 per cent.
Loss .	0·1021	0·2045	0·5210	0·8356	0·7590	0·0584	0·0233	nil

W. H. Hatfield observed that with cylinders of iron approximately 0·5 in. diam. and weighing 50 grms., in 85 c.c. of acid at 15°, the losses in grms. per sq. cm. in 24 hrs. were:

	Electrolytic iron	Armco iron	English wrought iron	Steel with 0·29 per cent.			
				15°	40°	60°	80°
N-HNO_3 . . .	0·1147	0·1406	0·1263	0·0957	0·0282	0·3215	0·3512
46 per cent. HNO_3 .	0·7261	0·7592	0·6399	0·6766	0·6538	1·3809	1·7278

B. C. Banerji and N. R. Dhar observed that with the 1 : 1 nickel-iron alloy (*q.v.*) the reaction with 5 to 20 per cent. nitric acid is periodic. According to A. J. Hale and H. S. Foster, with plates of 1 sq. dm., at 17° to 20°, and 0·2*N*-HNO_3, with a litre of acid, the losses with cast iron and wrought iron were respectively 2·60 and 1·30 grms. in 4 hrs.; with half a litre of acid per day for 7 days, the losses were respectively 15·4 and 14·5 grms.; and with half a litre of acid for 28 days, respectively 2·5 and 2·0 grms. H. Gautier and G. Charpy observed that at ordinary temp. clean iron wire in nitric acid of sp. gr. 1·21 does not give off any gas, but the metal is slowly attacked with the formation of iron nitrate, ammonia, and nitrogen peroxide, which remain in soln. The percentage losses in acids of different concentration were:

Specific gravity (HNO_3) .		1·28	1·34	1·38	1·48	1·53
Loss	First 2 days . .	0·82	0·75	0·29	0·34	5·80 per cent.
	First 10 days . .	0·59	0·45	0·25	0·33	5·75 ,,

The e.m.f. of the cell Fe : HNO_3 : Pt diminishes rapidly as the conc. of the acid increases from a sp. gr. below 1·21 to higher densities. In the latter case it is about 0·15 volt, and corresponds with the dissolution of the iron, for with circuits of different resistances, different intensities are obtained. By raising the temp., the limit of sp. gr. of the acid giving disengagement of gas and rapid attack is raised. At 60° it is only with concentrations above 1·38 that no disengagement of gas occurs. The limit is also raised by the presence of oxide on the surface of the iron; this is due to local heating caused by the solution of the oxide. If the iron be agitated in the acid until perfectly clean, it then behaves exactly as if the surface had not been coated with oxide. The same effect is produced if the oxide be electrolytically reduced.

W. Rohn found that unannealed iron in contact with 10 per cent. cold nitric acid loses 33·0 grms. per sq. dm. during 2 hrs., and with the hot acid, 40·0 grms. The attack on the annealed metal is rather slower. The subject was studied by W. Guertler and T. Liepus. J. I. Crabtree and G. E. Matthews found that with 5 per cent. acid, iron was corroded at the rate of 2·2 grms. per 100 sq. in. per day. According to F. Schmitz, 0·06, 0·42, and 0·92 per cent. carbon steel specimens, 20×20×10 mm. with a 4 mm. hole, lost respectively 100 per cent. in nitric acid (1 : 1) in 180 hrs., and in the conc. acid, respectively 0·113, 0·352, and 0·353 per cent. The loss with aqua regia was also 100 per cent. J. G. Thompson found that none of the iron alloys was so resistant to 100 per cent. nitric acid as aluminium and its alloys. Of all the iron alloys, a cast iron with 14 per cent. silicon (0·59 per cent. carbon) was the most resistant; one with 12·24 per cent. silicon and 1·17 per cent. carbon was less satisfactory. Molybdenum steel was little better than ordinary steel, but by adding 10 to 15 per cent. of chromium the steel resisted acids up to 68 per cent. HNO_3. Nickel counteracted the beneficent effects of chromium. For other observations, see the corrosion and the passivity of iron and steel.

A. Scheurer-Kestner observed that with nitric acid of sp. gr. 1·034, ferrous and ammonium nitrates are formed; with nitric acid of sp. gr. 1·073, ferrous, ferric, and ammonium nitrates are produced; while with nitric acid of sp. gr. 1·115, only ferric nitrate and no ammonia is formed. W. Heldt found that when ammonia is formed ferrous nitrate is produced, and when no ammonia is developed ferric nitrate is formed. With 32 per cent. nitric acid a hardened steel yields a black mass which slowly dissolves to form a brown soln. The dissolution proceeds more rapidly as the temp. is raised. This furnishes a mode of estimating the temper carbon in steel colorimetrically. Observations were made by H. von Jüptner, and E. Heyn. L. Schneider, and A. Tamm found that steels containing phosphorus yield a soln. containing phosphoric acid. J. M. Ordway observed that the products of the reaction depend on the conc. of the acid, the proportion of acid and metal employed, the degree of purity and the state of subdivision of the iron, and on the temp.; and J. H. Whiteley and A. F. Hallimond, that the products of the action also depend on the cold-work the metal has received, and on the carbon-content—*vide infra*. Y. Yamamoto, J. Hale and H. S. Foster, P. Kötzschke and E. Piwowarsky, and J. Sauvageot and L. Lauprète compared the rate of attack on different forms of iron. H. Endo showed that the rate of attack on 0·1 to 1·3 per cent. carbon steels increases almost linearly with the proportion of carbon. C. F. Burgess and S. G. Engle observed the losses in weight, in grams per sq. inch per hour, with N-H_2SO_4, at 22°, and found (i) 0·3728 grm. for the average with electrolytic iron; (ii) 0·0091 grm. with electrolytic iron heated to 1000° and cooled slowly; (iii) 0·0093 grm. with soft sheet iron low in carbon as used for transformer plates; (iv) 0·0971 grm. with a temper steel used in the manufacture of knife-blades; and (v) 0·0643 grm. with an ordinary grade of cast iron. The subject was studied by S. C. Bate, F. F. Chapman, N. R. Dhar, V. Duffek, H. Endo, L. F. Girardet and T. R. Kou, L. Loskiewicz, N. A. E. Millon, C. C. Palit and N. R. Dhar, W. D. Richardson, F. Schmitz, C. F. Schönbein, J. G. Thompson, and Y. Utida and M. Saito—*vide supra*, hydrochloric and sulphuric acids.

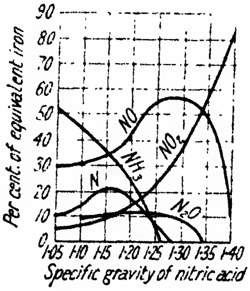

FIG. 348.—Products of the Action of Nitric Acid on Iron.

J. J. Acworth and H. E. Armstrong found that at 9° to 16°, the vols. of gas obtained per gram of metal, with nitric acid of varying concentration, are:

$HNO_3 : H_2O$.	1 : 1(16°)	1 : 2(13°)	1 : 4(10°)	1 : 4(13°)	1 : 8(12°)	1 : 12(9°)
Total . .	8064	5997	5330	5456	5904	5638 c.c.
NO . .	7392	5323	4598	4773	5542	5146 c.c.
N_2O . .	404	375	551	492	202	252 c.c.
N_2 . .	567	299	221	191	160	242 c.c.

The proportion of nitric oxide is relatively large. As the conc. of the acid decreases, the proportion of nitrous oxide at first increases and then diminishes; whereas, with nitric oxide, there is at first a decrease and then an increase. These differences correspond with the behaviour of the dissolved metal. With the 1 : 1- and 1 : 2-acids, the iron dissolves rapidly, producing a pale greenish-yellow liquid; with the 1 : 4-acid, the iron dissolves less rapidly, and the soln. is dark brown, as is also the case with the 1 : 8- and 1 : 12-acids, where the action proceeds still more slowly. It is inferred that by the action of the more conc. acid, the iron is immediately converted into the ferric salt, whereas with a more dil. acid, ferrous salt is first formed, and this is afterwards converted into ferric salt on heating the liquid. The hydrogen displaced in the formation of the ferrous salt is probably more active than that displaced in the formation of the ferric salt; and a similar conclusion follows from the manner in which the nitrous oxide is evolved. The last portion of gas with the 1 : 1- and the 1 : 2-acids is free from nitrous oxide. The mechanism of the reduction of nitric acid by the metals is discussed in connection with nitric acid.

J. J. Acworth and H. E. Armstrong assumed that the direct reduction products are nitrous and hyponitrous acids, hydroxylamine, and ammonia. If the nitric acid is present in large excess, and highly concentrated, the products will be richer in oxygen than where a small proportion of the acid is used. Thus, nitrogen peroxide predominates in the former case, and nitric oxide in the latter case. E. Divers classed iron amongst the metals which yield ammonia, hydroxylamine, hydrazine, or hydrogen. C. Montemartini found that the gases evolved on treating a gram of iron with an excess of 27·5 per cent. nitric acid were :

	NH_3	HNO_2	N_2O	N_2	NO	Total
Grams . .	0·02493	0·00195	0·00422	0·00045	—	0·03553

C. Montemartini said that the nitric oxide formed is of secondary origin, being derived partly from the decomposition of the nitrous acid and partly from the oxidation of the ferrous salts first formed. P. C. Freer and G. O. Higley found that with dil. nitric acid of sp. gr. 1·03 to 1·20, the products are nitrogen peroxide, nitric oxide, nitrous oxide, nitrogen, and ammonia in proportions which vary with the conc. and amount of acid employed ; with more conc. nitric acid of sp. gr. 1·35 to 1·40, the products are nitrogen peroxide and nitric oxide. The results are summarized in Fig. 348. The non-ionized acid is supposed to act merely as an oxidizing agent, because the results with silver, copper, and iron were practically the same with conc. nitric acid. Nitrogen peroxide is said to be the first product of the action, and nitric oxide is derived from this by the action of water, because the relative proportions of these two gases vary with the proportion of acid employed. For E. J. Joss's observations on the action of nitric acid on metals, *vide* **8**. 49, 45.

According to J. H. Whiteley and A. F. Hallimond, the gases obtained when nitric acid of different concentrations—grams HNO_3 per 100 c.c.—acts on 0·3 grm. of purified iron at 100° and 500 mm. press., are as follow (the nitrogen peroxide condensed in the receiver was not determined) :

Nitric acid (Grms. per 100 c.c.)	NO	N_2O	N_2	NH_3	Total gas (at n.p. θ)
11·5	32·0	2·5	13·3	14·0	47·5 c.c.
21·5	39·0	2·5	8·0	18·2	49·5 c.c.
22·7	41·0	2·0	8·0	18·3	51·0 c.c.
23·9	49·0	2·0	8·2	14·1	59·2 c.c.
25·1	74·0	2·5	5·5	5·6	82·0 c.c.
26·3	83·0	2·5	5·8	3·0	91·3 c.c.
27·5	87·0	2·5	4·3	2·0	93·8 c.c.
33·5	90·0	1·5	3·5	1·0	95·0 c.c.

There is a very striking discontinuity in the nature of the reaction when the conc. of the acid attains 24 grms. HNO_3 per 100 c.c. Much of the N_2+NH_3 mixture is replaced by a mixture of $NO+NO_2$ as the conc. of the acid changes from 23 to 25 grms. HNO_3 per 100 c.c. The sharp change in the character of the curves becomes less pronounced when a larger excess of nitric acid is employed. The products of the reaction depend on the concentration of the NO_3 as free acid or nitrate, and not on the acidity *per se*. No appreciable change occurred when the press. was reduced from 500 to 200 mm. By lowering the temp. of the reaction from 100° to 45°, the same general results were obtained, but there was an increase in the proportion of nitrogen at the expense of the ammonia. It is assumed that the ammonia combines with the nitrous acid formed in the reaction, and the resulting ammonium nitrite is subsequently decomposed : $NH_4NO_2=2H_2O+N_2$. The nitrous acid can also be formed by the action of nitric oxide on nitric acid : $2NO+HNO_3+H_2O=3HNO_2$. The proportion of nitrogen peroxide which is formed increases with the concentration of the acid, and decreases when the temp. of the reaction is lowered. The variations in the proportion of nitric oxide are dependent on the secondary reactions: $2NO_2+H_2O=HNO_3+HNO_2$, and $3HNO_2=HNO_3+2NO+H_2O$. It is suggested that the nitrous and nitric oxides are the result of the rapid decomposition of an unstable intermediate compound. E. Ramann represented the action of iron on the ferrous nitrate first formed: $4Fe(NO_3)_2+8H_2O+11Fe=4NH_4NO_3+5Fe_3O_4$. When ammonium nitrate acts on iron, nitrosyl-ammonium, NH_4NO, is said to be first formed as an intermediate product. J. H. Whiteley and A. F. Hallimond found that the composition of the nitrogenous gases involved on treating cementite by the method indicated above, was as follows:

Nitric acid (Grams per 100 c.c.)	NO	N_2O	N_2	NH_3
11·5	53·0	7·0	7·8	9·8
16·5	67·0	6·0	7·0	5·1
21·5	81·0	5·0	6·0	3·6
27·5	92·0	4·0	6·7	1·6
33·5	94·0	5·0	4·5	1·8
45·0	88·5	5·0	3·7	0·2

Some complex hydrocarbons, approximating on the average CH_2, are produced; and some of the hydrocarbons are slowly oxidized to carbon dioxide. Taking the weight of iron consumed in producing the ammonia and nitrogen as ordinate, and the conc. of the acid as abscissa, they obtained the so-called reaction curves, Fig. 349, for the effect with pearlitic steels. They found that the reaction curves are in accord with the mixture rule. The reaction curves of quenched steels indicate a high energy-content, and its gradual decrease in tempering.

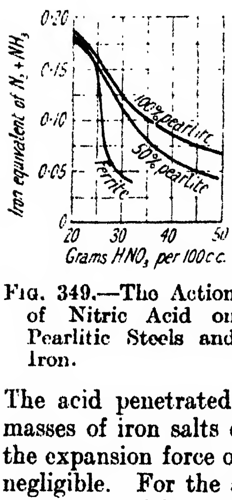

FIG. 349.—The Action of Nitric Acid on Pearlitic Steels and Iron.

Observations on the action of nitric acid on metals were also made by V. H. Veley, E. Divers, E. J. Maumené, J. J. Acworth, A. J. Ewart, C. Montemartini and E. Colonna, J. H. Stansbie, M. Drapier, W. D. Bancroft, E. J. Joss, and A. Klemenc. A. C. Cumming reported the bursting of cast-iron vessels containing a mixture of sulphuric and nitric acids. The metal contained large plates of graphite forming a network *viâ* which the acid could pass within. The acid penetrated the metal to a depth of one-third the thickness, and small masses of iron salts crystallized in the interior. The disruption was produced by the expansion force of the growing crystals, even though corrosion was practically negligible. For the action of conc. nitric acid whereby the iron becomes passive, see the special section on the passivity of iron. A. Quartaroli observed that oxidation facilitates the dissolution of iron in acids. P. Pascal found that for varying proportions of mixtures of nitric and sulphuric acid, there is a concentration between 10 and 20 per cent. of water at which the resistance of steel is a maximum. P. Pascal observed that the addition of 5 per cent. sulphuric acid to nitric acid considerably reduces the activity of the acid. R. C. Griffin observed that the attack on wrought iron, cast iron, and steel by 10 per cent. nitric acid is reduced in the presence of 1 per cent. of formaldehyde. According to L. E. Benson, iron is nitrogenized by heating it in a bath of 85 per cent. sodium nitrate, and 15 per cent. of sodium chloride, at 500°. The action of fused **alkali nitrates** on iron was discussed by E. Frémy, E. Berger, L. Moser, and C. S. A. Tatlock—*vide* the ferrates. A. E. Menke said that molten sodium nitrate with iron filings forms some sodium hyponitrite, but W. Zorn could not confirm this. L. Hackspill and R. Grandadam reported that when alkali nitrates and iron are heated in vacuo, the alkali metal is formed: *e.g.* $KNO_3+2Fe=Fe_2O_3+K+N$. Lithium nitrate does not react in this way. C. B. Gates observed no reaction between iron and molten silver nitrate; and A. Naumann, no reaction with iron and a soln. of **silver nitrate** in benzonitrile. J. A. Jones found that soln. of ammonium, sodium and calcium nitrates develop cracks in mild steel plates owing to their action on the intercrystalline cement. C. F. Bonilla studied the rate of attack by aqua regia.

The action of **phosphorus** on iron has been discussed in connection with the phosphides—**8.** 50, 12. G. Tammann and K. Schaarwächter[8] observed that the attack of iron by phosphorus can be detected at about 360°, and R. Vogel has investigated the effect of phosphorus on the arrests. The reaction was studied by M. V. Ruisakoff and I. N. Buschmakin. J. Percy pointed out that the presence of phosphorus reduces the malleability and strength of iron at ordinary temp., thus making the metal cold-short—*i.e.* brittle when cold. On the other hand, iron which contains enough phosphorus to be cold-short may be quite malleable at a high temp. such as that at which the metal is usually forged and rolled. C. J. B. Karsten said that if less than 0·5 per cent. of phosphorus be present, the quality is not seriously affected; with 0·6 per cent., the iron does not stand the breaking test; with 0·75 per cent., the iron fails under the breaking and bending tests, and its tenacity is low; with 0·8 per cent., the metal is decidedly cold-short. Observations were also made by L. Schneider, J. A. Barr, J. Wagner, B. W. Cheever, and H. von Jüptner. The interpretation of the equilibrium diagram, and the effect of phosphorus on the critical points of iron, were studied by E. Gerecke. J. E. Stead, J. L. Haughton, W. Venator, F. Wüst, K. Heitmann, J. H. Whiteley, P. Oberhoffer and C. Kreutzer, H. Esser and P. Oberhoffer, N. S. Konstantinoff, H. Gontermann, B. Saklatwalla, A. Allison, H. Voss, F. Osmond, H. M. Howe, J. E. Stead, E. Richarme, R. Mitsche, and P. Goerens and W. Dobbelstein examined the effect of phosphorus on the iron-carbon alloys, and their results have been previously described. K. Schichtel and E. Piwowarsky found that phosphorus reduces the solubility of carbon in liquid iron. W. F. Holbrook and co-workers studied the diffusion of phosphorus in molten iron. J. E. Stead showed that the effect of increasing proportions of carbon is to throw free iron tritaphosphide out of soln.:

Carbon .	0	0·125	0·180	0·70	0·80	1·40	2·00	3·50	per cent.
Fe_3P .	0	0·18	0·59	1·00	1·06	1·16	1·18	1·40	..
P in soln. .	1·75	1·37	1·18	0·75	0·70	0·60	0·55	0·31	..

With only 0·18 per cent. of carbon, free phosphide is formed, and the phosphide is then surrounded by pearlite; with 1·4 per cent. of carbon, the eutectic phosphide becomes surrounded by a layer of cementite which increases in thickness as the proportion of carbon increases. The interior has the character of a solidified eutectic. On reheating the mass to 900°, and allowing it to cool slowly, the cementite formed independent cells cutting up the pearlite into a number of small grains. The phosphide eutectic retained its original position and was no longer surrounded by the cementite; the cementite diffused throughout the iron at 900°, but not so the phosphide. When the carbon exceeds 2 per cent., there is evidence of a carbide-phosphide eutectic which contains 6·7 per cent. of phosphorus and 2·0 per cent. of carbon. This was confirmed by F. Wüst. J. E. Stead showed that phosphorus and carbon each require its quota of iron, and the presence of either diminishes the amount of the other simultaneously present in pig-iron; but phosphorus is without influence on the actual conditions of the carbon in pig-iron. This was confirmed by J. T. McKenzie, H. O. von Samson-Himmelstjerna, and K. A. Schreiber. K. Schichtel found that the introduction of phosphorus into the iron-carbon alloys altered the carbon solubility curve, the *SE* line, as indicated in Fig. 350. The effects of phosphorus on the proportion of carbon in the eutectic, and on the eutectic temp., are indicated in Fig. 351. Observations were also made by E. Söhnchen

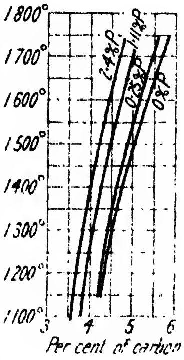

FIG. 350. — The Effect of Phosphorus on the Solubility of Carbon in Iron.

and E. Piwowarsky, M. Künkele, P. Bardenheuer and M. Künkele, H. Schenck, H. S. Rawdon, J. T. McKenzie, H. Sawamura, O. Bauer and K. Sipp, J. H. Higgins, R. Vogel, L. Jordan, F. Fettweiss, F. Sauerwald and W. Hummitzsch, and F. Wüst; whilst R. Vogel and O. de Vries studied the ternary system: Iron–phosphorus–sulphur. P. Goerens and W. Dobbelstein, E. Thews, and O. von Keil and R. Mitsche studied the influence of silicon on the system: Fe–P–C. J. H. Whiteley examined the distribution of the phosphorus in steel between the Ac_1- and the Ac_3-arrest. He concluded:

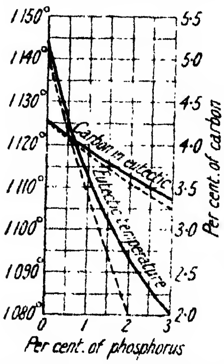

FIG. 351.—The Effect of Phosphorus on the Eutectic Temperature and on the Proportion of Carbon in the Eutectic.

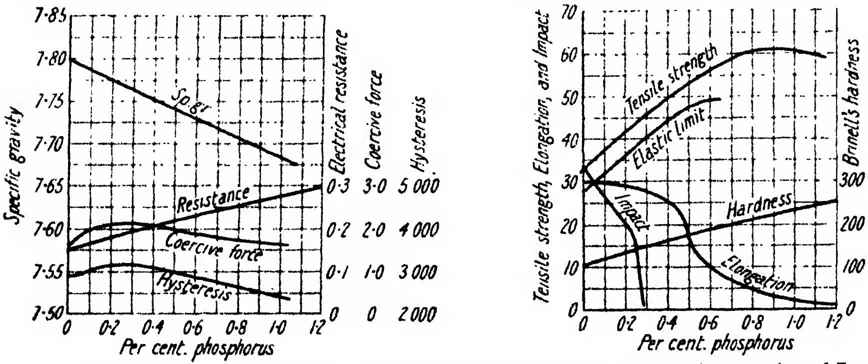
> When ordinary hypoeutectoid steel is heated to, and maintained at, temp. between the critical points Ac_1 and Ac_3, part of the phosphorus contained in the γ-iron diffuses into the adjacent ferrite owing to the fact that, under these conditions, the phosphorus is more soluble in the latter than in the former. With a series of steels in which the phosphorus varied from 0·006 to 0·12 per cent., it is phosphorus which diffuses out of the γ-iron. The lowering of the solubility in the γ-iron is most probably due to the presence of dissolved carbide. At temp. below 650°, phosphorus diffuses extremely slowly in ferrite; above this temp., the velocity gradually increases, and above 800° it is quite rapid, for a diffusion which requires 4 hrs. to complete at 740° is complete in 15 mins. at 830°. The velocity of diffusion of phosphorus in γ-iron also increases with the temp. in a similar manner, but it is never so high as that at which the carbon travels. At or near the Ac_3-arrest the speed of diffusion suddenly diminishes. By heating steels slowly through the critical range, a reticulated structure is produced which is also due to the movement of phosphorus in the γ-iron. The lowest temp. at which this structure is formed depends upon the carbon-content of the steel; with 0·18 per cent. of carbon it was about 820° and with 0·06 per cent. 870°. Owing to the fairly rapid rate at which phosphorus diffuses in γ-iron above 820°, it is possible, by heating sections of steel plates at a temp. just below the Ac_3 point, to remove completely the excess of phosphorus contained in the micro-ghost-line included in the areas occupied by the γ-iron. This treatment does not entirely remove the lines, however, for, although not so pronounced as formerly, they can still be detected by etching, even in samples containing less than 0·02 per cent. of phosphorus. Their presence would appear to be due, therefore, to the uneven distribution of some other substance besides phosphorus.

C. Kreutzer found that the X-radiograms agree with the assumption that with up to 1·7 per cent. of phosphorus, solid soln. are formed; that with increasing phosphorus, the indications of the tritaphosphide becomes stronger, and with 15·58 per cent. phosphorus the tritaphosphide with a tetragonal lattice having $a : c = 1 : 0·3482$ is formed; with 21·5 per cent. phosphorus, the hemiphosphide is formed; and with still more phosphorus, an unknown compound is produced. The subject was studied by F. Rogers, B. Kjerrman, H. Jungbluth, H. Schottky, J. B. Friauf, N. S. Konstantinoff, O. Kuhn, S. B. Hendricks and P. R. Kosting, H. le Chatelier and S. Wologdine, and G. Hägg. The solubility of phosphorus in iron was examined by J. E. Stead, A. E. Cameron, and E. D. Campbell and S. C. Babcock; the microstructure, by J. O. Arnold, J. E. Stead, N. S. Konstantinoff, E. Piwowarsky, B. Saklatwalla, and B. Strauss; the segregation of the phosphorus or phosphide, by P. Oberhoffer, J. W. Bolton, B. W. Cheever, L. Schneider, A. Carnot and E. Goutal, E. Piwowarsky, H. A. Schwartz and A. N. Hird, and J. E. Stead; and the sp. gr. by J. O. Arnold—C. Benedicks' results for liquid iron are indicated above, Fig. 350. F. Roll found that phosphorus partly favours, and partly hinders, the decomposition of the carbide in cast iron; O. von Keil and R. Mitsche, that phosphorus hinders graphitization; and K. Schichtel and E. Piwowarsky, that phosphorus decreases the solvent power of iron for carbon. C. H. Herty, and B. Kjerrman studied the effect of phosphorus on the pearlite interval; W. Bischof and E. Maurer, the distribution of phosphorus between iron and slags; H. Pinsl, Y. Yamamoto, and M. Künkele, the phosphide eutectic in cast iron; and P. Bardenheuer and M. Künkele, A. E. Cameron, and H. Jungbluth and H. Gummert, the effect of silicon on the phosphide eutectic. The effect of phosphorus on the casting shrinkage was studied by W. J. Keep; the diffusion of phosphorus in iron, by A. Fry, and N. C. Marples; the sp. vol., by C. Benedicks and co-workers; the hardness, by N. S. Konstantinoff, B. Saklatwalla, W. Köster, and E. d'Amico; J. J. Porter, and D. Saito and K. Hayashi, the fluidity which increases linearly with the proportion of phosphorus; and the mechanical properties, by C. J. B. Karsten, J. E. Hurst, F. F. McIntosh, F. Wüst and R. Stotz, A. Stadeler, J. S. Unger, N. J. Gebert, A. Müller-Haufe, E. W. Rettew and L. A. Lanning, E. C. Groesbeck, H. H. Beeny, A. E. M. Smith, R. C. Good, M. Hamasumi, F. Fettweiss, A. Wimmer, W. H. Hatfield, H. Ford, R. Moldenke, W. Guertler, E. Touceda, R. H. Smith, B. H. Paul, E. d'Amico, H. M. Howe, J. H. Higgins, G. R. Johnson, J. de Kryloff, E. Maurer and W. Haufe, H. I. Coe, J. E. Johnson, F. Graziani, W. E. Dennison, R. T. Rolfe, F. F. McIntosh, J. E. Fletcher, A. Ledebur, P. R. von Tunner, T. D. West, W. J. Keep, K. Taniguchi, J. E. Hurst, E. Piwowarsky and co-workers, and J. E. Stead. F. F. McIntosh found that the endurance properties and strength of steel increased with the phosphorus-content between 0·01 and 0·10 per cent., without producing a proportional loss in ductility. J. H. Teng found that malleable cast irons having approximately 0·80 to 0·90 per cent. combined carbon; 1·08 to 1·20 per cent. graphitic carbon; 0·200 to 0·210 per cent. silicon; 0·006 to 0·008 per cent. sulphur; no manganese, and variable proportions of phosphorus, had the mechanical properties in tons per sq. in.:

Phosphorus . .	0·010	0·046	0·096	0·144	0·210	0·302	0·412	0·508 per cent.
Yield-point . .	17·20	17·30	17·65	17·90	18·20	18·70	19·20	19·80
Max. stress . .	22·85	22·90	22·54	22·20	22·20	21·56	20·75	19·95
Elongation (4 ins.) .	3·8	3·5	3·5	3·1	3·2	2·9	2·2	0 per cent.
Reduction area .	3·12	3·00	3·10	2·80	2·85	2·00	1·5	nil per cent.
Transverse strength.	3·6	3·67	3·55	3·50	3·40	2·95	2·55	1·80
Deflection . .	0·57	6·57	0·56	0·56	0·53	0·44	0·37	0·18 in.
Angle of bend. .	60°	62°	58°	55°	55°	45°	30°	nil
Brinell's hardness .	175	180	184	193	203	224	253	308

He also found that the Izod test fell from 8·5 ft.-lbs. with 0·06 phosphorus to 3·0 with 0·465 per cent. N. S. Konstantinoff measured the electrical conductivity. The observations of E. d'Amico on the sp. gr., hardness, the mechanical properties, the electrical resistance, and the magnetic properties are summarized in Figs. 352 and 353, where the electrical resistance is expressed in ohms per metre per sq. mm. section; the coercive force is for $B=13{,}000$, and the hysteresis for $B=10{,}000$; the tensile strength and elastic limit refers to kilograms per sq. mm.; and the elongation is in percentages. One per cent. of phosphorus raises the electrical resistance 11·0 microhms per cm. cube. W. M. Hicks found that phosphorus and arsenic decreased the coercive and the hysteresis loss of iron. The subject was studied by F. Goltze, H. F. Parshall, and J. H. Partridge.



Figs. 352 and 353.—The Effect of Phosphorus on the Mechanical Properties of Iron.

According to R. Finkener, the general opinion is that phosphorus makes steel less resistant to corrosive influence, although C. Diegel did not find this to be the case with plates of iron exposed for sixteen months to sea-water in Kiel harbour. The results showed that the losses in weight per sq. dm. were :

P .	10·01	0·09	0·23	0·45	0·84	0·85 per cent.
Loss .	7·00	6·10	5·71	5·48	5·16	4·93 grms.

The resistance was ascribed to the formation of an iron phosphide which is not so readily corroded as iron. The experiments of E. Heyn and O. Bauer with iron containing larger proportions of phosphorus than those employed by C. Diegel, were very irregular. This is attributed to the unequal distribution of the phosphide favouring galvanic action. The subject was studied by L. Tronstad and J. Sejersted. H. Endo, Fig. 354, observed the losses in grams per sq. cm. during 5 hrs'. exposure at ordinary temp. from alloys with 0·35 to 0·45 per cent. of carbon and

Phosphorus .		0·75	1·35	1·81	3·10	6·84	12·17 per cent.
Loss	H_2SO_4 .	0·02688	0·03274	0·04255	0·03904	0·02478	0·00832
	HCl .	0·02388	0·02366	0·02566	0·01737	0·00847	0·00351
	HNO_3 .	0·06422	—	0·04642	0·05170	0·03177	0·02605

W. S. Calcott and co-workers, and M. Merlub-Sobel observed that the **phosphorus chlorides** readily attack iron ; and A. Granger found that in the vapour of **phosphorus trifluoride, trichloride,** and **tribromide,** iron phosphide is formed ; the metal is also attacked by **phosphorus iodide,** P_2I_4. A. Sieverts found that iron is dissolved by a soln. of **sodium hypophosphite.** H. Schackmann and W. Krings represented the action with **phosphorus pentoxide** by the equation: $5\ Fe+P_2O_5 \rightleftharpoons 5FeO+2P$. According to E. Erlenmeyer and O. Heinrich, a 48 per cent. soln. of **phosphoric acid** rapidly dissolves finely-powdered iron with the evolution of gas and the formation of a green liquid thought to contain $Fe(H_2PO_4)_2$. W. Rohn observed that cold, 10 per cent. phosphoric acid dissolves 0·27 grm. per sq. dm. from purified unannealed iron, and 0·14 grm. from the annealed metal; whilst the hot acid dissolves 5·77 grms. from the unannealed metal and 12·3 grms. from the annealed metal. According to P. R. Kosting and C. Heins, with 0·5 in. discs of armco iron and 50 per cent. phosphoric acid after an hour's action, the loss in weight was 0·13 grm. ; and with the addition of 0·49 per cent. arsenic oxide, 0·00 grm. ; with 0·75 per cent. HCl, 0·04 ; with 0·75 per cent. pyridine, 0·10 per cent. ; with 0·45 per cent. HF, 0·14 per cent. ; with 0·27 per cent. H_2SiF_6, 0·14 per cent. ; with 0·75 per cent. H_2SO_4, 0·16 per cent. ; with 1 c.c. of pine oil per 100 c.c. of soln., 0·05 per cent. ; and with 1 c.c. of mucilage per 100 c.c., 0·06 per cent. V. K. Pershke and co-workers studied the resistance to the acid of iron alloys containing copper, lead, aluminium, and zinc. Those with copper were best. R. L. Jenkins and co-workers found that the presence of about 0·1 per cent. of furfuraldehyde and 0·003 per cent. potassium iodide inhibits the action of 75 per cent. phosphoric acid on iron. The action of phosphoric acid on iron and its alloys was studied by F. Clarkson and H. C. Hetherington, R. Finkener, J. H. Gravell, J. Heimann, V. K. Pershke and co-workers, P. R. Kosting and C. Heins, A. M. Portevin and A. Sanfourche, M. V. Ruisakoff and I. N. Buschmakin, and M. Wunder and B. Janneret.

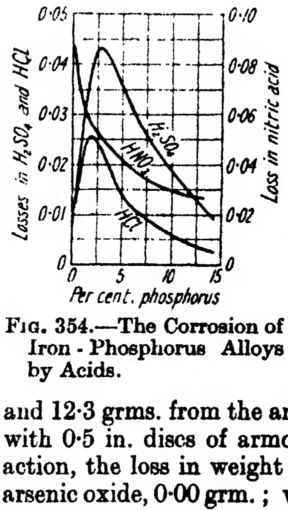


Fig. 354.—The Corrosion of Iron - Phosphorus Alloys by Acids.

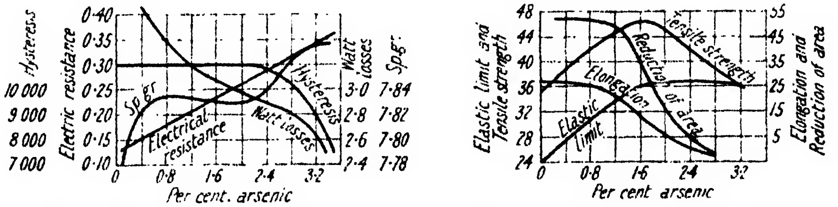
A method for protecting the surface of iron and steel from rusting was developed by T. W. Coslett,[9] and hence called *coslettizing*. The metal is coated with a basic iron phosphate by treating it with a dil. soln. of phosphoric acid to which some iron filings have been added to control the action. W. I. Oeschger modified the process by adding the oxide of some metal of the third, fourth, or fifth groups. In one modification, manganese dioxide is added to T. W. Coslett's soln. in order to accelerate the action by removing hydrogen from the metal surface. The patent was assigned to the Parker Co., and hence the process is called *parkerizing*. The subject was discussed by W. H. Allen, E. M. Baker and co-workers, E. L. Blassett, O. W. Roskill, J. Cournot and co-workers, L. E. Eckelmann, F. Kolke, L. C. Morrow, M. T. Murray, E. Rackwitz, and J. W. Wunsch.

The effect of **arsenic** on iron was discussed in connection with the iron arsenides—**9**. 51, 10. G. Tammann and K. Schaarwächter[10] observed that the attack of iron by arsenic begins at 420° and increases rapidly with a rise of temp. K. Friedrich gave the equilibrium diagram for the system: Fe–As. The alloys were discussed by O. Bauer, P. Blum, A. Carnot and E. Goutal, H. J. French and T. G. Digges, W. Guertler, W. N. Hindley, C. J. B. Karsten, E. Kordes, P. E. McKinney, J. Marchal, W. Mathesius, E. Maurer and W. Haufe, M. Merle, P. Oberhoffer, F. Osmond, and J. Weeren. C. F. Burgess and J. Aston found that alloys with 4 per cent. arsenic forge well, machine easily, and weld in the electric welder. With high arsenic, dull forging heats are not suitable. J. E. Stead found that 4 per cent. of arsenic had no marked influence on the working properties; while P. Blum said that 4 per cent. of arsenic makes steel brittle; and F. W. Harbord and A. E. Tucker found that the presence of 1·4 per cent. of arsenic does not make the metal red-short. F. Osmond added that arsenic raises the temp. at which the arrest A_3 at 855° occurs in the cooling curve, and makes the point less distinct; while it has no effect on the arrests A_2 and A_1, and it thus resembles the action of silicon—*vide infra*, the action of copper; and for P. Oberhoffer and A. Gallaschik's observations, *vide* **9**. 51, 10. J. Liedgens found:

Arsenic . . .	0·3	0·7	1·4	1·9	2·5	3·3	3·5 per cent.
Upper arrest, A_3	855°	859°	848°	—	—	—	—
Lower arrest, A_1	678°	659°	658°	655°	650°	639°	630°

Observations were made by A. E. Cameron, and P. E. McKinney. G. Hägg studied the X-radiograms of these alloys. J. O. Arnold measured the sp. gr. of the alloys. J. Liedgens' observations on the sp. gr., the mechanical properties, the electrical resistance, and the magnetic properties are summarized in Figs. 355 and 356. P. E. McKinney, and O. Bauer studied the mechanical properties of these alloys. The tensile strength and elastic limit are expressed in kilograms per sq. mm.; the elongation and reduction of area in percentages; the electric resistance, in ohms per metre per sq. mm. sectional area; the hysteresis, in ergs per c.c. C. F. Burgess and J. Aston also found that the magnetization of iron is improved by the presence of arsenic. The results for the magnetization, or magnetic induction, B, of alloys of iron and arsenic—unannealed, annealed at 675° and 1000°, and quenched from 900°—for magnetic fields of intensity H gauss, are given in Table XLIX, while the results for the coercive force ($H_{\max.}$=200), and retentivity ($H_{\max.}$=200) are given in Table L. "S" refers to Swedish iron, and "El" to electrolytic iron forged. Observations were also made by W. M. Hicks, E. K. Smith and H. C. Aufderhaar, and E. Maurer and W. Haufe.



FIGS. 355 and 356.—The Effect of Arsenic on the Mechanical, Electrical, and Magnetic Properties of Iron.

P. Berthier observed that arsenic alloys with iron are more readily corroded than iron alone. E. Heyn and O. Bauer's experiments appeared to support this state-

TABLE XLIX.—MAGNETIZATION OF IRON-ARSENIC ALLOYS.

ment, but they were not satisfied with the results. C. F. Burgess and J. Aston observed that with electrolytic iron alloyed with arsenic :

Arsenic . .	0	0·292	0·430	0·915	1·810	3·862	4·141	5·362%
Acid corrosion .	1·300	0·448	0·815	0·405	0·131	0·086	0·102	0·144
Atm. corrosion .	0·499	0·405	0·343	0·425	0·352	0·312	0·361	0·306

the acid corrosion refers to the loss in grams per sq. dm. when immersed in 20 per cent. sulphuric acid for an hour ; and atmospheric corrosion to the loss in kgrms. per sq. metre per year when exposed to the weather for 162 days from July to February. The resistance to atm. corrosion is about the same as for electrolytic iron. L. Lindet noted that the presence of **arsenic trioxide** retards the corrosion of iron—*vide infra*—and C. F. Burgess and S. G. Engle, and E. Heyn and O. Bauer made a similar observation with arsenic trioxide in sulphuric acid. E. Heyn and O. Bauer's results with 1 per cent. sulphuric acid are illustrated in Fig. 357, taking the result with no arsenic trioxide present as the standard. The addition of 0·0069 grm. reduced the attack to one-third. H. Anthes observed the formation of arsine when arsenical sulphuric acid acts on iron. Observations were made by W. N. Hindley, and A. E. Cameron and G. B. Waterhouse—*vide supra*, sulphuric acid. When iron is allowed to stand in contact with anhydrous **arsenic trichloride**, L. Kahlenberg and J. V. Steinle found that some arsenic separates out; at 100°, there is a feeble reaction. They

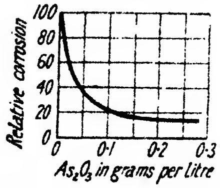

FIG. 357.—The Effect of Arsenic Trioxide on the Attack of Iron by Dilute Sulphuric Acid.

also observed no separation with **arsenic tribromide.** The effect of hydrochloric acid on the corrosion of iron by arsenic trichloride was studied by H. E. Patten.

G. Tammann and K. Schaarwächter [11] observed that **antimony** begins to attack iron at about 610°, and the rate increases rapidly with rise of temp. C. J. B. Karsten found that 1 per cent. of antimony acts very injuriously on iron; 0·144 per cent. made bar iron so cold-short as to be worthless. L. J. Thénard observed that an alloy of antimony with twice its weight of iron, sparks when it is filed. The equilibrium diagram was studied by N. S. Kurnakoff and N. S. Konstantinoff—*vide* **9**. 52, 9. G. Tammann and W. Salge studied the residue left after treating the alloy with an acidified soln. of ammonium persulphate. P. Goerens and K. Elligen observed that the temp. of the primary separation of austenite from molten pig-iron, and the solidification temp. of the eutectic, are lowered by antimony; the temp. of the pearlitic change is not affected; and the magnitude of the recalescence decreased as the proportion of antimony was increased. G. Hägg studied the X-radiograms. E. K. Smith and H. C. Aufderhaar, and A. M. Portevin found that antimony affected the mechanical properties like arsenic does. A. L. Norbury, and H. J. French and T. G. Digges studied some of the alloys. C. F. Burgess and J. Aston said that the alloys of antimony seem of no value as a magnetic material. The alloys are difficult to work. W. Guertler, and P. Oberhoffer discussed the alloys, and A. Lotti observed that iron pans are corroded by molten lead containing antimony and copper. H. E. Patten studied the corrosion of iron by **antimony pentachloride** in the presence of hydrochloric acid. The reduction of antimony from soln. of **antimony salts** has been previously discussed—**9**. 52, 6. The reaction was studied by J. Thiele.

C. J. B. Karsten found that 1 per cent. of **bismuth** had little effect on the quality of the iron, but the metal did not work so well; C. F. Burgess and J. Aston examined this subject. The alloys were discussed in connection with the bismuthides—**9**. 53, 7. G. Hägg studied the X-radiograms. C. F. Burgess and J. Aston found 2 per cent. of diamagnetic bismuth improved the ferromagnetism of iron; otherwise, the alloys furnished no features of particular interest. For the action of antimony, *vide* the antimonides, **9**. 52, 9; and bismuth, *vide* the bismuthides, **9.** 53, 7. P. Oberhoffer discussed the alloys. N. Ageeff and M. Zamotorin studied the diffusion of bismuth in iron. E. K. Smith and H. C. Aufderhaar found that bismuth softens and decreases the strength of cast iron. The reduction of bismuth from soln. of **bismuth salts** has been previously discussed—**9**. 53, 5. F. E. Brown and J. E. Snyder found that **vanadyl trichloride,** $VOCl_3$, does not act on iron either at ordinary temp. or at the b.p.

S. Konobejewsky [12] discussed the solid soln. of iron in graphite; the solid soln. of carbon in iron has been previously discussed. G. Tammann and K. Schaarwächter observed that **carbon** begins to attack iron at about 1145°. H. Trapp discussed the mechanism of the attack of iron by carbon. For the action of carbon, *vide infra*, corrosion; cementation; the allotropic forms of iron; the carbides, **6**. 39, 20; and *vide supra* for the effect of carbon on the physical properties of iron. F. Fischer and H. Bahr studied the carbides; and W. F. Holbrook and co-workers, the diffusion of carbon in molten iron. A. Rossel, and A. Rossel and L. Franck found that when iron is heated with **calcium carbide** in air some iron nitride, and calcium oxide are formed. O. Meyer studied the action of **silicon carbide, chromium carbide,** and **molybdenum carbide** on iron, and found the metal is attacked at temp. approximating 1500°. The absorption of **methane** by iron is indicated in connection with Table LI. G. Charpy and S. Bonnerot said that when iron is heated in contact with graphite it does not become carburized at 950° unless at least traces of oxygen or of a carbon oxide are present, but F. Giolitti and co-workers do not agree. W. Hempel, and F. Osmond found that the diamond reacts with iron at 1160°, and sugar-charcoal and graphite at about 1400°. According to R. Schenck, the action of methane can be represented by the equation $3Fe+CH_4=Fe_3C+2H_2-35{,}811$ cals., where

$CH_4 = C + 2H_2 - 21{,}368$ cals. The relative proportions of the gases at different temp., and under atm. press., in the system: $CH_4 \rightleftharpoons C + 2H_2$, are:

	310°	445°	580°	680°	710°	720°	740°
CH_4 . . .	99·20	77·00	36·65	16·82	13·00	11·95	10·90
H_2 . . .	0·80	23·00	65·35	83·18	87·00	88·05	98·10

and in the system: $3Fe + CH_4 \rightleftharpoons Fe_3C + 2H_2$:

	310°	360°	445°	580°	680°	710°	720°
CH_4 . . .	—	98·30	95·70	59·80	22·70	15·23	12·07
H_2 . . .	trace	1·70	4·30	40·20	77·30	87·77	87·93

The results are plotted in Fig. 358. The two curves intersect at 720°. The reaction was studied by T. Watase, and F. Eisenstecken—*vide* cementation. The reaction was studied by A. Johansson and R. von Seth, E. D. Campbell, M. Mayer and V. Altmayer. F. Durau and C. H. Teckentrup found that the absorption of methane by iron is purely adsorption, and similarly with methane, **ethane**, and **propane**. H. S. Taylor and R. M. Burns observed that at 25°, 100°, and 218°, one vol. of iron absorbs respectively 0·25, <0·05, and <0·05 vol. of **ethylene.** The reaction was studied by R. N. Pease and H. S. Taylor, and W. Ipatéeff and N. Kliukvin. A. Magnus and R. Klar studied the absorption of ethylene by pyrophoric iron; and F. Durau and C. H. Teckentrup found the adsorption of ethylene is purely an adsorption process, and similarly with **propylene.** H. Hollings and R. H. Griffith studied the adsorption of hydrocarbons. H. Moissan and C. Moureu observed that finely-divided iron catalytically decomposes **acetylene** into its elements, and at the same time forms a trace of a condensation product of acetylene. The action of acetylene on metals was also discussed by H. Reckleben and J. Scheiber, W. R. Hodgkinson, E. Tiede and W. Jenisch, and J. F. Durand and M. Banos. U. Hofmann and E. Groll observed that the solid phase produced when benzene vapour acts on iron at 700° contains carbon, iron, and principally cementite. S. I. Levy and R. Defries studied the corrosive action of **turpentine** on iron. U. Hofmann and E. Groll found that at 700°, **benzene** passed over iron furnishes carbon and cementite. S. P. Uspensky and N. I. Laduizhnikova observed a loss of 10 mgrms. per sq. cm. by 8 months' exposure of iron to motor benzene. E. W. Kanning and O. W. Brown studied the catalytic decomposition of **kerosene** by iron.

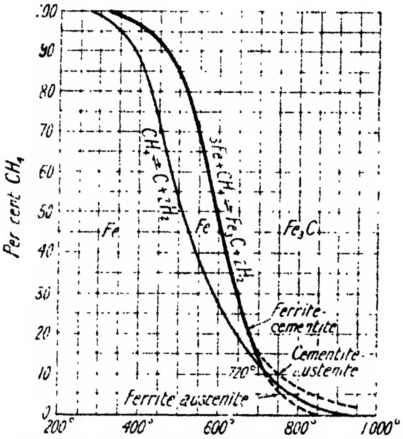

FIG. 358.—Equilibrium Curves for the System with Methane and Iron.

For the absorption of **carbon monoxide** by iron, *vide* Table LI. A. F. Benton and co-workers, K. Iwase, F. Rapatz, and A. Villachon and G. Chaudron also discussed the subject. F. Durau and C. H. Teckentrup showed that the absorption is purely an adsorption process. According to H. S. Taylor and R. M. Burns, one vol. of iron absorbs 0·70, 0·20, and 0·10 vol. of carbon monoxide respectively at 25°, 110°, and 218°. A. Stoffel said that the pentacarbonyl which is formed is adsorbed by the iron, and it forms a protective film on the surface of the metal. N. Parravano and C. R. del Turco found that deoxidizing agents in steel reduce the occluded carbon monoxide; and they also usually reduce carbon monoxide and dioxide at high temp. K. A. C. Elliott studied the oxidation of cystein and thioglycollic acid with iron catalysts. P. Farup discussed the catalytic action of iron ores in reducing carbon monoxide. R. N. Pease and L. Stewart compared the catalytic activity of iron, nickel, cobalt, copper, and silver on the hydrogenation of ethylene ; S. Kodama, C. M. Loane, and H. Ritter studied the catalytic action of iron in the synthesis of oils, etc. R. Yoshimura, A. Jaeger, J. H. Jones and co-workers, S. Kodama and K. Fujimura, R. N. Pease and H. S. Taylor, P. Rischbieth, H. Tropsch and A. von Philippovich, O. Warburg, O. Warburg and W. Brefeld, and R. Yoshimura, the activation of charcoal catalysts by iron ; O. Baudisch and L. A. Welo, the formation of a blue colour with benzidine hydrochloride and hydrogen dioxide, and the growth of the *Bacterium lepisepticum* ; and M. C. Boswell and C. H. Bayley, the action of ceric oxide as a promoter of the catalytic activity of iron. B. S. Srikantan compared the atomic energy and efficiency of iron as a catalyst.

H. F. Coward and P. G. Guest compared the ignition temp. of gases by heated metal bars, and found that iron did not give comparable results. H. C. Greenwood, and A. Johansson and R. von Seth, studied the surface decarburization of steel by heating it in carbon dioxide. N. Parravano and C. R. del Turco found that the deoxidation of steel reduces the amount of absorbed carbon monoxide, and that the usual deoxidizing agents, employed in the steel industry, reduce both carbon monoxide and dioxide at high temp. H. St. C. Deville observed that carbon monoxide, like hydrogen, can diffuse through red-hot iron ; and a similar observation was made by T. Graham. According to C. Decroly, at atm. press., carbon monoxide does not diffuse through a steel tube of 3·5 mm. thickness at 800° and at 1000°. L. Cailletet found that the gases which escape from cast iron in a state of fusion contain some carbon monoxide as well as hydrogen and nitrogen. T. Graham obtained the gas from meteoric iron. P. A. Klinger found that electrolytic iron with 0·03 per cent. of carbon contained 0·0075 per cent. CO and 0·0078 per cent. CO_2, and after heating to redness in carbon monoxide, contained 0·0050 per cent. CO, and 0·0059 per cent. CO_2 ; while with electrolytic steel with 1·2 per cent. of carbon and containing 0·0050 per cent. CO and 0·0108 per cent. CO_2, after heating to redness in carbon monoxide, contained 0·0044 per cent. CO and 0·0138 per cent. CO_2. Observations were made by V. Lombard, H. C. H. Carpenter and C. C. Smith, N. Nikitin, and A. Villachon and G. Chaudron. With the molten metals, P. A. Klinger found the results indicated in Table LI. P. D. Merica discussed the effect of absorbed gas on the magnetic properties.

TABLE LI.—THE EFFECT OF THE ABSORPTION OF CARBON MONOXIDE BY MOLTEN IRON.

		Before			After saturation with CO			
	C per cent.	O per cent.	CO per cent.	CO_2 per cent.	C per cent.	O per cent.	CO per cent.	CO_2 per cent.
Electrolytic iron .	0·04	0·002	0·0525	0·0079	0·03	0·022	0·0450	—

Crucible steel . .	0·72	0·002	0·0575	—	0·60	0·021	0·1337	—

The formation of iron carbonyls by the action of carbon monoxide on finely-powdered iron at about 120° was discussed in connection with the carbonyls—5. 39, 27. T. Bahr observed that at 400° to 600°, some substances similar to humic acid are formed along with the carbon. J. Garnier inferred from the luminosity of the flame of furnaces in the manufacture of iron and steel, and from the nature of the flue-dust, that volatile compounds of iron and carbon monoxide are formed in the furnace ; and H. Morton, in manufacturing gas. A. Villachon and G. Chaudron considered that in molten iron, some carbon monoxide is dissolved as a carbonyl.

V. Falcke, A. N. Guntz, H. Nippert, H. Nishimura, and H. J. van Royen found that iron reacts with carbon monoxide at about 600°, forming ferrous oxide and carbon. The reactions were discussed in connection with the blast-furnace. R. Schenck found the equilibrium conditions in the reaction: $2CO \rightleftharpoons C+CO_2$:

	450	480°	500°	580	640°	700	800°
CO . .	2·0	3·5	5·0	11·75	35·5	59·0	86·1 per cent.
CO_2 . .	98·0	96·5	95·0	82·25	64·5	41·0	13·9 ,,

and for the reaction: $3Fe+2CO \rightleftharpoons Fe_3C+CO_2$:

	480°	500°	580°	640°	680	700°
CO . . .	12·12	15·50	32·36	47·80	58·86	64·00 per cent.
CO_2 . . .	87·87	84·50	67·64	52·20	41·14	36·00 ,,

The results are plotted in Fig. 359 along with an approximation for the reaction: $2CO+Fe_3C \rightleftharpoons Fe_3C_2+CO_2$. There are also many other side-reactions, *e.g.* $Fe_3C+4CO_2 \rightleftharpoons 3FeO+5CO$, discussed L. Gruner, W. Leybold, H. C. H. Carpenter and C. C. Smith, V. Falcke, S. Hilpert and T. Dieckmann, A. Gautier and P. Clausmann, etc.—in connection with the different iron oxides (*q.v.*), and with the reactions in the blast-furnace (*q.v.*). J. E. Stead discussed the action of blast-furnace gases on iron. W. P. Fishel and J. F. Wooddell observed more carbon dioxide is formed with iron in carbon monoxide than corresponds with the equilibrium value at 800° to 1100°. U. Hofmann discussed the form of the carbon or graphite deposited on iron at 900°. According to A. Gautier and P. Clausmann, when a mixture of moist carbon monoxide and hydrogen is passed over iron at 250° to 300°, formaldehyde, as well as a fatty substance of m.p. 35°–36°, can be detected in the products of the reaction; and L. Vignon observed that methane is formed between 500° and 1000°. H. Remy and H. Gönningen, H. Remy, J. V. Vaughen and W. A. Lazier, A. Bramley and H. D. Lord, W. Gluud and R. Schönfelder, E. Audibert and A. Raineau, K. Fujimura, T. Watanabe, and H. Tutiya studied the catalytic decomposition of carbon monoxide by iron.

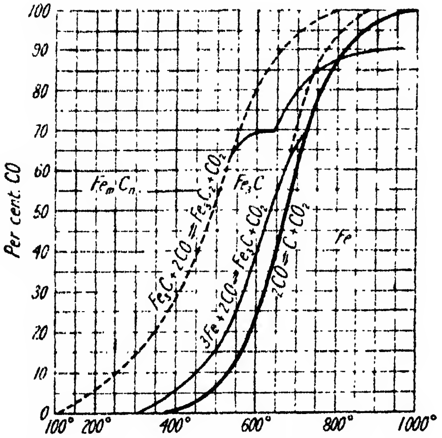

FIG. 359.—Equilibrium Curves for the System with Carbon Monoxide and Iron.

According to G. Tissandier, at 1000°, iron in an atm. of carbon monoxide forms ferrous oxide; and in an atm. of **carbon dioxide** at 900°, ferrous oxide is formed, while at 1200°, ferrosic oxide is produced. The reaction is discussed in connection with the respective iron oxides. B. Beer discussed the absorption of carbon dioxide by iron, see Table LII. F. Durau and C. H. Teckentrup showed that the

TABLE LII.—ACTION OF CARBON DIOXIDE ON IRON.

absorption process is purely one of adsorption. A. Magnus and B. Klar, and N. I. Nikitin found that carbon dioxide is strongly absorbed by pyrophoric iron even at ordinary temp.; and a chemical action occurs at 500°; and R. Ruer and J. Kuschmann, that 100 grms. of reduced iron powder absorbed 5 mgrms. of carbon dioxide. P. P. Fedotéeff and T. N. Petrenko observed that the action of carbon dioxide at 1000° to 1100° resembles the action of steam—*vide supra.* H. S. Taylor and R. M. Burns found that a little carbon dioxide—less than 0·05 vol. per vol. of metal—is absorbed at 25° and 110°. F. G. Finzel observed that a sample of non-pyrophoric iron adsorbed more carbon dioxide than did a sample of pyrophoric iron. P. P. Fedotéeff and T. N. Petrenko studied the oxidation of iron by carbon dioxide at 1000° to 1100°, and found that the composition of the product varies continuously from ferrous to ferrosic oxide. Observations on the action of carbon dioxide at a high temp. were also made by F. von Bacho, G. Neumann, P. A. Klinger, W. H. Hatfield, and C. B. Marson and J. W. Cobb. H. Tutiya observed the formation of no new compound in the catalysis of the decomposition of carbon monoxide by iron, the reduction proceeds $Fe_2O_3 \rightarrow Fe_3O_4 \rightarrow FeO \rightarrow Fe_3C$.

In 1774, T. Bergman observed that iron dissolves in water holding carbon dioxide in soln. J. Tillmans and B. Klarmann found that oxygen-free water, containing carbon dioxide in soln., dissolves iron until its water has attained a $H^{\cdot}$-ion conc. of 10^{-7}. The rate of dissolution depends on the velocity of flow, the time of contact with the pipes, the size and nature of the pipes, and the $H^{\cdot}$-ion conc. of the water. The presence of iron tends to form a supersaturated soln. of ferrous carbonate, the solubility product of $FeCO_3$ being $2{\cdot}7 \times 10^{-10}$. Water with less than 100 mgrms. of H_2CO_3 does not attack iron pipes to any great extent; but with more conc. soln. or carbonic acid, the attack is marked. Carbonic acid, although a very weak acid, can act appreciably on iron; with an excess of carbon dioxide in the absence of air, the reaction is symbolized: $2H_2O+2CO_2=H_2(HCO_3)_2$; and if an excess of iron be present, $Fe+H_2CO_3=H_2+FeCO_3$. G. T. Moody observed that 250 c.c. of a sat. soln. of carbon dioxide in water at one atm. press. dissolved after:

	20 hrs.	56 hrs.	96 hrs.	26 days
FeO per litre	0·2546	0·3771	0·8172	2·139 grms.

The soln. was colourless in the absence of air; but when air was present, the mixture was coloured by the ferrous carbonate, and ferrous and ferric hydroxides in varying proportions. This reaction was also studied by G. Just, R. Girard, A. Bramley and H. D. Lord, and G. W. Whitman and co-workers—*vide infra,* Fig. 360. W. Leybold, and B. Klarmann discussed the solubility of iron in carbonic acid—*vide infra.* According to A. Schleicher and G. Schultz, the relative corrosion factors for wrought iron and cast iron in soln. of carbonic acid are, respectively, 100 and 273 in the absence of air, and 100 and 152 in the presence of air. H. Henecka, and E. Müller and H. Henecka found that carbonic acid under a

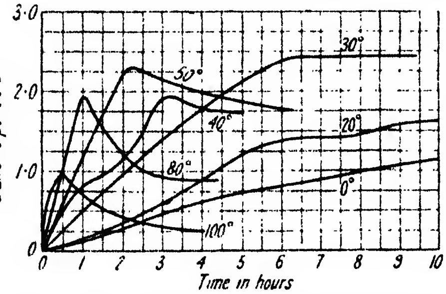

FIG. 360.—The Effect of Temperature on the Solubility of Iron in Carbonic Acid.

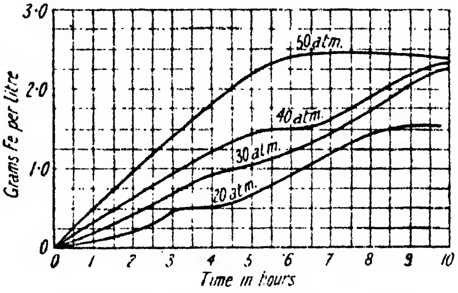

FIG. 361.—The Effect of Pressure on the Solubility of Iron in Carbonic Acid.

high press. dissolves iron to form easily-soluble ferrous hydrocarbonate; the equilibrium constant for the reaction $Fe+2H_2CO_3=Fe(HCO_3)_2+H_{2gas}$, is $K=[Fe(HCO_3)_2]/H_2CO_3]^2$, or $K=1{\cdot}2\times10^3$. There is also the reaction $Fe(HCO_3)_2 \rightleftharpoons FeCO_3+CO_2+H_2O$. H. Henecka's observations on the rate of soln. of iron in water saturated with carbon dioxide at 50 atm. press., and at temp. between 0° and 100°, are summarized in Fig. 360, and the rate of soln. of iron in water saturated with carbon dioxide at 30° and 20 to 50 atm. press., in Fig. 361—*vide infra*, ferrous hydrocarbonate. W. Leybold observed that water sat. with carbon dioxide at atm. press. in 10 weeks dissolved 1·058 grms. of iron. According to A. Bruno, the vigorous shaking for thirty-six to forty hours of a steel bottle containing water and iron-filings in an atm. of carbon dioxide causes the whole of the carbon dioxide to be replaced by hydrogen according to the equation: $CO_2+H_2O+Fe=FeCO_3+H_2$. If a glass vessel is used, this reaction is accompanied by the absorption of part of the carbon dioxide by the alkali of the glass. Further, a mixture of iron-filings, water, and nitrobenzene yields aniline just as if a strong acid were employed. P. Petit found that when water containing 638 mgrms. of calcium carbonate per litre dissolved in carbon dioxide, but neutral to phenolphthalein, is brought in contact with finely-powdered iron, more than half the carbonate is precipitated, and iron is dissolved. Water sat. with carbon dioxide will dissolve as much as 500 mgrms. of iron per litre, with liberation of an eq. quantity of hydrogen. The iron is converted into ferrous carbonate, and if the soln. is exposed to air, ferric oxide is precipitated. The water of the Moselle was found to dissolve 3·15 mgrms. of iron per litre; if previously treated with a current of carbon dioxide for a few minutes, it dissolved 200·6 mgrms.; but if mixed with lime-water until slightly alkaline to phenolphthalein, it dissolved no iron at all. J. V. Emmons, and A. Johansson and R. von Seth studied the surface decarburization of steel by heating it in carbon dioxide. P. A. von Bonsdorff observed that rusting does not occur in an atmosphere containing traces of carbon dioxide provided the conditions are such that no water can deposit on the metal. U. R. Evans found that iron and steel rusted a little particularly along the small grooves left by the emery treatment when exposed to water vapour alone; and carbon dioxide did not produce any great acceleration in the corrosion of iron and steel, though it appeared to favour the rusting.

A. Bolis observed that the loss suffered by cast iron in contact with boiling **carbon tetrachloride** for 10 hrs. is inappreciable; the metal acquires a dark coating which preserves it from further attack. If the carbon tetrachloride is saturated with moisture, the metal is appreciably attacked by the boiling liquid. A mixture of carbon tetrachloride with one-third its vol. of water caused cast iron to lose about 5 per cent. of its weight in the course of 10 hrs.' boiling. The subject was investigated by A. E. Wood and co-workers, E. V. Zappi, H. W. Doughty, A. W. Smith, A. Bolis, J. R. Crocker, H. E. Pattèn, S. G. Sastry, J. Milbauer, L. Vernitz and A. Kudinova, and F. H. Rhodes and J. T. Carty. T. Midgley and A. L. Henne found steel resists the action of **carbon difluorodichloride** at 175°. J. Formanek found that the action of carbon tetrachloride during 8 months is negligibly small; but with **trichloroethylene** and **tetrachloracetylene,** the action is small but perceptible; J. Milbauer observed that the presence of ethyl alcohol increases the rate of attack by boiling carbon tetrachloride. H. E. Patten observed no action occurs with iron and **chloroform,** or **ethyl chloride.** F. Durau and C. H. Teckentrup observed that the absorption of chloroform by iron is purely an adsorption process. J. G. Tapley and co-workers, H. R. S. Clotworthy, B. R. Parkinson, and J. B. Peel and P. L. Robinson found that when iron is heated in the vapour of **carbon disulphide,** at 1000°, impure ferrous sulphide is formed. M. Delépine and L. Ville investigated the action of **carbonyl chloride** on iron. J. Tapley and co-workers, J. F. G. Hicks, and B. R. Parkinson discussed the corrosive action of **hydrocyanic acid** in town gas on the conveying pipes (*vide infra*); and G. P. Gray and E. R. Hulbert, the action of hydrocyanic acid on various metals, most of which promote the decomposition of liquid hydrogen cyanide. The action of **cyanogen,** and of **cyanides** on iron has been discussed in connection with the cementation process. F. Durau and C. H. Teckentrup found that the absorption of cyanogen by electrolytic iron is a chemical process. V. E. Hillman and E. D. Clark, H. Braune, H. Fay, W. Giesen, J. E. Johnson, and J. K. Smith studied the nitrogenization of iron by means of cyanides. M. Berthelot observed no reaction between iron and cyanogen in a sealed tube at 100°; at 300° some iron cyanide is formed without the evolution of nitrogen, and at 500°, free nitrogen and some polymerization products are formed. H. Braune noted that the reaction with cyanogen is very slow at 600° to 700°, but rapid at 1000°. L. Hackspill and R. Grandadam found that iron reacts with the alkali cyanides in vacuo at 600° in accord with the equation: $2NaCN+Fe=2Na+N_2+$Iron carbide; L. Hackspill did not get the corresponding result with lithium cyanide. W. Heike, and A. Vournasos did not observe any reaction between iron and fused potassium cyanide. L. Elsner observed that at ordinary temp. iron dissolves in a soln. of potassium cyanide, and hydrogen is evolved; and C. Reichard said that cyanogen is given off. M. Centnerszwer and J. Szper, and E. F. Kern observed that iron is dissolved in the electrolysis of soln. of potassium cyanide—*vide supra*, the passivation of iron. A. Brochet and J. Petit studied the action of soln. of potassium cyanide on metals under the influence of an alternating current. F. W. Bergstrom observed that a soln. of **ammonium cyanide** in liquid ammonia, with iron, forms a complex $(NH_4)_4[FeCy_6]nNH_3$; with mercuric cyanide, and with **ammonium thiocyanate,** under similar conditions, there is a very slow reaction; and with **mercuric thiocyanate,** the complex $Hg(CyS)_2.4NH_3$ is formed. When iron is heated with **potassium thiocyanate** it forms potassium ferrocyanide. N. Tananajeff and G. Tkatschenko found that an aq. soln. of the salt dissolves iron, forming ferrous thiocyanate. A. Brochet and J. Petit found that iron dissolves in a soln. of **potassium cyanate,** hydrogen is evolved, and potassium ferrocyanide is formed.

H. Adkins and W. R. Peterson found that **methyl alcohol** is oxidized to form aldehyde, using iron or iron-molybdenum as catalyst. W. Ledbury and E. W. Blair, and E. W. Blair and co-workers observed that a 10 per cent. soln. of **formaldehyde** readily reacts with iron in a sealed tube at 155°. Hence the danger of iron apparatus in the distillation of formalin. H. Will and F. O. Landtblom found iron and steel are not attacked by a dil. soln. of formalin, but a conc., 40 per cent. soln. readily attacks iron—possibly owing to the presence of some formic acid; W. Löb noted that a 20 per cent. soln. of formaldehyde slowly attacks iron. G. Batta found that the presence of a little formaldehyde in acids facilitates the dissolution of iron. H. Tropsch and O. Roehlen studied the catalytic decomposition of formaldehyde by iron, and A. Schellenberg, and H. Tropsch and A. Schellenberg, by **methanol.** J. Malmejac studied the action of 95 per cent. **alcohol** on iron; and the action of absolute alcohol on the metal was studied by L. Lindet, E. Boulanger, E. Heinzelmann, K. R. Dittrich, and M. Wawrziniok. S. P. Uspensky and N. I. Laduizhnikova found that with commercial ethyl alcohol, iron lost 29·9 mgrms. per sq. cm. in 9 months, and with commercial methyl alcohol, 43·6 mgrms. per sq. cm. in the same time; whilst with the vapour of commercial methyl alcohol, 7 mgrms. per sq. cm. were lost in 9 months' and with refined methyl alcohol, 6·7 mgrms. per sq. cm. in the same time. With **acetone,** iron lost 9·8 mgrms. per sq. cm. in 8 months. C. Dufraisse and R. Horclois studied the catalytic effect of iron on various organic compounds, sodium sulphate, etc.; and S. Swann, the electro-reduction of ketones at iron cathodes.

A. Hébert studied the action of **organic acids** on iron. A. Scheurer-Kestner, and K. A. Hofmann and G. Bugge found iron dissolves in **formic acid,** producing ferrous formate. H. J. Prins found that the attack is hastened if nitrobenzene be present. J. H. G. Monypenny found that mild steel lost 0·33 mgrm. per sq.

cm. per hr. in 10 per cent. formic acid. J. C. G. de Marignac observed that when iron is allowed to stand in contact with **acetic acid** for a few weeks, crystals of ferrous acetate are formed. The dissolution of iron by vinegars, and the corrosion of iron in the acetic acid industry, was observed by B. Franz, C. Luckow, A. Steinmetz, and W. Hoffmann; and H. Wieland and W. Franke studied the speed of rusting in dil. acetic acid. P. A. von Bonsdorff, and N. A. Bouchkoff noted the rapid corrosion of iron in the vapour of acetic acid and air. S. Leet noted the graphititis of cast-iron retorts in the distillation of vinegar—*vide infra*. According to W. Rohn, cold, 10 per cent. acetic acid dissolves in 24 hrs. 0·14 grm. per sq. dm. from the unannealed metal, and 0·21 grm. from the annealed metal at ordinary temp.; and with the hot acid, in 1 hr., 0·79 grm. was dissolved from the annealed, and 0·76 grm. from the unannealed metal. F. Schmitz observed that with steels containing 0·06, 0·42, and 0·92 per cent. of carbon, 20×20×10 mm. with a 4 mm. hole, the losses with 80 per cent. acetic acid were, respectively, 0·700, 0·584, and 0·886 grm. in 180 hrs. The action of acetic acid on iron was also studied by M. Ballay, W. Guertler and T. Liepus, A. Jouve, G. W. Whitman and R. P. Russell, P. Bardenheuer and K. L. Zeyen, P. Kötzschke and E. Piwowarsky, O. Kröhnke, and M. L. Hamlin and F. M. Turner. According to W. H. Hatfield:

				Steel			
	Electrolytic iron	Armco iron	Wrought iron	0·39 per cent. C	0·92 per cent. C	Steel 11·75 per cent. Mn	Cast iron 3·3 per cent. C
Wine vinegar . .	0·0061	0·0053	0·0139	0·0044	0·0042	0·0397	0·2640
Acetic acid, 33 per cent..	0·0128	0·0133	0·2810	0·2072	0·1697	0·0999	0·6693
Citric acid, 5 per cent. .	0·0106	0·0163	0·1943	0·2025	0·1843	0·0965	0·1950

J. H. G. Monypenny found that the losses of mild steel in mgrms. per sq. cm. per hour with 5, 15, and 33 per cent. acetic acid were, respectively, 0·067, 0·105, and 0·115; and with glacial acetic acid, 0·124. H. J. Prins found that the dissolution of iron in acetic acid is accelerated by the presence of nitrobenzene. The effects with various alloy steels (*q.v.*) were studied by J. H. G. Monypenny, W. H. Hatfield, O. K. Parmiter, H. S. Rawdon and A. I. Krynitsky, A. Fürth, and M. L. Hamlin and F. M. Turner. G. Arth observed that in dil. acidic soln. of **alkali acetate,** and a low current density, iron goes into soln., but at higher current densities the metal becomes passive. F. Wüst and N. Kirpach found the average losses per sq. cm. per hour with iron in an agitated 40 per cent. soln. of **monochloroacetic acid** were 0·10 mgrm. in the first 24 hrs., 0·16 mgrm. in the second 24 hrs., 0·14 mgrm. in the third 24 hrs. A. Renard observed that **propionic acid** dissolves iron, forming pale green crystals of the ferrous salt.

According to A. Hébert, **stearic acid,** and other fatty acids, when heated with iron to 350°, form ketones which decompose at that temp. The reaction was studied by A. Mailhe, T. H. Easterfield and C. M. Taylor, and G. Schicht and A. Grün, who assumed that the formation of a ferrous salt precedes the formation of the ketone. W. Singleton found that steel is corroded after standing 1000 hrs. at 80° in contact with stearic acid, whilst **oleic acid** at 60° and 80° did not corrode the metal. C. B. Gates obtained a similar result with oleic acid, but A. Gunn and E. F. Harrison found that at ordinary temp. iron is perceptibly attacked during a prolonged contact with oleic acid, and the acid is coloured dark red or brown. M. Welwart made analogous observations. E. Marazza said that wrought iron resists attack by the fatty acids better than steel or cast iron—*vide infra*, greases, and oils. Stainless steel was found by J. H. G. Monypenny to resist attack by oleic acid at ordinary temp. and at 60° for prolonged periods of time. C. B. Gates found that copper is precipitated by iron from a soln. of copper oleate, or from fused **copper palmitate, stearate,** or **margarate.** O. F. Hunziker and co-workers studied the action of **lactic acid** and milk on iron. F. Schmitz found that with **citric acid** (1 : 2) and samples of iron, 20×20×10 mm., containing 0·06, 0·42, and 0·92 per cent. of carbon, when the test-pieces had a 1 mm. hole, the losses were respectively 0·195, 0·370, and 1·842 per cent. in 180 hrs.; W. H. Hatfield's observations with 5 per cent. citric acid are indicated above. K. K. Järvinen also studied this subject. J. H. G. Monypenny found mild steel lost 0·260 mgrm. per sq. cm. per hour in 6 per cent. citric acid. T. N. Morris and J. M. Bryan noted that traces of a salt of tin inhibit the corrosive action of citric acid. V. Duffek, and A. Jouve studied the corrosive action of **tartaric acid**—*vide infra.* J. H. G. Monypenny found that mild steel lost, respectively, 0·062 and 0·14 mgrm. per sq. cm. per hour in normal and in 25 per cent. tartaric acid. A. Jouve studied the corrosive action of **oxalic acid.** O. Bauer and W. Mecklenberg observed that dil. oxalic acid has a mild action on iron and it forms a protective film of ferrous oxalate on the metal. J. H. G. Monypenny found that mild steel in a normal soln. of oxalic acid lost 0·036 mgrm. per sq. cm. per hour, and F. Wüst and N. Kirpach observed that the losses in mgrm. per sq. cm. per hour in cold sat. soln. of oxalic acid were 0·052 during the first 24 hrs., 0·070 during the second 24 hrs., and 0·060 during the third 24 hrs. V. Duffek studied the action of oxalic acid. F. W. Bergstrom observed that a soln. of **ammonium oxalate** in liquid ammonia acts very slowly on iron. R. Girard studied the attack by **carbolic acid** or **phenol**—*vide supra,* hydrochloric acid. J. H. G. Monypenny found that mild steel loses 0·005 mgrm. per sq. cm. per hour when in contact with 5 per cent. carbolic acid. F. Zetzsche and co-workers observed that the hydrogen of the OH-groups of some phenols can be replaced directly by iron when the soln. also contains some water. D. Müller, R. E. Lyons and L. T. Smith, G. Bunge, H. Kast, L. Loskiewicz, J. Saposchnikoff, and F. W. Richardson examined the action of **picric acid** on iron. According to H. Pomeranz, the nitro-groups of picric acid, in hydrochloric acid soln. in contact with iron, are reduced to amino-groups; the ferrous picrate first formed is rapidly oxidized to ferric picrate. F. Wüst and N. Kirpach found that the losses in mgrm. per sq. cm. per hour in a cold, sat. soln. of picric acid were 1·20 in the first 24 hrs., and 0·70 in the second 24 hrs.; after that, a protective film appeared on the metal. *Vide supra,* the etching of iron by picric acid and picrates, discussed by H. H. Shepherd, J. H. G. Monypenny, and Société Grauer et Weil. J. B. Trommsdorff observed that iron is very slightly soluble in an aq. soln. of **benzoic acid**; and S. Barilari, that **salicylic acid,** with iron filings, develops a little hydrogen, very slowly at ordinary temp. and more rapidly when warmed. F. Zetzsche and co-workers added that the evaporation of the soln. furnishes ferrous salicylate. W. J. Clark found that **gallic acid** forms ferrous gallate in contact with iron—*vide infra,* inks. M. Schirmonsky, and St. Reiner studied the action of **naphthenic acid** on iron.

According to S. Micewicz, **nitrobenzene** is readily reduced to aniline by powdered iron, and in an aq. soln. of magnesium chloride—the compound $2C_6H_5NH_2.MgCl_2.6H_2O$ is said to be formed at an intermediate stage of the reaction. S. G. Sastry, and H. W. Doughty examined the corrosion of metals by **organic halides.** L. Luuyt noted that soln. of **sugar** attack iron. According to D. Klein and co-workers, if iron is heated with a soln. of cane-sugar in a sealed tube at 115° to 125°, it is strongly attacked, and hydrogen is evolved. Some ferrous acetate is formed. Similar results were obtained with **invert-sugar** and **maltose,** but **glycerol** and **mannite** acted more slowly. J. H. Gladstone, C. Kosmann, A. Lodin, L. Kayser, J. H. G. Monypenny, D. Klein and A. Berg, I. McNiece, and K. K. Järvinen studied the corrosive action of soln. of sugar on iron at ordinary temp. If air is excluded, no action occurs. M. L. Hamlin and F. M. Turner found that **molasses** slowly attacks iron. J. A. N. Friend and co-workers, W. H. Hatfield, and J. H. G. Monypenny discussed the action on iron of organic colloids and **foodstuffs.**

P. H. Emmett and R. W. Harkness studied the catalytic decomposition of **azomethane, dimethylhydrazine,** and **ethylamine** by iron. L. Vignon, J. T. Wood, T. L. Phipson, and L. Manstetten examined the corrosive action of **tannin** on iron plates. J. I. Crabtree and G. E. Matthews observed that **hydroquinone,** and

pyrogallol developing baths are discoloured by iron; and they, and also E. Eule, examined the action of other photographic soln. on the metals. A. Benedicenti and S. Rebello-Alves found that powdered iron unites with the **protein** when shaken with a soln. of egg-albumin or blood serums. According to H. Handowsky, the oxidation of **leucine** is not affected when a 0·5 to 1·0 per cent. soln. is shaken in air or oxygen with ferrous sulphate, ferrosic oxide, ferric oxide hydrosols, and a mixture of iron and iron oxide obtained by heating the oxalate. Iron obtained by the hydrogen reduction of the oxide effects the oxidation of leucine with the production of carbon dioxide, ammonia, and isovaleraldehyde (isolated as the nitrophenylhydrazone). **Glycine, alanine, valine, tyrosine, histidine, formyl-leucine, and glycyl-leucine** are similarly oxidized by the reduced iron, yielding substances which give a positive fuchsine-sulphurous acid reaction. The oxygen uptake with leucine is never more than 19 per cent. of that required for complete combustion; and the oxidation is inhibited by hydrocyanic acid. When the heated reduced iron is cooled in nitrogen a black iron powder is obtained which has no oxidizing action on leucine, but if the inactive iron is reheated for some time and subsequently cooled in hydrogen, the oxidizing power is regenerated. Consequently, it is not the iron but the hydrogen dissolved in it which effects the oxidation of amino-acids, and the "active" hydrogen reacts with oxygen to give hydrogen peroxide which is catalytically decomposed on the surface of the iron. Similarly, animal charcoal loses its power to catalyze the oxidation of leucine when heated and cooled in nitrogen, but regains this power when reheated and cooled in hydrogen. The *active iron* was studied by O. Baudisch and L. A. Welo, and by A. Simon and K. Kötschau. It gives a blue colour in contact with an alcoholic soln. of guaiacum resin and hydrogen dioxide; and it also gives a blue colour with a soln. of benzidine—*vide* ferrous salts. J. C. Elgin and co-workers studied the effect of iron and nickel catalysts on the sulphur **naphthas** and **petroleums**; and K. A. C. Elliott, and N. W. Pirie, the catalytic action of iron in the oxidation of **cysteine,** and **thioglycolic acid.**

The corrosion of iron by the by-products in the manufacture of coal-gas was discussed by E. Donath,[13] P. Parish, W. E. Dennison, and A. R. Warnes and W. S. Davey; **coal-tar,** by F. J. R. Carulla; coal-tar fractions, by A. R. Warnes and W. S. Davey, U. Ehrhardt and G. Pfleiderer, W. A. Damon, W. E. Dennison, and F. Fischer; **liquid fuels**—gasoline, etc.—by E. K. O. Schmidt, S. H. Diggs, and K. R. Dietrich. According to A. R. Warnes and W. S. Davey, the dissociation of ammonium chloride, ammonium sulphide, ammonium hydrosulphide, ammonium cyanide, and the subsequent action of the dissociation products upon the iron are the chief causes of the corrosion, the rate of the action being probably increased by electrochemical conditions. Strain may have contributed towards corrosion by producing a certain amount of molecular instability in portions of the iron plates, thus rendering those parts more easy of attack. The final products into which the corroded iron is converted are chiefly ferrous sulphide and ammonium ferrocyanide. Ammonium chloride exerts a more corrosive action upon the iron than ammonium sulphide. The corrosive effects of **oil refining products** were studied by O. N. Edgar, G. Egloff, G. Egloff and J. C. Morrell, R. Lind, W. R. Finney and H. W. Young, R. R. Matthews and P. A. Crosby, R. V. A. Mills, H. F. Perkins, D. E. Pierce, H. Schmidt, F. W. L. Tydemann, and R. E. Wilson and W. H. Balke. B. Bleyer and J. Schwaibold determined the corrosion of iron by **tea** and **coffee** at 75° in grams of metal per sq. m. in 24 hrs., and found the losses to be:

Time	10″	1′ 10″	5′ 10″	42′ 30″	2·5 hrs.	5 hrs. 40′	22 hrs. 40′
Tea	42·5	42·5	35·0	18·0	15·0	6·3	5·0
Coffee	16·3	17·5	15·0	11·3	5·5	4·5	5·0

The corrosion of iron by coffee vapours was studied by R. Evans. G. N. Quam[14] found chrome-steel suffered no perceptible loss after 30 mins'. contact with **milk.** The corrosion of iron by **beer** was studied by J. Brand, L. Nathan, and H. Seyffert;

wood, by F. C. Calvert, and P. Rohland; flour **paste,** by T. Thomson; by **inks,** by O. Bauer and W. Mecklenberg; by **gunpowder,** by E. H. Schulz, and A. Wright; by **tanning liquors,** by A. Gansser, and M. P. Balfe and H. Phillips; by **india-rubber,** by C. O. Weber, and W. Thomson and F. Lewis; by **paper,** by P. Klemm; and by **perspiration,** by W. J. Huff, and H. E. Yerbury.

Corrosion may be hindered or inhibited by **grease** which acts by preventing water from coming in contact with the metal and thus suppressing one of the conditions necessary for corrosion. Thus grease may be associated with water in the form of an emulsion. Many forms of grease and oil are really salts of organic acids. Thus, olive oil is a glyceryl oleate which forms glycerol and oleic acid when hydrolyzed by water. The glycerol was found by D. Klein and A. Berg[15] to have no action on iron, but the organic acids slowly attack the iron, forming, say, ferrous oleate, which is decomposed by the oxygen of the air to form hydrated ferric oxide and oleic acid. E. A. Cowper emphasized the deleterious effects of the conversion of common grease into acid grease in boilers; and J. Stingl, and F. J. Rowan, the corrosive effects produced by the introduction of greasy water into boilers. The action of lubricating oils on metal was discussed by S. Aisinmann, A. H. Allen, P. T. Bruhl, P. Cuypers, J. Dewrance, S. Reiner, E. Donath, W. R. Finney and H. W. Young, M. Cook and U. R. Evans, C. Fichandler, J. A. N. Friend, J. E. Hackford, H. von der Heyden and K. Typke, W. J. Huff, A. F. Meston, W. Singleton, H. Schmidt, H. G. Smith, H. Spurrier, C. W. Volney, and H. J. Young; and of liquid fuels, by K. R. Dietrich. H. von der Heyden and K. Typke discussed the action of transformer oils in iron; R. E. Wilson and W. H. Balke, and H. F. Perkins, the corrosion of iron in oil refineries; E. K. O. Schmidt, M. Wawrziniock, and H. J. Young, the corrosive effect of motor oils; F. G. Hoffmann, the corrosive action of tar and benzene vapours; Wo. Ostwald, benzene; and F. Schuster, naphthalene and the protective action of tetralene, $C_{10}H_{12}$.

The **drying oils** employed in the manufacture of paint exert very little solvent action on iron. W. H. Watson's observations on the marked effect of linseed oil in 24 hrs. are so different from those of W. Marcey, and J. A. N. Friend, that it is probable that the oils he employed were very impure. W. Marcey observed no action during 3 days' exposure of iron to linseed oil, and J. A. N. Friend observed no action with raw linseed oil, poppy oil, and tung (or Chinese wood) oil when alternately heated to 100° and cooled for 12 days; also when the iron was exposed to the action of the oil for 5 months. The metal always remained bright. With boiled linseed oil, the metal was dulled in every case, and the slight loss through the solution of the iron was more or less counterbalanced by the gain due to oxidation. L. L. Steele studied the effect of iron soaps on the drying of linseed oil. W. Marcey found that with 10 days' exposure to the action of **non-drying fatty oils,** there was a loss of 0·0025 grm. with 2·1830 grms. of iron with olive oil; and with this as an arbitrary standard of 100, the solvent action with sperm oil was 48; with neatsfoot oil, 44; with cotton-seed oil, 36; with castor oil, 28; with lard oil, 20; with almond oil, 16; and with rape oil, none. R. M. Corelli studied the action of castor oil on several metals. A. E. Tucker found that with 500 c.c. of oil acting on iron for 26 hrs., the following amounts of metal dissolved: sperm oil, 0·0370 grm.; lard oil, 0·0120 grm.; olive oil, 0·0314 grm.; castor oil, 0·0034 grm.; valvoline, nil; cylinder oil of sp. gr. 0·921, trace; and lubricating oil of sp. gr. 0·915, a trace. I. J. Redwood found the following percentage losses of metal during 12 months' action at atm. temp. with mineral lubricating oil, 0·02693; olive oil, 0·17187; rape oil, 0·04418; tallow oil, 0·20603; lard oil, 0·11111; cotton-seed oil, nil; sperm oil, 0·09210; whale oil, 0·12279; seal oil, 0·01539. Signs of rusting occurred with the tallow, lard, cotton-seed, and seal oils. D. Holde also examined the action of some lubricating oils on plates of iron 30 mm.×4 mm. in an autoclave at 10 atm. press. for 2, 4, and 6 hrs., with light mineral oil the losses were respectively, 3, 3, and 4 mgrms.; with heavy mineral oil, 4, 4, and 4; with raw rape-seed oil, 0, 5, and 41; with refined rape-seed oil, 1 to 15, 12·5 to 66, and 118 to 205; and with tallow, 0, 21, and 168. R. M. Corelli examined the action of castor oil on metals; S. Macadam, and C. Engler, the action of petroleum, and paraffin oils; G. Egloff, oil-refining products; and Wo. Ostwald, the action of benzol. A. Boutaric and R. Amiot measured the adhesion of lubricating oils to iron.

For the action of **silicon,** *vide* the silicides—**6.** 40, 13; and *vide infra*, Fe-Si alloys. F. Osmond[16] observed that as the proportion of silicon increases, the conversion of α- to β-iron is retarded, and with 2 per cent. of silicon, the conversion is practically zero; the arrest in the cooling curve A_2 at 730°—720° takes place at 710°—700°; and the arrest A_1 at 660°—650° is raised to 710°—700° —*vide infra*, the silicon steels. H. Hanemann found carburized iron reduced silica from **fireclay** crucibles to silicon. L. Troost and P. Hautefeuille observed a siliceous rock rapidly attacked cast iron at an elevated temp. A. Becker and H. Salmang did not observe any reaction with **glass** and iron of a high degree of purity at 1450°, although with ordinary iron containing carbides and silicides there is a reaction. U. R. Evans found that a soln. of **sodium silicate,** like other alkaline soln., retards the corrosion of iron. E. Vigouroux represented the reaction with **silicon tetrachloride** at a high temp.: $SiCl_4+4Fe=Fe_2Si+2FeCl_2$. The reaction was studied by G. Rauter, and H. E. Patten. H. zur Strassen applied the mass law to the action of iron on **nickel silicate**: $Fe+NiSiO_3 \rightleftharpoons Ni+FeSiO_3+7{\cdot}6$ to 9·5 Cals., and found that for the equilibrium constant in $[Fe][NiSiO_3]=K[Ni][FeSiO_3]$, $K=6{\cdot}53\times10^{-3}$ at 750° K., and $7{\cdot}25\times10^{-3}$ to $7{\cdot}44\times10^{-3}$ for $T=1840°$ K. W. Heike represented the reaction with **ferrous silicate**: $3Fe+FeSiO_3 \rightleftharpoons 3FeO+FeSi$. G. Tammann and H. Bohner observed that iron precipitates 58 per cent. of the nickel from the slag, $CaO.NiO.2SiO_3$. O. Ruff and R. Ipsen observed that at a red-heat, **titanium tetrafluoride** is reduced by iron; and L. Lévy, that **titanium tetrachloride** is not decomposed by iron at a red-heat. H. E. Patten observed that iron is not corroded by **stannic chloride**. For the action of **boron,** *vide* the borides **5.** 32, 4. Iron containing boron was found by F. Osmond to behave like iron with carbon in that the arrest A_3 is lowered from 855° to 805°, and partly at 735° to 725°, or becomes coincident with A_2—*vide infra*, the action of copper. H. Moissan found that **boron trichloride** acts on iron at a red-heat, forming ferrous chloride and ferroboron.

The action of iron on the **metals** is discussed in connection with the alloys and intermetallic compounds. K. A. Hofmann and H. Hiendlmaier[17] found that iron is readily attacked by burning **potassium.** W. G. Imhoff, E. J. Daniels, and C. Diegel found that molten **zinc** at galvanizing temp. readily attacks cast and malleable iron, and that the presence of chromium and nickel does not make the metal more resistant; R. Perrin said that interpenetration occurs when steel is heated in contact with **bronze**; R. Genders, with **brass**; and C. E. Schwartz, with **lead.** L. Hackspill observed that at 1400°, under a press. of 0·1 mm., **lithium oxide** is reduced by iron to form lithium. G. Tammann and E. Kordes found that **copper oxide** can react with iron in the solid state, at 610°, and B. Garre observed that when a mixture of powdered iron and copper oxide is compressed and heated to 700°, the tensile strength rises from 7·0 to 46·8 kgrms. per sq. cm., and it is supposed there is a diffusion from iron to copper oxide and conversely. J. E. Stead also found that cupric oxide is reduced by iron at 780° to form copper. H. Moissan found that molten **calcium oxide** rapidly attacks iron. According to G. Tammann, G. Tammann and E. Kordes, and D. Balareff, iron reacts with **lead oxide** in the solid state at 460°. G. Tammann and E. Kordes observed that **tungstic oxide** reacts with iron at 300° to 340°. L. A. Hallopeau found that molten **lithium tungstate** dissolves iron. M. Billy found that **ferric oxide** is reduced to a lower oxide when heated with iron; **ferrosic oxide** under similar conditions reacts at 570°, and the reaction was studied by L. B. Pfeil. B. Garre found that **nickel oxide** reacts with iron at 640°, and the reaction was studied by J. E. Stead. H. zur

Strassen represented the action of nickel oxide on iron by the equation: $Fe+NiO=Ni+FeO+6{\cdot}4$ to 14·2 Cals.

The early workers, J. L. Gay Lussac and L. J. Thénard, H. St. C. Deville, and H. Debray observed that at an elevated temp., iron reduces the **alkali hydroxides** to the corresponding metal. L. Hackspill and co-workers observed that iron displaces the alkali metals, excepting lithium, from sulphates and arsenates at their m.p.; from thiocyanates at 650°; from borates and phosphates at about 1400°; and from the aluminates at the m.p. of iron. Lithium is formed from the oxide or silicate at 1300°. Potassium sodium and lithium hydroxides are reduced: $2Fe+3KOH\rightleftharpoons Fe_2O_3+1\frac{1}{2}H_2+3K$, the reaction with potassium hydroxide begins at 500°, and at 600° to 650°, 70 to 80 per cent. of the hydroxide is reduced to metal, they also obtained potassium and sodium by heating the alkali hydroxide with iron and coke.

A. Scheurer-Kestner found that fused alkali hydroxide rapidly attacks iron, particularly under the influence of pressure wrought iron is more rapidly attacked than cast iron. C. E. Groves found that solid potassium hydroxide, with 5 per cent. of water, and fused at a gentle heat, attacks steel readily under conditions where the action of sodium hydroxide is much less. W. Venator observed that different kinds of iron—cast iron, wrought iron, steel, and forged iron—were strongly attacked by boiling soda-lye, and hydrogen was given off. Commercial sodium hydroxide was employed, and pieces of metal of 32 sq. cm. surface area and weighing nearly 50 grms., were submerged in the alkali. The alkali was contained in a silver vessel which exerted no electrolytic action on the iron. The following losses were observed, under similar conditions:

	Fused NaOH		80 per cent.-lye	46 per cent.-lye	20 per cent.-lye
	400°	350°	200°	150°	150°
Cast iron . . .	0·1969	0·1568	0·3680	0·0345	0·0000
Wrought iron . .	0·1660	0·0348	—	0·1928	0·0723
Steel	0·2072	0·0193	0·1422	0·1322	0·0133

The results show that the action of the fused alkali is intensified by a rise of temp.; the effect of dilution is to reduce the action on cast iron so that with a 20 per cent. soln. at 150° no perceptible action was observed. According to M. le Blanc and O. Weyl, fused potassium hydroxide attacks iron appreciably between 550° and 660°, but evidence that potassium or hydrogen are formed is lacking; in the case of fused sodium hydroxide between 400° and 720°, the evolution of hydrogen and the formation of water were taken by M. le Blanc and L. Bergmann to prove that a compound $Fe(ONa)_n$ is formed. The dehydration of sodium hydroxide which occurs at 400°, and the stability of the products at temp. up to 720°, show that the formation of water cannot be due to the simple reaction: $2NaOH=Na_2O+H_2O$. The action of fused alkali hydroxides on different forms of commercial iron was studied by R. Rossberg, C. Föhr, and A. Scheurer-Kestner. W. Hentschel observed that at a red-heat iron does not act on sodium hydroxide with up to 1 per cent. of water, but if 1 to 4 per cent. of water is present, the action is turbulent, but the action is mild at temp. below a red-heat. A. Thiel and H. Luckmann noted that with 25 grms. of iron powder and $0{\cdot}01N$-NaOH, at ordinary temp., 0·01 c.c. of hydrogen is evolved per hour. The subject was studied by J. Woost, and F. Haber and L. Bruner. J. M. van Bemmelen and E. A. Klobbie said that the primary reaction is the formation of sodium ferrite, $Na_2O.Fe_2O_3$. St. Meunier noted the formation of a ferrate when the fused alkali hydroxide attacks the metal in air. The action of fused sodium hydroxide on iron and steel was also discussed by W. Dittmar, T. Wallace and A. Fleck, H. Ostermann, H. Brunck and C. Graebe, A. Fry, J. A. Jones, J. H. Andrew, H. E. Balsford, M. L. Hamlin and F. M. Turner, J. L. Everhart, and H. F. Whittaker.

A. Payen, and A. Wagner found that dil. alkali-lye retarded the rusting of iron at ordinary temp., and G. Lunge found that while a 10 to 20 per cent. soln. of soda-lye has a slight action, a 50 per cent. soln. attacks the metal strongly. E. Heyn and O. Bauer found a maximum attack occurs with a conc. of 0·0025 mols. per litre, or 0·1 grm. per litre; as the conc. of the soln. increases, the action is lessened, so that with 1 grm. per litre there is scarcely any action at all. F. N. Speller and C. R. Texter did not get a maximum in the curve; within the limits 0·005 to 1·05 grm. per litre, *i.e.* in the p_H interval 8·4 to 12·8, the corrosion decreases with the alkalinity of the soln. G. W. Whitman and co-workers suggest that the maximum with experiments in open vessels is due to the action of atmospheric carbon dioxide. The formation of a protective skin on the metal was discussed by F. Haber and F. Goldschmidt, and W. R. Dunstan and J. R. Hill—*vide supra,* passivity.

The action of soln. of alkali hydroxides is discussed in connection with the corrosion of iron and steel. J. A. N. Friend observed that the corrosion of wrought iron or steel in dil. soln. of the alkali hydroxides, like $0·02N$-NaOH or $0·02N$-NH_4OH is prevented, and cast iron acquires a thin film of a bronze-coloured oxide. T. Turner found that whilst acids attack the ferrite and leave the graphite, cementite, and phosphide of cast iron, conc. alkali-lye leaves the ferrite and attacks the carbide of a pearlite. J. C. Poggendorf, F. Haber, and W. Pick showed that when iron is made the anode in alkali-lye, cast iron is more readily attacked than other forms of iron, and that when iron is boiled gently in conc. soda-lye, ferrous oxide passes into soln., and on exposure to air, ferric oxide is precipitated—*vide infra,* the ferrites. If iron is made the anode in a conc. soln. of soda-lye or potash-lye, using a low current density—say, 0·001 amp. per sq. cm.—alkali ferrate is formed. Soda-lye acts more rapidly than potash-lye because of the greater solubility of sodium ferrate. At 100°, A. Thiel and H. Luckmann found that 0·01 to $0·1N$-NaOH attacks iron less than does distilled water, and the reaction rapidly slackens as a protection skin is formed on the metal. In an autoclave at 200°, the protective oxide film is continuously dissolved. E. Berl and F. van Taack found that at 1000 atm. press. and 310°, a maximum attack occurs with $0·02N$-NaOH (0·8 grm. per litre). E. Berl and co-workers found that soda-lye with 0·5 to 5·0 grms. per litre and at press. up to 50 atm. exerts only a small action on iron, but the action increases with rising temp. and press.; soln. with 100 to 400 grms. of sodium or potassium hydroxide per litre have a deleterious action on the mechanical properties of iron. The presence of atm. oxygen does not strengthen the attack by conc. alkali-lye. With 10 grms. of powdered iron, after 16 hrs.' action, at 50 atm. press.:

NaOH . .	0·55	1·15	2·17	3·0	5·4	11·80 grms. per litre
Hydrogen .	60	100	170	175	370	550 c.c.
Fe . .	99·01	99·28	99·32	99·07	99·12	98·10 per cent.
FeO . .	0·17	0·37	0·34	0·50	0·52	1·32 ,,

No ferric oxide is formed. With lye containing 1·15 grms. per litre:

Pressure .	30	50	80	100	150	200 atm.
Hydrogen .	Small	100	240	270	320	410 c.c.
Fe . .	99·48	99·30	99·38	98·70	97·25	91·08 per cent.
FeO . .	0·13	0·10	0·10	0·29	0·82	7·25 ,,
Fe_2O_3 . .	—	—	—	—	0·11	0·82 ,,

The variations in the degree of oxidation with press. and conc. of lye are plotted in Fig. 362. The reaction can be symbolized by $Fe+NaOH+H_2O=HO.Fe.ONa+H_2$, followed by $HO.Fe.ONa+H_2O=Fe(OH)_2+NaOH$; or $Fe+2NaOH+H_2O=HO.Fe(ONa)_2+1\frac{1}{2}H_2O$, followed by $HO.Fe(ONa)_2+2H_2O=Fe(OH)_3+2NaOH$. W. Dittmar, G. Zirnite, C. H. Cribb and F. W. F. Arnaud, M. V. Pershke and L. Popova, J. L. Everhart, F. N. Speller and C. R. Texter, H. F. Whittaker, C. E. Stromeyer, P. D. Merica, M. L. Hamlin and F. M. Turner, J. H. Andrew, F. Lyon, E. Heyn and O. Bauer, and A. J. Hale and H. S. Foster examined the effect of aq. soln. of the alkali hydroxide on iron. The utilization of the facts in alleviating the attack of water on boilers was discussed by R. Baumann, E. Berl and co-workers, R. E. Hall and co-workers, G. Neumann, S. W. Parr and F. G. Straub, A. Splittgerber, F. G. Straub, R. Stumper, A. Thiel and co-workers.

F. Schmitz found that with 0·06, 0·42, and 0·92 per cent. carbon steel, 20×20×10 mm. with a 4 mm. hole, the losses in potash-lye (1 : 2) were 0·000 per cent. during 180 hrs.' attack. J. A. Jones observed that cracks develop in mild steel plates in soln. of potassium hydroxide, and this was attributed to the action of the alkali on the intercrystalline cement—*vide infra*. T. Geuther discussed the formation of hydrogen by heating powdered iron with **calcium hydroxide.** E. Heyn and O. Bauer found that calcium hydroxide, even in dil. soln., passivates iron, and they observed no maximum in the curve representing the effect of varying the concentration of the soln. The retarding action of calcium hydroxide soln. was discussed by C. Bücher, and M. Groeck. St. Meunier found that in the presence of calcium, barium, or magnesium oxide, iron forms a ferrate when heated in air with sodium hydroxide. W. Heike studied the reaction with **manganese oxide :** $Fe+MnO \rightleftharpoons FeO+Mn$. W. Krings and H. Schackmann studied the equilibrium in this system at 1550° to 1560°, and observed that $K=[Mn][FeO]/[Fe][MnO]$ is 0·0032 when concentrations are taken in percentages.

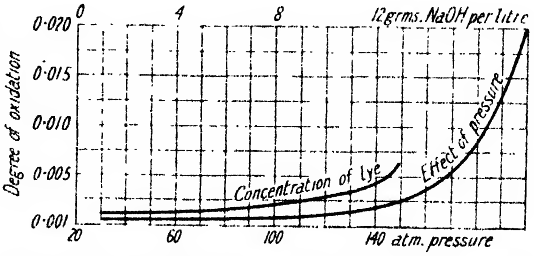

FIG. 362.—The Effect of Pressure and the Concentration of the Soda-Lye on the Oxidation of Iron.

The corrosive action of soln. of many **metal salts** is discussed in connection with the corrosion of iron and steel—*vide infra*. H. Krause[18] studied the colouring of fused salts by iron and its alloys. T. Peczalsky found that iron increases in volume and electrical resistance if it be heated in the presence of salts, although no reaction occurs. L. Hackspill and R. Grandadam observed that when iron and **alkali fluorides** are heated in vacuo to 1000°, a reaction : $Fe+2KF=FeF_2+2K$ takes place. The reaction with sodium fluoride was tried industrially for the preparation of sodium by the Société d'Electrochimie. L. Hackspill and R. Grandadam found that with the **alkali chlorides**—potassium, rubidium, cæsium, and sodium chlorides—the reaction is symbolized : $Fe+2KCl=FeCl_2+2K-115\cdot9$ Cals. L. Hackspill did not obtain the corresponding result with lithium chloride. M. E. Chevreul observed that sodium and potassium chlorides are decomposed by iron in a moist atmosphere. A. Sanfourche observed no reaction between molten or vaporized sodium chloride. A. M. Portevin, and L. Hackspill and E. Schwarz studied the decarburization of iron by the alkali chlorides, whilst L. Hackspill and R. Grandadam observed that **alkali bromides,** and **alkali iodides** behaved like the corresponding chlorides towards iron. F. Streintz observed that iron has no action on potassium iodide test paper.

A. E. Dolbear found that **potassium sulphide** at a red-heat is reduced by iron to form potassium. E. Heyn and O. Bauer found that iron rusts in dil. soln. of **sodium sulphide,** but not when the concentration exceeds $0\cdot1N$-Na_2S. G. Lunge observed a black film is formed on the iron dipped in conc. soln. of the sulphide. B. Garre observed no reaction when iron is heated with solid **sodium sulphate,** but A. Gorgeu observed a brisk evolution of sulphur dioxide when iron is added to the molten salt ; sodium oxide and sulphite, and a double sulphide of sodium and iron are formed, but with a more protracted heating the sulphide and sulphite disappear. When the product is washed with water, ferrosic oxide remains. The reaction was studied by A. d'Heureuse, and A. Stromeyer. According to F. Projahn, iron in the absence of air, reacts with the heated sulphate, in accord with the probable equation : $Na_2SO_4+3Fe=Na_2O+FeS+Fe_2O_3$; and L. Hackspill and R. Grandadam represented the reaction in vacuo by the equation : $2Na_2SO_4+3Fe=Fe_2O_3+2FeS+5O+4Na$. The reaction occurs at 900°, and with potassium sulphate, at 1000°. There is an intermediate formation of ferrous sulphate ; L. Hackspill did not observe the reaction with lithium sulphate. The Société d'Electrochimie proposed to utilize the reaction for the preparation of sodium. O. Pettersson and A. Smit, and M. Websky observed that in the reaction with steel, **potassium hydrosulphate** forms ferric sulphate, oxidizes the carbon to carbon dioxide, and leaves the graphite untouched. L. Hackspill and R. Grandadam found that in vacuo the **alkali carbonates** react with iron in accord with $2Na_2CO_3+2Fe=Fe_2O_3+CO_2+CO+4Na$. Almost all the sodium carbonate is reduced in 2 hrs. at 1000°. B. Garre observed that solid sodium carbonate reacts with iron at a high temp., and E. Deiss, that powdered iron reacts with the molten salt. J. E. Fletcher studied the action of **sodium carbonate** on cast iron.

According to J. J. Berzelius, an aq. soln. of **copper chloride** extracts all the iron from cast iron leaving behind the whole of the carbon mixed with copper. R. Böttger found much heat is developed when anhydrous cuprous or **cupric chloride** is reduced with powdered iron and wetted with water, and G. Tammann observed a vigorous reaction when iron is added to molten cuprous chloride; and the reaction was studied by C. B. Gates. According to W. Eidmann, iron reduces a soln. of cupric chloride in acetone; and, according to A. Naumann, and E. Alexander, a slow reaction occurs with a soln. of cupric chloride in ethyl acetate. The precipitation of copper from soln. of **copper salts** by iron has been discussed in connection with copper—**3**. 21, 3. Observations on the subject were made by R. M. Caven, and G. L. Oldbright and co-workers. The precipitation has been used in a wet process for the extraction of copper. J. C. Essner found that the structure of the iron employed exerts a marked influence on the form of the copper obtained, so that by selecting suitable iron it is possible to obtain the reduced copper in a fibrous or granular condition. The formation of a mud of hydrated ferric oxide is prevented by the presence of a little sulphuric acid. With dil. soln. of copper salts F. Mylius and O. Fromm, and G. Tammann observed that some hydrogen may be developed, and the iron is associated with the precipitated copper. J. B. Senderens found that the deposition of copper from soln. of cupric nitrate, by iron, is rather slow at ordinary temp., with soln. of medium concentration the gases evolved contain 80 per cent. of nitrogen peroxide and 20 per cent. of nitrogen with some nitric oxide at the beginning; the precipitated copper contains some ferric hydroxide, and the soln. contains ammonium and ferrous nitrates. D. Tommasi found that the precipitation from soln. of cupric chlorate is only partial; J. B. Senderens, that no copper is precipitated from soln. of the acetate; and C. B. Gates, that copper is precipitated by iron from soln. of copper salts of many organic acids.

H. Forestier observed that the rate of dissolution of 99·86 per cent. iron immersed for 10 mins. in a 2 to 12 per cent. soln. of cuprous chloride at 15° increases with the magnetic field up to 4500 to 5000 gauss, after which it remains constant. The rate of dissolution is tripled for 2 per cent. soln., but the stimulating effect of the magnetic field decreases with the conc. of the reagent up to 8 per cent., and then remains approximately constant. Copper sulphate soln. act similarly but the effect is less marked, possibly owing to the formation of a protecting layer of copper. T. Andrew found that magnetized iron dissolves in a soln. of cupric chloride about 3 per cent. more quickly than the same iron not magnetized; and C. M. Kurtz and R. J. Zaumeyer studied the subject. A. A. Blair discussed the dissolution of steel in a soln. of copper sulphate, and E. Goutal, by feebly acidified soln. with 40 per cent. potassium cuprous chloride. K. Ulsch utilized the reduction of nitrites or nitrates to ammonia by an iron-copper couple for the determination of these salts in soln.; and D. Tommasi also reduced chlorates to chlorides. The iron-copper couple was obtained by the action of *ferrum hydrogenio reductum* on a soln. of copper sulphate. The decomposition of **cuprous sulphide** by iron was studied by O. Reuleaux; and B. Garre found that **cupric sulphide** is reduced at 400°, and that the thermal value of the reaction is 11·4 Cals. F. P. Treadwell observed that in the presence of powdered iron, the sulphides, insoluble in dil. acids, in a current of carbon dioxide, and at a dull red-heat, form ferrous sulphide. According to

J. J. Berzelius, **silver chloride** is reduced when in contact with cast iron under water acidified with hydrochloric acid; and C. J. B. Karsten said that the iron is dissolved, leaving a residue of silver and graphite, and iron carbides. C. B. Gates studied the reaction. The reduction of **silver salts** by iron was discussed in connection with silver—**3.** 22, 5. G. Tammann found that iron acts slowly on molten silver chloride. C. J. B. Karsten, and J. Percy studied the reduction of molten **silver sulphide** by iron. J. B. Senderens observed that unworked iron is far more active in precipitating silver from dil. soln. of silver nitrate than is the case with worked iron. The difference is attributed to a difference in the physical condition of the different forms of iron. W. Heldt said that the precipitation from silver nitrate soln. is slower the more conc. the soln. Steel acts more slowly than iron. The silver separates more slowly from ammoniacal than from neutral soln., and some ferric salt is formed. J. B. Senderens added that iron goes into soln. faster than the silver is precipitated, and some nitrites are formed. The reaction was also discussed by J. S. de Benneville, and by N. Schilow. F. Mylius and O. Fromm, and G. Tammann found that the precipitated silver always contains some iron. V. Lenher studied the precipitation of gold from soln. of **gold chloride** by iron. F. Mylius and O. Fromm, and G. Tammann found that the gold is always contaminated with iron.

A. M. Portevin, and L. Hackspill and E. Schwarz discussed the decarburization of iron (*q.v.*) by the **alkaline earth chlorides.** C. B. Gates said the molten calcium chloride does not act on iron. A. d'Heureuse observed that the **alkaline sulphates** at a red-heat react with iron, forming ferrous sulphide, and ferrosic and ferric oxides. R. Finkener, and G. Hilgenstock obtained with calcium sulphate at a white-heat in an evacuated tube, ferrous sulphide and lime. F. Martin and O. Fuchs observed that in a current of nitrogen, calcium sulphate reacts with iron at 750°, strontium sulphate at 850°, and barium sulphate at 950°, forming respectively $3CaO.2Fe_2O_3$, $2SrO.Fe_2O_3$, and $BaO.Fe_2O_3$. According to L. A. Bhatt and H. E. Watson, when the mixture $3CaSO_4+8Fe$ is heated in a current of nitrogen at 950°, for 5 hrs., 46·6 per cent. of the original sulphur remains as $CaSO_4$; 13·9 per cent. forms $CaS+FeS$; 28·2 per cent. as SO_2; 2·5 per cent. as SO_3; and 8·6 per cent. as sulphur. An excess of silver retards the reaction. F. Hundeshagen observed the formation of magnesium ferrite when iron acts on **magnesium chloride** melted in its water of crystallization, but B. Garre observed no reaction with anhydrous magnesium chloride at a high temp. For the action of aq. soln. of magnesium chloride on iron, *vide infra.* S. Micewicz found that the speed of decomposition of aq. soln. of sodium, potassium, calcium, and magnesium chloride increases in the order named. T. Petitjean recommended reducing **magnesium sulphide** by iron in order to prepare magnesium, but F. G. Reichel did not succeed with the process. A. Mourlot said that at a dark red-heat magnesium sulphide is not decomposed by iron. B. Garre studied the reaction between iron and **magnesium sulphate** at an elevated temp.

C. J. Reed, and W. M. Camp found that iron is attacked only slightly by a soln. of **zinc chloride,** in contrast with the attack by a soln. of sodium chloride. N. N. Jefremoff and J. M. Jakimez found that ferrosilicons are more resistant. G. Tammann studied the action of iron on molten zinc chloride. C. A. Graumann found that metallic iron in a reducing atmosphere attacks **zinc sulphide,** forming iron sulphide and zinc. H. Heinrichs observed that a mixture of **cadmium sulphate** and iron in a crucible at 900° yields a mixture of cadmium and ferrous sulphides. R. Varet observed the slow reduction of soln. of **mercuric chloride** to mercurous chloride by iron; and R. Böttger noted that with a boiling soln. some mercury or amalgam is formed. E. Alexander, and A. Naumann found that iron precipitates ferrous and mercurous chlorides from a soln. of mercuric chloride in ethyl acetate; W. Eidmann, and A. Naumann obtained a similar precipitate from a soln. in methylal; and A. Naumann, from a soln. in benzonitrile; R. Varet observed that iron produces no change in a soln. of mercuric chloride in pyridine, but if water is added, and the soln. warmed, mercury, mercurous chloride, and oxidized iron are formed. W. Guertler and T. Liepus noted that a 1 : 500 soln. of mercuric chloride is unstable in contact with iron. The reaction was studied by V. Majer. G. F. Hildebrandt found that when iron is heated with **mercuric sulphide**, mercury and ferrous sulphide are formed.

F. C. Calvert and R. Johnson observed that iron aluminides are formed when **aluminium chloride** is passed over red-hot iron. T. Petitjean recommended reducing **aluminium sulphide** with iron in order to prepare aluminium, but F. G. Reichel did not succeed with the process. L. Hackspill observed that when heated with iron in vacuo, **alkali aluminate** furnishes the alkali metal.

The reduction of tin from soln. of **tin salts** by the addition of iron has been previously discussed—**7**. 46, 5. N. W. Fischer found that tin is not usually precipitated by iron from soln. of stannous chloride, and the reduction of stannic to stannous salts was discussed by C. Tookey, J. Attfield, W. L. Clasen, etc., with dil. acidic soln. A. Thiel and K. Keller, and J. Thiele found that some tin may be precipitated. B. Schultze added that tin is slowly and completely precipitated from neutral soln. if ferrum reductum be employed as reducing agent. Air should be excluded. The subject was discussed by N. Bouman, and J. M. Kolthoff. According to A. Thiel and K. Keller, the fact that when iron is added to a soln. of the chlorides of tin and antimony, only antimony is precipitated, is in contradistinction to the position of iron and tin in the electrochemical series. Tin is actually precipitated, but only in very minute quantity, forming a very thin protecting layer of a tin-iron alloy on the surface of the iron. Iron dissolves much less rapidly in an acid if a tin salt is present. If iron is introduced into a vessel containing a conc. electrolyte, and tin in the lower part, and a more dil. electrolyte free from tin in the upper part, the iron becomes covered with crystals of tin where it dips into the conc. electrolyte, but remains free from tin if immersed completely in either the conc. or the dil. soln. G. Tammann found that iron slowly acts on molten stannous chloride. H. Biltz and V. Meyer found that iron is strongly attacked by the vapour of stannous chloride ; H. E. Patten found that iron is not affected when placed in liquid stannic chloride or in a hydrochloric acid soln. of that salt. The Chemische Fabrik Buckau reported that in the cold, the vapour of stannic chloride warms up iron, particularly if some chlorine be present ; the metal becomes very hot if the temp. at the start be 100°. chlorine alone begins to act on iron at about 300°. The reduction of lead from soln. of **lead salts** by iron was discussed in connection with lead—**7**. 47, 3. G. L. Oldbright and co-workers observed that lead is precipitated from a soln. of lead chloride by iron, but D. Tommasi, and H. Schiff noted that lead chlorate soln. are not so reduced. L. Taricco observed that lead is deposited on iron from alkaline soln. of lead cyanide. G. Tammann observed that some lead separates when iron acts on molten lead chloride. The decomposition of lead sulphide by iron was studied by J. Fournet, J. Percy, W. Guertler, and H. von Jüptner. B. Garre said that the reaction occurs at 390°, and that the thermal value of the reaction is 2·2 Cals. N. W. Fischer found that at a red-heat iron and carbon reduce **lead sulphate** to lead. G. Tammann and E. Kordes found that solid lead sulphate and iron react vigorously. The reaction begins at 540°, and the thermal value of the reaction is less than 11 Cals.

F. A. Abel and W. A. Deering found that conc. soln. of **chromic acid** dissolve steel. The kinetics of the dissolution of iron by chromic acid were studied by R. G. van Name and D. U. Hill. According to W. R. Dunstan and co-workers, iron can be kept bright in a soln. of chromic acid for 10 years, but W. Moody found that there is a slow dissolution ; and R. G. van Name and D. U. Hill observed that with chromic acid in the presence of an excess of sulphuric acid, iron is rapidly corroded. J. A. N. Friend found that dil. soln. of chromic acid had no perceptible action on cast iron during 14 years' exposure in sealed tubes. U. R. Evans observed that with soln. containing *n* mols. per litre of the acids, the average losses in weight during 6 hrs. at 14°, were :

H_2SO_4 .	0·05	0·05	0·05	0·05	*Nil*	0·02	0·05	0·09
CrO_3 .	*Nil*	0·005	0·01	0·02	0·01	0·01	0·01	0·01
Loss .	9·7	25·9	42·7	77·9	0·2	38·2	42·7	55·8

So that chromic acid, in virtue of its strong oxidizing and weak base-dissolving properties, produces passivity by the formation of a protective film when present alone, but stimulates corrosion in the presence of sulphuric acid. The subject was discussed by E. Heyn and O. Bauer, G. W. Heise and A. Clemente, and P. Rohland—*vide infra*. E. Heyn and O. Bauer, H. Endo, P. Rohland, and G. P. Vincent studied the action of **potassium dichromate** soln. on iron; and E. Berl and F. van Taack observed that under a high pressure, soln. of the dichromate attack iron more strongly than do soln. of **potassium chromate.** Some reduction occurs, and the liquid becomes alkaline. *Vide infra*, for the action of chromates and dichromates on the corrosion of iron. H. Endo observed that iron can be kept in 0·002 to 0·1*M*-soln. of **potassium permanganate** for a year without being perceptibly attacked, but corrosion occurs in 10 hrs. in a 0·0002*M*-soln. R. Vogel and H. Baur, and E. C. Krekel studied the reaction between iron and **manganese sulphide** and noted that the mixtures show an eutectic point—*vide infra*, iron-manganese alloys.

According to F. E. Brown and J. E. Snyder, molten **ferrous chloride** attacks iron; and H. Heinrichs studied the reaction between iron and **ferrous sulphate.** C. F. Schönbein observed that iron precipitates an oxide from soln. of ferrous chloride or sulphate. The action of iron on soln. of ferric salts was studied by T. E. Thorpe, H. Schild, and M. Troilius. According to J. C. Essner, dil. soln. of **ferric sulphate** when treated with iron yield ferrous sulphate; and the basic ferric sulphate precipitated by iron from soln. of copper sulphate reacts with iron: $3Fe_2(OH)_4SO_4+Fe=3FeSO_4+4Fe(OH)_3$. O. Collenberg and S. Bodforss, and R. G. van Name and D. U. Hill studied the rate of dissolution of iron in a soln. of ferric alum in the presence of 0·01*M*- to 5·0*M*-H_2SO_4; and observations were made by J. Napier. O. P. Watts and N. D. Whipple found that the presence of arsenic retarded the rate of attack. The corrosion of iron by water containing iron salts in soln. was studied by A. E. Menke, and N. R. Dhar. W. Spring found that a conc. soln. of **ferric chloride** has little action on iron, but the metal readily dissolves in a dil. soln. R. G. van Name and D. U. Hill studied the rate of dissolution of iron in a soln. of ferric chloride in the presence of 0·1*M* and 0·5*M*-HCl; and observations were made by J. Napier, and H. F. Whittaker. O. P. Watts and N. D. Whipple found that the presence of arsenic slows down the rate of attack. H. Pauling obtained a cell with electrodes of iron and carbon in a conc. soln. of ferric chloride. The e.m.f. is 0·9 volt; and the cell is cheap and free from smell. A constant flow of ferric chloride through the cell can be maintained so as to ensure depolarization. F. W. Küster represented the reaction: $2Fe^{\cdots}+Fe=3Fe^{\cdot\cdot}$. Owing to the carbon impurities in the iron, local action like the main reaction must occur. The iron dissolves as ferrous chloride, not as ferric chloride, since when the iron plate is immersed in a soln. of sodium chloride, and the carbon plate in a soln. of ferric chloride, and the current is allowed to pass for some time, the soln. in the vicinity of the iron plate contains ferrous salt alone, without a trace of ferric salt. B. Garre observed that the reaction between iron and **nickel sulphide** begins at 380°, and that the thermal value of the reaction is 5·7 Cals. F. Mylius and O. Fromm observed that platinum precipitated from soln. of **platinum salts** readily alloys with the iron. O. Ruff and F. W. Tschirch found that the vapour of **osmium octofluoride** strongly attacks iron.

Some reactions of analytical interest.—The salts of bivalent and tervalent iron, respectively **ferrous salts** and **ferric salts,** behave as if they were salts of two totally different elements. Neither series of salts gives any precipitate when treated with **hydrochloric acid,** nor does the acidic soln. of either salt give any precipitation of an iron compound when treated with **hydrogen sulphide.** If the soln. of ferrous salt is dilute and neutral, a small amount of ferrous sulphide may be precipitated; and, according to J. L. Gay Lussac,[19] C. C. Grischow, R. Winderlich, and H. W. F. Wackenroder, soln. acidified with some of the weaker acids—carbonic, oxalic, citric, tartaric, acetic, succinic, formic, and benzoic acids—may give an incomplete precipitation of ferrous sulphide. In the case of acetic acid, for example, there are presumably balanced reactions involving the dissolution of ferrous sulphide, and its conversion of the sulphide into acetate: $FeS+2HC_2H_3O_2 \rightleftharpoons Fe(C_2H_3O_2)_2+H_2S$, and the escape of hydrogen sulphide as a gas, allows more ferrous sulphide to pass into soln. to preserve the balance. By adding to the soln. a considerable excess of alkali acetate, the balance is disturbed owing to the decreased solubility of the sulphide. Ferric salts are reduced to ferrous salts by hydrogen sulphide with the separation of sulphur: $2FeCl_3+H_2S=2FeCl_2+2HCl+S$. The sulphur appears as a milk-white or bluish turbidity. According to H. Rose, a small proportion of sulphuric acid is produced in soln. of the chloride, but not with soln. of the acid acetate; and in ferric salts of the weaker acids, *e.g.* the acetate, H. W. F. Wackenroder observed that some hydrated ferric sulphide may be precipitated if the acid is not in excess; and also from soln. of ferric salts of one of the strong acids if a large excess of sodium acetate be present. Iron is completely precipitated from soln. of ferrous salts by **ammonium sulphide:** $FeCl_2+(NH_4)_2S=2NH_4Cl+FeS$; the precipitate is readily soluble in acids with the evolution of hydrogen sulphide. If very dil. soln. are employed, green colloidal ferrous sulphide is formed; it coagulates to a black precipitate on long standing, or in the presence of ammonium chloride. According to H. N. Stokes, **ammonium polysulphide** will give a precipitate containing ferric sulphide. Ammonium sulphide with ferric salts gives a precipitate of ferrous sulphide and sulphur: $2FeCl_3+3(NH_4)_2S=6NH_4Cl+2FeS+S$, but with an excess of soln. of yellow ammonium sulphide, J. J. Berzelius said that ferric sulphide is precipitated. Similar results are obtained with alkali sulphides on soln. of ferrous and ferric salts; and the precipitate is insoluble in an excess of the reagent, but H. N. Stokes added that with alkali sulphides the precipitate is always ferric sulphide. According to J. Roth, an aq. soln. with one part of iron in 100,000 parts of water gives a black precipitate with ammonium sulphide; with 1 : 200,000, a dark green mixture is produced; with 1 : 400,000, greyish-green; and with 1 : 800,000, a greyish-green colour in a few minutes. F. Jackson found that ammonium sulphide enables one part of ferrous or ferric iron in 128,000 to be detected. Acidic ferrous salt soln. give no precipitate with **ammonium thioacetate,** but with alkaline soln., ferrous sulphide is precipitated; soln. of ferric salts are reduced to ferrous salts by this reagent.

Ferrous salts, in neutral soln., give an incomplete precipitation of white ferrous hydroxide when treated with **ammonia.** If ammonium salts be present, *e.g.* in chloride soln., a soluble complex salt, $(NH_4)_2FeCl_4$, is formed so that if sufficient ammonium chloride be present, ammonia gives no precipitate with soln. of ferrous salts. If the soln. be exposed to air, it becomes turbid, green, and finally brown or black from the precipitation of brown, hydrated ferric or ferrosic oxide (*q.v.*). **Alkali hydroxides** give a complete precipitation of ferrous hydroxide from ferrous salt soln., and the precipitation is only partially prevented by the presence of ammonium salts. According to J. Roszkowsky, non-volatile organic acids, sugar, etc., retard or inhibit the precipitation of ferrous salts by ammonia or alkali hydroxides. F. Jackson found that 1 : 8000 of ferrous iron could be detected by precipitation with ammonia, or alkali hydroxides. Ammonia, or alkali hydroxide soln. with ferric salts give a precipitate of brown, gelatinous, hydrated ferric oxide (*q.v.*): $FeCl_3+3NH_4OH=3NH_4Cl+Fe(OH)_3$, which is soluble in acids. According to J. Roszkowsky, non-volatile organic acids, sugar, etc., inhibit or hinder the precipitation of hydrated ferric oxide by ammonia or alkali-lye owing to the formation of complex salts. G. C. Wittstein said that hydrated ferric oxide is slightly soluble in conc. alkali-lye, but L. Schaffner showed that this is a mistake; the ferric oxide is only in "a state of fine mechanical suspension." F. Jackson observed that the precipitation occurs with ammonia in soln. with ferric iron 1 : 16,000, and with sodium hydroxide 1 : 32,000.

Ferrous salts give a white precipitate when treated with an **alkali carbonate:** $FeCl_2+Na_2CO_3=2NaCl+FeCO_3$; the ferrous carbonate rapidly oxidizes in air; with ferric salts, a brown, basic carbonate is precipitated, which, in a boiling soln., is hydrolyzed to hydrated ferric oxide. According to J. N. von Fuchs, F. von Kobell, W. Schopper, and H. Demarçay, the **alkaline earth carbonates,** and **manganous, zinc, magnesium, and cupric oxides** precipitate hydrated ferric oxide from cold soln. of ferric salts, but not so with soln. of ferrous salts unless boiling. The reaction with zinc oxide is symbolized: $2FeCl_3+3ZnO+3H_2O=3ZnCl_2+2Fe(OH)_3$; and similarly also with **mercuric oxide.** According to C. H. Pfaff, **sodium phosphate** with ferrous salts precipitates white ferrous phosphate, and the reaction is sensitive to 1 : 1,000; while with ferric salts, yellowish-white ferric phosphate is precipitated sensitive to 1 : 1500; ferrous salts with **sodium arsenate** give a white precipitate sensitive to 1 : 1000; and ferric salts, a white precipitate sensitive to 1 : 20,000.

According to J. von Liebig, ferric salts in cold, neutral soln. of **alkali acetates or formates** give a brown coloration: $FeCl_3+3NaC_2H_3O_2=3NaCl+Fe(C_2H_3O_2)_3$; and on boiling the soln. the iron is precipitated: $Fe(C_2H_3O_2)_3+2H_2O=2HC_2H_3O_2+Fe(OH)_2(C_2H_3O_2)$, the precipitated basic acetate redissolves as the soln. cools, or when the precipitate is washed with cold water. The basic acetate process was discussed by J. W. Mellor. The presence of organic oxy-acids—like tartaric, citric, and malic acids—and of polyhydric alcohols—like glycerol, erythritol, mannitol, and sugars—prevent these reactions because they form complex salts. C. H. Pfaff observed that **alkali succinates and benzoates** give light reddish-brown precipitates with ferric salts sensitive to 1 : 5000 provided an excess of acid is not present. Ferrous salts give a yellow coloration with **oxalic acid** and acid alkali oxalates, and on standing a yellow precipitate is formed; with **alkali oxalate** the yellow precipitate is formed at once; ferric salts give a yellow colour with oxalic acid, but no precipitation. Ferrous salts do not give a coloration or a precipitate with **tincture of galls;** but in air or in the presence of ferric salts a violet-black or purple colour is developed. According to C. H. Pfaff, and J. Roth, the precipitation occurs with ferric chloride with a concentration of the ferric salt of 1 : 120,000; a bluish-black coloration is produced with a dilution of 1 : 200,000; a greenish-blue with 1 : 400,000; and a greenish-blue on standing a few minutes with a dilution of 1 : 800,000. P. Harting said that the limit of the reaction with ferric sulphate is 1 : 300,000. If one of the stronger acids is present no precipitation occurs unless alkali acetate is present. O. Lutz found that if a few drops of a soln. of **protocatechuic acid,** and then an excess of sodium carbonate be added to a soln. of an iron salt, an intense red coloration occurs sensitive to 1 : 10,000,000; the presence of ordinary inorganic or organic acids does not interfere with the test. The reaction was studied by H. Hlasiwetz and co-workers, and R. F. Weinland and K. Binder. G. von Knorre, and M. von Ilinsky and G. von Knorre observed that **nitroso-β-naphthol,** dissolved in 50 per cent. acetic acid, gives a voluminous, green precipitate with dil. soln. of ferrous salts; and a voluminous, brownish-black precipitate with ferric salt soln. H. Kofahl, I. Bellucci and A. Chiucini, J. Papish and L. E. Hoag, C. Meineke, L. L. de Koninck, E. A. Atkinson and E. F. Smith, and F. C. Mathers studied the reaction. K. W. Charitschkoff found a soln. of **naphthenic acid** in light petroleum gives a reddish-brown soln. with ferrous salts—the petroleum extracts the iron from aq. soln.—ferric salts must be first reduced to ferrous salts. P. Slawik found that a most sensitive reaction for ferrous salts is to add tartaric acid to a drop of a ferrous salt soln., then 1 c.c. of alcoholic **dimethylglyoxime,** then an excess of ammonia, when an intense red coloration is produced which disappears by atm. oxidation, but is restored by reducing agents. The reaction was studied by L. Tschugaéeff, L. Tschugaéeff and B. Orelkin, R. Nakaseko, P. N. van Eck, M. Matsui, E. J. Kraus, and W. Vaubel. A faint rose-red is perceptible with a dilution of 1 : 1,600,000. J. Dubsky and M. Kuras found that 1 c.c. of a 1 per cent. alcoholic soln. of **di-iso-nitrosoacetone** added to 5 c.c. of a ferrous salt soln. gives an intense blue. The colour develops in 2 hrs., with 0·00001*N*-soln., and in 3 hrs. with 0·000001*N*-soln. G. von Knorre observed that 2, 4-**dinitrosoresorcinol** gives a green colour or a green precipitate with ferric salt soln., and in feebly acidic or feebly alkaline soln. of ferrous salts, a green colour. The reaction was studied by M. L. Nichols and S. R. Cooper, W. R. Orndorff and M. L. Nichols, and M. Goldstück. The ammonium salt of **phenylnitrosohydroxylamine**—or **cupferron**—gives a red precipitate of a complex ferric salt with acidic soln. of ferric salts. The reaction was studied by E. H. Archibald and R. O. Fulton. O. Baudisch, O. Baudisch and V. L. King, I. Bellucci and A. Chiucini, J. Brown, H. Biltz and O. Hödlke, E. Ferrari, R. Fresenius, G. E. F. Lundell, G. E. F. Lundell and H. B. Knowles, H. Nissenson, A. Pinkus and F. Martin, K. Schröder, and H. Weber. P. Cazeneuve found that a soln. of **diphenylcarbazide** in benzene, when shaken with a soln. of a ferric salt, gives a peach-red coloration. A. W. Gregory estimated that the violet colour, produced when an acetic acid soln. of **salicylic acid** is added to ferric chloride in soln. with sodium acetate, is sensitive to 1 : 50,000. The reaction was first reported by R. Piria, and studied by A. Almén, R. Böttger, E. Brücke, A. Conrady, A. Dollfus, M. Frehse, J. E. Gerock, A. Hantzsch and M. Singer, M. Konowaloff, O. Langkopf, H. Marty, P. Nicolardot, S. Pagliani, L. Rosenthaler, A. Sagaidatschin and M. Rawitsch, E. Schaer, E. F. Smith, J. Traube, A. Vogel, R. F. Weinland and A. Herz, H. Weiske, and J. Wolff. H. B. Pulsifer utilized, for colorimetric determinations, the red colour produced by ferric salts with **acetyl acetone.** R. Berg recommended **o-oxyquinoline derivatives** as a precipitant.

A soln. of **potassium cyanide** and a ferrous salt give a reddish-brown precipitate soluble in excess to form potassium ferrocyanide ; with a ferric salt soln., potassium ferricyanide is formed in an analogous way. Ferrous salts with **potassium ferrocyanide,** in the complete absence of air, give a white precipitate of ferrous ferrocyanide or ferrous potassium ferrocyanide, in air, a pale blue colour is due to oxidation to ferric ferrocyanide (Prussian blue) ; with ferric salts under similar conditions, an intense blue precipitate of Prussian blue is formed. C. H. Pfaff said that the reaction is sensitive to 1 : 100,000 ; P. Harting, to 1 : 420,000 ; and F. Jackson, 1 : 64,000. Ferrous salts with **potassium ferricyanide** give a dark blue precipitate of Turnbull's blue ; and with ferric salts, only a brown coloration is developed. Ferrous salts give no coloration with **potassium thiocyanate ;** but with ferric salts a blood-red coloration is produced: $FeCl_3+3KSCy \rightleftharpoons Fe(SCy)_3+3KCl$. The reaction is reversible, and the ferric thiocyanate can be extracted with ether. C. H. Pfaff added that the coloration is sensitive to 1 : 20,000 ; A. Wagner, 1 : 1,600,000 ; E. C. Smith, 1 : 8,000,000 ; and J. Roth added that with 1 : 25,000 the colour is red ; with 1 : 200,000, orange ; with 1 : 800,000, pale orange ; and with 1 : 1,600,000, a scarcely perceptible yellow. The coloration cannot be recognized in the presence of an excess of alkali acetate ; organic oxy-compounds—*e.g.* tartaric acid—in neutral soln., not in acid soln. ; and mercuric chloride destroys the coloration. The subject was studied by E. Kahane. Ferric salts give an intense blue colour with **potassium molybdenocyanide.**

A. Richaud and M. Bidot said that a sky-blue coloration is produced with ferrous salts, not ferric salts, when treated with a soln. of **sodium phosphatotungstates,** acidified by hydrochloric acid, and the liquid then made alkaline with sodium hydroxide, but A. Popesco showed that other reducing agents produce the same coloration. If a ferrous salt soln. is treated with an excess of conc. sulphuric acid, and a crystal of **potassium nitrate** is introduced, a brownish-red ring is produced which, according to L. Blum, enables a ferrous salt to be detected in the presence of a ferric salt—*vide* nitric oxide. According to E. Lenz, with ferrous salts, **sodium thiosulphate** gives no precipitation ; while ferric salts are coloured violet and finally reduced to ferrous salts without precipitation.

According to N. W. Fischer,[20] **zinc** precipitates from neutral soln. of ferrous chloride or sulphate a mixture of ferrous hydroxide and metal if air be excluded ;

otherwise, a mixture of ferric hydroxide and metal. J. A. Poumarède obtained a similar result, but not E. F. Anthon. H. N. Warren observed that **magnesium** precipitates iron mixed with the hydroxide from soln. of the acetate, and by this means iron can be separated from chromium. D. Vitali stated that when a soln. of a ferric salt is treated with magnesium, flecks of hydroxide are formed, and these are gradually reduced to the metallic state.

The physiological action of iron salts.—In the first century of our era some medicinal uses of iron were described by Pliny, in his *Historia naturalis* (**34**. 44). In classical times there was a general belief that iron lent its strength to the body, and later on this belief was reinforced by the association of iron with the planet Mars. Mars was assumed to control the blood, and accordingly "iron" was employed to strengthen and purify the blood. In the Middle Ages several writers—*e.g.* J. L. Bausch[21]—discussed the therapeutics of iron compounds. The medicinal use of iron increased during the sixteenth and seventeenth centuries, and the therapeutic reputation of iron was supported by its curative effect on chlorosis or green sickness; and by its helpful action in counteracting the effects of excessive blood-letting so generally practised in that period. Iron was also a general remedy for cachexia and ill-health. The popularity of iron led to an increase in the number of available preparations as a knowledge of chemistry increased, and a number of secret preparations appeared in the eighteenth century—*vide infra*, iron chlorides. To-day it is estimated that over 600 preparations are available for medicinal purposes! The physicians of the seventeenth and eighteenth centuries thought so highly of the curative properties of iron that H. Boerhaave could say: *In ferro est aliquid divinum.*

The action of iron salts on the animal organism was discussed by G. C. Gmelin[22] in 1825—*vide supra,* the occurrence of iron—and by A. J. Clark. The iron salts have no particular action on the unbroken skin, and when applied locally to the abraded skin, sores, and the mucous membranes, ferric salts are powerful astringents because they coagulate albuminous fluids. The administration of iron in health has very little action on the blood. If iron be injected subcutaneously or directly in the veins, it may cause gastro-intestinal irritation and paralysis. The iron administered during hæmorrhage does not influence the hæmoglobin of the blood. The ferric salts act as local hæmostatics and arrest severe hæmorrhage by coagulating the blood and plugging bleeding vessels. The iron salts have a styptic taste, and may blacken the teeth and tongue owing to the formation of iron sulphide from the sulphur in the food and the "tartar" of the teeth. Ferric salts are converted in the stomach into chloride—maybe also a little ferrous chloride is formed—by the action of the hydrochloric acid there present. The iron salts thus have an astringent action in the stomach. As the iron salts pass into the intestine, the contents of which are alkaline, hydrated iron oxide or carbonate is formed which probably remains in soln. owing to the presence of organic substances. Lower down the intestine, the sulphur compounds, nascent hydrogen, and other readily oxidized products of decomposition convert the iron into ferrous sulphate and tannate—the tannic acid being derived from the vegetable matter of the food—and these ferrous compounds are eliminated as such with the fæces which are thereby turned black. The oxide, sulphide, and carbonate of iron are non-astringent. If an excess of iron in the form of an astringent preparation is administered, the excess has a constipating effect, since it is not acted on in the stomach and intestine. F. Wohlwill observed that iron causes capillary hyperæmia of the alimentary canal, and the accompanying nervous symptoms indicate a direct action on the central nervous system. W. Schürmann and T. Baumgärtel observed that ferric chloride precipitates red corpuscles from the blood of normal oxen or sheep. L. Massol and M. Breton found that the injection of a milligram of ferrous sulphate in the brain of a guinea pig did not cause death. H. W. Armit studied the toxic action of iron carbonyl.

The total iron in the adult body, amounting to about 3 grms., is derived from the food; about 2 grms. of this iron is combined in the hæmoglobin; and more than half the remainder is stored as a reserve in the spleen, liver, lymphatic glands, and marrow. The rest of the body contains about 5 mgrms. of iron per kilogram, and this is important because the respiration of every cell in the body depends on the small traces of iron it contains.

C. G. Lehmann, and others found that men starving for long periods excreted 8 mgrms. of iron daily, and this corresponds with a wastage of body tissue. G. von Wendt, and W. Lintzel agree that with diets adequate in amount, but poor in iron alone, the iron excretion is not more than 2 to 5 mgrms. daily—*vide supra*, occurrence of iron. About a milligram of iron is eliminated in the urine of man per diem, and this remains nearly constant under all circumstances. An excessive elimination may follow subcutaneous injection or excessive absorption from the intestine, and some may be eliminated through the intestinal membranes.

The amount of iron required in the food in order to maintain a balance is comparatively small. About 20 mgrms. per diem is usually considered sufficient; but W. Lintzel and co-worker observed that a mixed daily diet only contains about 10 to 14 mgrms. of iron, and probably less than this is needed by an adult on a mixed diet. Most of the iron is present in the meat, and in green vegetables. The iron contents, in mgrm. per 100 grms., of some foods rich in iron are—liver, 15; spinach, 5; and meat, 2 to 5; and in some foods poor in iron—cow's milk, 0·2; white flour, 1·5; and potatoes, 1·2—*vide supra*, occurrence of iron. The poverty of iron in cow's milk explains the nutritional anæmia of bottle-fed babies. M. Blauberg observed that a breast-fed human infant of 5 months retained 10 mgrms. of iron daily, and that this represented about 70 per cent. of the total amount supplied with the milk.

Ruminants, feeding on grass, etc., growing on soils with a low proportion of "iron," acquire a wasting disease, which, in New Zealand, is called *bush sickness*, and, in Kenya, *nakuruitis*. These diseases are characterized by arrested growth, and by excessive anæmia, which is ultimately fatal unless the animals are supplied with "iron" in some suitable form. Accordingly, B. C. Aston called the disease *iron starvation*. The subject was discussed by J. B. Orr. W. Lintzel found that a deficiency of iron arrested the growth of young rats; and J. P. McGowan and A. Crichton, that young pigs became œdematous, and frequently died suddenly—a post-mortem showed fatty degeneration of the heart and liver. Hence, while a deficiency of iron may cause anæmia, it may have serious deleterious effects on various tissues of the body.

According to G. von Bunge, the iron reserves in the liver and spleen play an important part in the blood formation of infant animals, and, added A. J. Clark, in many cases new-born animals have large iron reserves in their liver, and, although they receive but little iron in their mother's milk, yet by drawing on these reserves, they can avoid anæmia. W. Lintzel showed that a calf, for example, starts with a rich iron store in its liver, and hence does not suffer from the fact that cow's milk contains very little iron. On the other hand, young pigs, and human infants have only a moderate iron store, but receive a better iron supply from their mother's milk. Naturally, when a human infant is fed on cow's milk it tends to become anæmic, because it has no large iron store and receives very little iron in its food.

G. von Bunge doubted whether inorganic salts of iron can be absorbed directly from the alimentary canal. He supposed that the only iron absorbed is present in the food as organic salts, but the presence of inorganic salts of iron in the alimentary canal favours the absorption of the organic iron by combining with and precipitating any sulphur as iron sulphide, thus preventing the sulphur from decomposing the organic iron salts. The hypothesis was disproved by E. Abderhalden, and S. Tartakowsky, who showed that inorganic iron hastens the formation of hæmoglobin in adult animals rendered anæmic by repeated bleeding whilst supplied with food deficient in iron. G. H. Whipple and co-workers also showed that iron salts administered in sufficiently large doses definitely increased the rate of formation of hæmoglobin. E. B. Hart and co-workers found that nutritional anæmia in young rats was not cured by the administration of iron alone, but was cured if a small amount of copper was simultaneously given. This subject was studied by I. J. Cunningham, E. B. Hart and co-workers.

According to W. H. White, soln. of iron salts are antiseptic. The effect of iron on vegetation was studied by J. L. Lassaigne. F. C. Calvert found that dil. soln. of ferrous sulphate do not prevent bacterial or fungoidal growths in albumin. C. Richet observed that at 16° to 20°, a soln. of 0·24 grm. of ferric chloride per litre will hinder the development of bacteria, and 0·014 grm. per litre will kill marine fishes in 48 hrs. L. Nathan found that black iron is active in checking the fermentation of apples, and beer-wort, whilst polished iron has but a slight action. L. Nathan and co-workers showed that iron is very injurious to the fermentation of fruit musts and beer-wort. A. Chassevant and C. Richet observed the toxic action of iron salts on lactic fermentation.

§ 24. The Corrosion of Iron and Steel

> Nature, in conformity with her usual benevolence, has limited the power of iron, by inflicting upon it the punishment of rust.—Pliny (6. 40).

The tendency of ordinary iron to rust on exposure to air is inherent in its nature; and A. S. Cushman,[1] in discussing *The Conservation of Iron*, said that the rusting is essentially a process of slow combustion which is annually burning up an untold and unknown quantity of this precious metal. No partnership between industry and Nature will ever again reclaim the iron that has fallen away to rust. D. M. Buck considered that the annual charge due to the corrosion of iron and steel is between £17,000,000 and £23,000,000; but R. A. Hadfield estimated that the annual cost of wastage due to the rusting of the world's iron and steel is probably well over £500,000,000. W. S. Johnston estimated that 2 per cent. of iron and steel is lost per annum by corrosion. The cause and prevention of rusting is therefore a subject of surpassing importance unless we are to be mere passive spectators of this enormous loss. The subject was discussed by J. T. Milton, R. J. McKay, E. H. Schulz, W. Wiederholt, E. H. Schulz and R. Kühnel, C. H. Desch, B. D. Saklatwalla, E. Maass, and W. H. Creutzfeldt. Quite a number of books have been published on the rusting of iron; and the *Reichsausschuss für Metallschutz* publishes a journal, *Korrosion und Metallschutz*, devoted to this subject. The special works are:

There have been numerous discussions on the corrosion of iron and steel—*e.g.* W. van W. Scholten,[2] A. Matagrin, G. Masing, V. Sallard, C. O. Bannister, A. M. Portevin, etc. Methods for measuring the corrosion of metals were described by G. D. Bengough [3] and co-workers, W. H. J. Vernon, E. K. O. Schmidt, etc. ; and microscopic tests, by C. H. Desch [4] and co-workers.

According to U. R. Evans and G. D. Bengough,[5] the term *abrasion* denotes friction between one solid body and another resulting in change of shape or removal of material from one or both sides ; *corrosion* means the chemical or electrochemical action of a liquid or gas on the surface of a metal resulting in a passage from the elementary to the combined state ; and *erosion* denotes the removal of material from some part of a surface by means of abrasion, by capillary action, or otherwise, without a change of composition at the moment of removal although changes may occur afterwards. Both abrasion and erosion may operate on either metal or scale. J. A. N. Friend used the term erosion to designate corrosion such as that induced by acids when a more or less soluble product is formed which exposes the underlying metal to attack ; and *surrosion* for that type of corrosion which results in the production of insoluble oxide or rust which clings to the unattacked metal ; and W. H. J. Vernon used the term surrosion for cases where the total action is quantitatively represented by the increase in weight of the specimen.

The action of water on iron.—Some observations on this subject have been discussed in connection with the chemical properties of iron. B. D. Saklatwalla [6] noted that the condensation of gases on the surface of metals would tend to impart surface activities that would depend on the degree of adsorption. When iron is covered by a thin layer of water, and exposed to air, hydrated ferric oxide is formed, but with a thicker layer of water, F. Wöhler found that hydrated ferrosic oxide is produced. The water carries oxygen from the air to the iron. M. M. Hall, and N. J. B. G. Guibourt found that iron powder, out of contact with air, does not decompose thoroughly boiled water, though a feeble evolution of hydrogen may occur at 50° to 60°, and ferrosic oxide be formed. J. A. Wanklyn and L. Carius found that iron reduced by hydrogen gives no hydrogen when heated with purified water at 50° to 60° ; and R. Lenz said that electrodeposited iron, re-heated to redness in vacuo, rapidly oxidizes in contact with boiling water, the water is decomposed and the hydrogen which is formed is absorbed by the iron. E. Ramann also said that finely-divided iron slowly decomposes boiling water ; thus, 12 c.c. of hydrogen were obtained by boiling 10 grms. of iron—reduced in hydrogen—in water for an hour ; he also noticed that the glass containing vessel was corroded when the boiling was continued for several days. J. A. N. Friend also observed that the reaction between iron and boiling water occurs about one-fourth as quickly in a copper vessel as it does in a glass vessel. M. M. Hall, and N. J. B. G. Guibourt said that if the iron be in contact with electronegative substances like ferric oxide, or mercury, it can decompose water under conditions where it otherwise would not do so. The case is as different with iron *en masse*, as it is with, say, pyrophoric iron and ordinary iron in air.

The action of water on iron was discussed early last century by J. Keir, C. Becker, C. Girtanner, J. B. Trommsdorff, N. J. B. G. Guibourt, M. Meyer, R. Adie, J. Spennrath, M. Traube, and M. M. Hall ; and later by E. A. and L. T. Richardson, J. Rothe and F. W. Hinrichsen, A. Bobierre, K. Hasegawa and S. Hori, W. R. Dunstan and co-workers, W. H. Walker and co-workers, A. S. Cushman, V. Andström, E. Heyn and O. Bauer, W. Palmaer, W. R. Whitney, A. Wagner, W. P. Mason, W. van Rijn, H. W. Clark and S. D. Gage, R. S. Weston, M. Kernbaum, V. M. Isnardi, W. P. Jorissen, A. W. Stuart, J. W. Cobb and G. Dougill, O. Bauer and E. Wetzel, G. D. Bengough and co-workers. W. A. Bradley, A. B. Bradley, D. Geoghegan, P. J. Thibault, J. W. Shipley and co-workers,

J. Tillmanns and co-workers, R. E. Wilson, J. R. Baylis, F. N. Speller and C. R. Texter, G. M. Enos, H. Klut, M. Heegewaldt, T. Steel, A. T. Stuart, G. J. Burrows and C. E. Fawsitt, W. R. Fleming, C. F. Hickethier, and K. Inamura.

There is the electrolytic theory of corrosion which is independent of the ionic hypothesis and all that is implied by the term " ions." The ionic theory is the electrolytic theory with the theory of ions as a subsidiary hypothesis. The theory of ions is another story. Here, it is convenient to regard the two theories of corrosion as the same, but expressed in different ways. According to the **ionic hypothesis** advocated by W. R. Whitney,[7] F. N. Speller, F. W. Hinrichsen, H. Endo and S. Kanazawa, H. Friedmann, E. K. Rideal, W. J. Sweeney, G. Bresch, J. W. Shipley and I. R. McHaffie, W. Palmaer, W. T. Hall, W. G. Whitman, T. Fujihara, C. F. Burgess, W. H. Walker and co-workers, and A. S. Cushman and co-workers, it is assumed that water and air are sufficient to cause rusting. The action of an acid on iron is represented as an exchange of electric charges between the $\mathrm{H}^{\cdot}$-ions of the acid, and the neutral atoms of the metal which then pass into soln. as metal ions. Water is supposed to be slightly ionized: $\mathrm{H_2O} \rightleftharpoons \mathrm{H}^{\cdot}+\mathrm{OH}'$, and when a metal is immersed in this liquid, it is assumed that the electric charges are transferred from the $\mathrm{H}^{\cdot}$-ions to the iron atoms so that the water in the vicinity of the metal has $\mathrm{Fe}^{\cdot\cdot}$-ions, and OH'-ions corresponding with a dil. soln. of ferrous hydroxide. If oxygen has access to the latter, the ferrous hydroxide is oxidized to hydrated ferric oxide, and deposited as rust. The de-electrified $\mathrm{H}^{\cdot}$-ions form molecular hydrogen. In order to establish this hypothesis it was necessary to demonstrate that iron passes into soln. under these conditions, and, as indicated elsewhere, this has not been satisfactorily done. The tendency of iron to pass into soln. in water depends on (i) the so-called solution pressure, and (ii) on the solubility product $[\mathrm{Fe}^{\cdot\cdot}][\mathrm{OH}']^2$. The reaction $\mathrm{Fe}+2\mathrm{H}^{\cdot}=\mathrm{Fe}^{\cdot\cdot}+\mathrm{H_2}$ is in equilibrium when $k_1=[\mathrm{Fe}^{\cdot\cdot}][\mathrm{H}^{\cdot}]^2 \cdot 67\times10^{-14}$, or since for water at 18°, $[\mathrm{H}^{\cdot}][\mathrm{OH}']=0{\cdot}56\times10^{-14}k_2$, $[\mathrm{Fe}^{\cdot\cdot}][\mathrm{OH}']^2{:}\ 2{\cdot}1\times10\ ^{14}$. This assumes that the ferrous hydroxide is completely ionized in soln. As indicated later, the value for the solubility product of ferrous hydroxide is not accurately known. If the solubility product $[\mathrm{Fe}^{\cdot\cdot}][\mathrm{OH}']^2$ be less than k_1, some hydroxide will be precipitated before equilibrium is attained. One of the values for the solubility product, $1{\cdot}9\times10^{-14}$, is very near the value of k_1. W. J. Sweeney found that the solubility product is $10^{-18\cdot8}$. A. L. McAulay and G. L. White studied the effect of the $\mathrm{H}^{\cdot}$-ion concentration on the potential of the iron- *vide supra*—and H. O. Halvorson and R. L. Starkey calculated that the relations between the $\mathrm{H}^{\cdot}$-ion conc. and the ferrous or ferric ions held in soln.—parts per million—are:

p_{H} . .	3·0	4·0	5·0	6·0	7·0
$[\mathrm{Fe}^{\cdot\cdot}]$ . .	270	2·70	0·027	$0{\cdot}0_3 27$	$0{\cdot}0_5 27$
$[\mathrm{Fe}^{\cdot\cdot\cdot}]$ . .	$6{\cdot}1\times10^{-1}$	$6{\cdot}1\times10^{-2}$	$6{\cdot}1\times10^{-5}$	$6{\cdot}1\times10^{-8}$	$6{\cdot}1\times10^{-11}$

The driving force of the reaction $2\mathrm{Fe}+\mathrm{O_2}+2\mathrm{H_2O}=2\mathrm{Fe(OH)_2}$ is equal to the difference of the potentials $\epsilon'=\frac{1}{4}RT \log \{[\mathrm{O_2}]/[\mathrm{OH}']\}^4$ and $\epsilon''=\frac{1}{2}RT \log \{[\mathrm{Fe}^{\cdot\cdot}]/[\mathrm{Fe}]\}$, so that if $[\mathrm{Fe}^{\cdot\cdot}][\mathrm{OH}]^2=k$, and $[\mathrm{Fe}]$ is constant, $\epsilon'-\epsilon'=\frac{1}{4}RT \log \{[\mathrm{O}^2]/k^2\}$. M. Randall and M. Frandsen calculated the free energy to be —2·28 Cals., indicating that the reaction, $\mathrm{Fe}+2\mathrm{H_2O}=\mathrm{Fe(OH)_2}+\mathrm{H_2}$, can progress at 25°.

According to M. Mugdan, the potential of iron immersed in various salt soln. varies considerably with the nature of the dissolved salt. Since the dissolved salts cannot be supposed to take part in the reaction, this should not be the case. The phenomena can be regarded only as further instances of a metal assuming a more or less passive condition. Thus, iron can dissolve with the elimination of hydrogen in soln. of chlorides, bromides, iodides, fluorides, sulphates, perchlorates, and nitrates, whilst in soln. of the salts of weak anions (chlorate, acetate, hydroxide, cyanide, chromate, and permanganate), the reverse occurs. The different potentials show that the rusting in one case and not in the other is due to some modification of the iron impressed on it by contact with the soln. The fact that many of the salts, in soln., which do not attack the iron are reducing agents, speaks against the passivity being due to a layer of oxide. W. J. Sweeney showed that a small decrease of free energy occurs when iron is attacked by water to form ferrous hydroxide in the absence of oxygen; and K. Murata studied the thermodynamics of the phenomena. W. D. Bancroft gave a bibliography of the ionic theory of corrosion and discussed the available data.

As the ions pass from the metal into soln., an eq. number of hydrogen ions are discharged on the electrode so as to form a hydrogen electrode. As the conc. of the metal ions in the soln. increases, the potential of the combination: Metal : Metal ions, becomes nobler; and conversely, as the H -ion conc. of the soln. becomes less, the potential of the hydrogen electrode becomes more basic. The solubility product of the metal hydroxide is limited by a change in the conc. of the metal ions, and the $H^{\cdot}$-ion conc., and this limits the value of the potential. With base metals like zinc, the limiting value of the potential of the metal electrode and the hydrogen electrode cannot be attained at atm. press., and, in consequence, the action of water on these metals does not come to a standstill; but with iron, when air is excluded, no reaction occurs. The hydrogen potential with a decreased press. becomes nobler, and there must be a press. less than the atmospheric, at which the limiting potential is attained, and the reaction between iron and water can come to a standstill. Since the potential of iron against a sat. soln. of ferrous hydroxide was given by F. Förster as $-0{\cdot}54$ volt—W. Palmaer gave $-0{\cdot}57$ volt—the potential of the hydrogen electrode is $E=-0{\cdot}29 \log\{p/[H^{\cdot}]^2\}$, where the gas press. of the hydrogen is p, and the $H^{\cdot}$-ion conc. is $[H^{\cdot}]$, or, according to W. G. Whitman and co-workers, $[H^{\cdot}]=2{\cdot}5\times10^{-10}$. Then, by substitution and simplification, $p=0{\cdot}25$ atm., or 190 mm. Hg (approximately).

G. Schikorr found that the press. generated by the hydrogen in the action of water on iron (with 0·18 per cent. of carbon, and notable amounts of other impurities) is very much greater than this. For instance, at about 20°:

	0	23	51	82	113	148	days
Press. (mm.) . .	8	163	414	550	633	748	mm.
	0	24	79	104	156	236	days
Press. (atm.) . .	1	1·2	2·3	2·7	4·0	5·8	atm.

This is taken to mean that other factors are concerned in the reaction. Ferrous hydroxide can act on water at 200° producing hydrogen and ferrosic oxide; and W. Traube and W. Lange found that when a gel of ferrous hydroxide is heated with spongy palladium, hydrogen is developed, and ferrosic oxide is formed. Again, J. Preuss observed that powdered iron boiled in water with hydrated ferric oxide produces a black powder, and hydrogen is evolved; and F. Wöhler showed that the black powder is ferrosic oxide, and that the reaction can be symbolized: $Fe+2FeO(OH)=Fe_3O_4+H_2$. R. Stumper also showed that hydrogen is developed in the reaction between rust and iron. G. Schikorr showed that the hydrated ferric oxide does not attack the iron directly, rather is it reduced to hydrated ferrosic oxide, and some ferrous hydroxide passes into soln. The dissolved ferrous hydroxide attacks the iron. The rate of formation of hydrogen in this reaction is proportional to the cube root of the press. Raising the temp. from 25° to 35° doubles the rate of formation of hydrogen. The attack on dense, compact iron is comparatively slow.

Purified water free from air was reported by M. M. Hall,[8] C. J. B. Karsten, J. F. Westrumb, J. Persoz, and R. Mallet to have no action on iron at a temp. below the b.p. of water; and R. Adie reported that he kept iron in water, entirely free from dissolved air, for six months without its showing any sign of attack. B. Lambert and J. C. Thomson showed that commercial iron will dissolve under these conditions. W. R. Whitney found that purified water and purified iron sealed up in flasks, so that the contents were free from oxygen and carbon dioxide, could be kept an indefinitely long time without the iron undergoing any perceptible change; but when air was admitted, the water rapidly became cloudy owing to the formation of metal oxide. It was therefore inferred that a portion of iron must previously have passed into soln. J. A. Collins, J. F. G. Hicks, A. S. Cushman, M. Traube-Mengarini and A. Scala, and W. H. Walker and co-workers described modified experiments in agreement with the assumption that purified water can dissolve purified iron. A. S. Cushman estimated that the solubility of iron in purified air-free water is 0·0006 to 0·00117 grm. per litre. W. R. Fleming, and W. R. Dunstan and co-workers were unable to confirm W. R. Whitney's conclusion; and H. Nordensen, and J. A. N. Friend raised the objection that it is quite probable that the precautions taken by W. R. Whitney, and the others were not sufficient to remove all the residual gas carbon dioxide and oxygen from the water, and from the walls of the containing vessels, so that a trace of iron may have passed into soln. as carbonate. This is supported by W. Scoresby's observation that air cannot be removed from water by merely boiling, since water which has been thoroughly boiled furnishes bubbles of gas on freezing; and A. Leduc's calculation that at least 1 c.c. of gas remains in a litre of water which has been thoroughly boiled. A large portion of this gas is probably carbon dioxide. The fair inference from the observations is that iron is very slightly soluble in ordinary water, or well-boiled water when air or free oxygen is excluded; but it cannot seriously be claimed that the solubility of iron in water, quite free from dissolved gases, has been adequately demonstrated.

The action of damp air on iron.—J. P. Barruel[9] said that he kept electro-deposited iron for many years in a cupboard in which acid vapours were continually present, and yet it presented not the faintest trace of rust; but there is some mistake, for J. Percy said that such iron rapidly rusts when exposed to the joint action of air and moisture. In 1782, S. Rinman observed that dry air does not corrode iron, but moist air does. Hence, he inferred that " rust must be formed by some kind of acid, which, in the presence of moisture, will exert a dissolving, attacking, or corroding influence. . . . Other less noble metals seem likewise to be partially corroded by moist air." J. Spenrath, and others also noted that iron does not rust in dry air. S. Rinman also added that in accord with C. W. Scheele's theory of the nature of air, in a confined space, the good air (oxygen) is absorbed by the rusting drillings of pig-iron. P. A. von Bonsdorff also observed that iron remains unaltered in damp air provided no liquid water is deposited on the metal; similar results were obtained in damp air containing ammonia and carbon dioxide. These observations were confirmed by W. R. Dunstan and co-workers; they enclosed pieces of 99·94 per cent. iron, free from occluded gases, in tubes containing dry and moist oxygen, dry and moist carbon dioxide, and a mixture of moist carbon dioxide and oxygen. No visible action occurred in a set of tubes maintained at a constant temp.; while in a similar set kept at ordinary temp., no visible action occurred in the tubes containing dry oxygen, and dry and moist carbon dioxide; but copious rusting occurred in the tubes containing moist oxygen, and a mixture of moist oxygen and carbon dioxide. In the tubes kept at ordinary temp., there are fluctuations in which the conditions favour the deposition of moisture. Consequently, it is not the water vapour in the atmosphere which evokes the rusting of iron; for if the temp. be above the dew-point, iron initially free from rust does not corrode. A. C. Hanson, W. S. Patterson, and J. C. Hudson observed the rate of corrosion is fastest in the presence of water, and this is attributed to the greater condensation of moisture.

F. C. Calvert observed that in some cases no oxidation occurred on exposing iron to moist oxygen, that in the light of W. R. Dunstan's results, it is probable that no corrosion took place when no moisture condensed on the metal. M. Meyer, P. A. von Bonsdorff, F. von Hutten, and J. Spenrath previously observed that iron does not change in moist air provided no liquid condenses on the surface of the metal. W. M. Thornton and J. A. Harle regarded the attack by the deposited moisture as a kind of electrolysis. J. C. Hudson measured the vap. press. of the moisture in air required for the deposition of films of moisture, and found, with iron, this critical press. is near the saturation point. The rusting of iron in an apparently dry atmosphere, the so-called *dry corrosion*, was discussed by W. H. J. Vernon, U. R. Evans, and G. D. Bengough and J. M. Stuart—*vide supra*, the action of oxygen on iron—*cf.* Fig. 330. E. A. and L. T. Richardson, W. G. Whitman and E. L. Chappell, W. F. Robertson, J. Aston and C. F. Burgess, V. V. Kendall and E. S. Taylerson, E. I. Duirmont, and C. E. Reinhard, discussed the rate of the atmospheric corrosion of iron. Experiments on the action of superheated steam at 186° were made by F. Hanaman, and the subject merges into the equilibrium relations between iron, the iron oxides, and steam discussed below.

The corrosion of iron exposed to the atmosphere is affected by climatic conditions—large diurnal variations of temp., etc., discussed by O. Hähnel, and U. R. Evans; by the presence of foreign gases—*e.g.* sulphurous gases, discussed by J. F. Barkley, U. R. Evans, J. Rothe and F. W. Hindrichsen, P. Siedler, and W. Wislicenus—*vide supra*; hydrogen chloride, by U. R. Evans—*vide supra*; gases from manure heaps, etc., by M. Meyer, and P. A. von Bonsdorff; by the presence of dust—*e.g.* soot—by W. H. J. Vernon; and by the elements associated with the iron, by K. Arndt, J. A. Aupperle, O. Bauer, H. Böringer, J. Aston and C. F. Burgess, A. S. Cushman, G. M. Enos, U. R. Evans, H. Fischer, J. A. N. Friend, L. E. Gruner, R. A. Hadfield, E. A. and L. T. Richardson, W. Rosenhain, F. N. Speller, G. Tammann, and H. Wölbling.

T. Bergman,[10] in 1773, observed that water saturated with aerial acid corrodes and dissolves metallic iron. In F. C. Calvert's experiments, dry oxygen, dry carbon dioxide, a dry mixture of carbon dioxide and oxygen, and a dry mixture of oxygen and ammonia did not corrode iron; in three experiments with moist oxygen, corrosion occurred in only one case; with the mixture of moist oxygen and ammonia, no oxidation occurred; and in all cases where moist carbon dioxide was present, the corrosion was very marked. G. Wetzlar, and A. Payen found that iron does not rust in water containing alkaline substances—*e.g.* in aq. soln. of potassium hydroxide of sodium carbonate, or of ammonia, even though the soln. be dilute. M. M. Hall also observed that iron does not rust in water containing magnesia or lime, and he discussed what he called *the concealed agency of carbonic acid* in determining the oxidation of iron by water. A. Payen inferred that the preservative effect of the alkaline soln. does not, in all probability, arise from their power of withdrawing carbon dioxide from the water, because iron is corroded even under thoroughly boiled water in contact with air free from carbon dioxide. In view of these results, and of F. C. Calvert's observation, no carbonic acid, no corrosion, F. C. Calvert and A. C. Brown developed **the acid theory of corrosion** in which it was assumed that the action is primarily the result of an attack by an acid, usually carbonic acid. It was supposed that the carbonic acid reacts with the iron to form ferrous carbonate, $FeCO_3$, or possibly ferrous hydrocarbonate, $Fe(HCO_3)_2$, and the liberated hydrogen unites with the dissolved oxygen to form water. The ferrous carbonate is then oxidized by dissolved oxygen to form hydrated ferric oxide, or rust. The liberated carbon dioxide then attacks a fresh portion of iron, and the cycle begins anew, so that a small amount of carbon dioxide in the presence of water and oxygen can convert, catalytically, an indefinitely large amount of iron into rust. The inhibition of rusting by alkaline soln. was attributed to their power of neutralizing traces of free acid.

The acid hypothesis has assumed several forms. T. Fujihara said that water and air free from carbon dioxide form a protective film on iron electrolytically, and once this film is formed, carbon dioxide is necessary to produce rusting. The removal of the protective film by the carbon dioxide exposes a fresh surface to attack. N. M. Gariloff and co-workers interpreted the effect of carbon dioxide on iron as follows:

The iron in contact with air and water acquires a film of ferrous oxide; this is oxidized to ferric oxide, which is gradually reduced by the iron, and the metal below is simultaneously oxidized. In contact with water containing carbonic acid, the superficial film of ferrous oxide dissolves and ferrous hydrocarbonate is oxidized to hydrated ferric oxide. After a long period under a soln. of ferrous hydrocarbonate in the presence of carbon dioxide the iron is almost passive, but the activity is regained by shaking the iron so as to detach the protective film of hydrated ferric oxide. Corrosion is specially favoured at a low temp., in an atm. with not more than 5 per cent. of oxygen and not less than 14 to 15 per cent. of carbon dioxide.

J. H. Paul assumed, without proof, that the carbonic acid reacts: $Fe+CO_2+H_2O=FeCO_3+2H$; and on hydrolysis of the ferrous carbonate, ferric oxide, carbonic and formic acids are formed: $2FeCO_3+2H_2O=Fe_2O_3+H.COOH+H_2CO_3$, and the carbonic acid is free to attack more iron, while the formic acid attacks the metal: $Fe+2H.COOH=Fe(H.COO)_2+2H$, and some formate is reduced to formaldehyde by the nascent hydrogen: $2Fe(H.COO)_2+4H=Fe_2O_3+3H.COH+H.COOH$. The formaldehyde escapes from the system while the formic acid reacts with more iron. H. E. Armstrong's modification is indicated below. The acid hypothesis was fashionable for a good many years; but investigators began to inquire: Is the presence of an acid necessary for the corrosion of iron?

Observations on the action of carbonic acid on iron and its alloys were made by V. Andström, E. E. Basch, G. Bresch, G. Bruhns, C. Chorower, W. T. Clous, A. S. Cushman, E. Donath and A. Indra, W. R. Dunstan and co-workers, F. Ensslin and F. Buschendorf, T. Fujihara, J. A. N. Friend, R. Girard, O. Haehnel, A. C. Hanson, C. von Hauer, E. Heyn and O. Bauer, J. F. G. Hicks, K. Inamura, B. Klarmann, H. Klut, J. M. Kolthoff, O. Kröhnke, W. Leybold, H. Lührig, B. G. McLellan, A. A. Markson and P. Fritz, G. T. Moody, J. E. Orloff, J. D. Pennock and D. A. Morton, P. Petit, J. Rothe and F. W. Hinrichsen, E. Sauer, J. T. Saunders, K. Scheringa, J. W. Shipley and I. R. McHaffie, H. J. Smith, J. Spennrath, W. A. Tilden, J. Tillmans and co-workers, J. B. Trommsdorff, J. Ville, W. H. Walker, G. W. Whitman and co-workers, W. R. Whitney, R. E. Wilson, and B. G. Worth—*vide* H-ion concentration of natural waters, and also the action of coal-gas on iron.

The work of W. R. Dunstan and co-workers, W. A. Tilden, and J. F. G. Hicks shows that the presence of carbon dioxide, or other acidic substances, is not necessary for the corrosion of iron, nor did J. F. G. Hicks find that moist oxygen rusts iron more quickly if carbon dioxide be present. V. Andström showed that the quantity of iron removed by corrosion in water is independent of the proportion of dissolved carbon dioxide; and is proportional to the amount of dissolved oxygen. The ratio of iron to oxygen corresponds with Fe_3O_4; and the dissolved iron is present as $Fe(HCO_3)_2$. When very little oxygen is present, and the soln. contains a large proportion of carbon dioxide, corrosion proceeds very slowly. Hence, it is inferred that rusting principally is due to the action of oxygen, probably with the intermediate formation of hydrogen dioxide. The subject was discussed by T. Fujihara. The deleterious effects produced by the products of combustion of coal, formerly attributed to carbon dioxide, are now considered to be produced by the oxides of sulphur. U. R. Evans said:

> The corrosive qualities of carbon dioxide have been exaggerated in the past, and probably the damage attributed to carbon dioxide has really been due to sulphur dioxide or hydrogen chloride. If water is allowed to condense in droplets on iron, some of them develop rust, whilst others (which do not happen to rest on a weak point) remain clear; this is true whether carbon dioxide is present or absent, and the clear drops may be dried up in a current of carbon dioxide without developing rust; hydrogen chloride vapours quickly produce rusting. A soln. of carbonic acid causes at first slight corrosion of the hydrogen-evolution type, but the p_H rapidly rises and the formation of hydrogen ceases; the ferrous bicarbonate produced yields ferric hydroxide at the water-line, and this obstructs diffusion of oxygen and prevents attack of the oxygen-absorption type. In effect, therefore, a soln. of carbonic acid is not dangerously corrosive; but it must be remembered that the presence of excessive free carbonic acid in a hard natural water may prevent the deposition of calcium compounds which would otherwise bring the action to a standstill.

The action of aerated water on iron.—W. R. Dunstan and co-workers found that provided liquid water, oxygen, and iron are brought into contact, rusting will occur even in the absence of carbonic or any other acid. K. Inamura obtained similar results. W. A. Tilden also said that commercial iron, liquid water, and oxygen are alone sufficient for the production of rust; carbonic acid is not necessary, but when present it hastens the reaction. E. Heyn and O. Bauer, and A. S. Cushman came to the same conclusion.. B. Lambert and J. C. Thomson prepared iron of a high degree of purity. If platinum vessels were used in place of iridium as a container for the ferric oxide during its reduction to iron, the product always corroded at the places where it had been in contact with the platinum. T. W. Richards and G. P. Baxter had previously observed that iron always contained some platinum when prepared under these conditions. B. Lambert and J. C. Thomson inferred that thoroughly purified iron does not undergo visible oxidation in contact with purified water and purified oxygen, but that a small trace of impurity in the iron is sufficient to cause oxidation under exactly the same conditions even if the impurity be not of an acidic nature or likely to produce an acid during the reaction. The conclusions were discussed by J. A. N. Friend, T. M. Lowry, H. Richardson, J. Meehan, W. R. Dunstan, C. E. Stromeyer, W. A. Davis, H. E. Armstrong, W. D. Bancroft, and G. T. Moody. There is the difficulty in removing air and carbon dioxide from the liquids, and from the inside surfaces of the glass containing vessels; and the fact that commercial iron and steel invariably contain foreign substances like sulphur, phosphorus, etc., which, on exposure to air, readily oxidize to produce acids where their presence may not have been suspected. The contention that the conclusion is invalid because the carbon dioxide clings to glass vessels and other substances so tenaciously that it cannot be effectively removed except by washing with alkali-lye or some other drastic treatment, has perhaps led some *excolare culicem, camelum autem glutire.* U. R. Evans said:

> It is not clear, however, why, if the residual carbon dioxide is supposed to have remained clinging tenaciously to the glass in these very careful experiments, it should have been considered capable of promoting the rusting of iron. In some of J. A. N. Friend's iron experiments, not only the glass, but also the metal was washed with caustic alkali, a substance which is distinctly tenacious in clinging to metallic substances, and which is notably prejudicial to corrosion. J. A. N. Friend found no rusting when normal sodium hydroxide has been used to wash the iron, but he found that iron rusted after treatment with $\frac{1}{50}N$-sodium hydroxide (followed by washing with water)—a fact which he attributed at the time to the small quantity of carbon dioxide which is capable of existing in equilibrium with alkali of that concentration!

J. Tillmans and B. Klarmann said that the carbonic acid dissolves the iron in accord with the equation $Fe+2CO_2+2H_2O \rightleftharpoons Fe(HCO_3)_2+H_2$; and H. J. Smith observed that a definite concentration of carbon dioxide in the soln. is necessary to keep the hydrocarbonate in soln., and he found that this concentration, the cube root of the carbon dioxide in soln., is proportional to the concentration of the dissolved iron, or $[Fe^{\cdot\cdot}]=K(CO_{2\text{dissolved}})^{\frac{1}{3}}$. With natural calcareous waters, part of the dissolved carbon dioxide is free carbonic acid, and part is present as calcium hydrocarbonate, $Ca(HCO_3)_2$. J. Tillmans and co-workers designate the carbon dioxide so fixed as *zugehörigen* or *attached carbonic acid*, and the unattached carbon dioxide in soln. as *aggressive carbonic acid.* E. Müller and H. Henecka studied the effect of pressure, and found that the action of the soln. on iron is thereby augmented. J. Tillmans observed that if a natural water has a $H^{\cdot}$-ion concentration between $0{\cdot}2\times10^{-7}$ and $0{\cdot}4\times10^{-7}$ it does not have a deleterious effect on iron.

According to W. H. Johnson, iron which has been dipped in acid for the removal of scale after heating becomes brittle, and the brittleness is lost if the metal be subsequently stored for any length of time. A. Ledebur made similar observations all tending to show that adsorbed hydrogen was the source of the brittleness. Similarly, J. H. Andrew observed that when iron is immersed for some time in a sat. soln. of sodium hydroxide at 100°, wrought iron becomes brittle owing to the absorption of hydrogen, but if the immersion is continued a longer time, the metal becomes tough again. The initial brittleness is attributed to the more rapid absorption of hydrogen by the amorphous, intercrystalline layer than by the crystals themselves, and the resulting expansion forcing the crystals apart, and weakening their cohesion. When the hydrogen has had time to diffuse into the crystals themselves, the intercrystalline strains are relieved, and the brittleness disappears.

Again, according to J. A. N. Friend, when electrolytic iron foil is immersed in conc. soln. of potassium or sodium hydroxide for several weeks, and, after a thorough washing, allowed to corrode in water, the water becomes contaminated with potassium or sodium salts; and W. H. Perkins obtained similar results with soln. of ammonium, lithium, and barium hydroxides. Here, again, it is supposed that minute quantities of the alkali penetrate the metal between the crystals of ferrite, viâ the pores in the intercrystalline cement. The subject was also discussed by C. A. Edwards, R. S. Williams and V. O. Homerberg, H. van de Loo and co-workers, F. Hundeshagen, P. W. Evans, H. Kriegsheim, S. E. Langdon and M. A. Grossman, A. Ledebur, E. Liebreich, H. L. Hess, L. H. Marshall, V. H. Hillman, C. J. Morrison, H. Sutton, P. Longmuir, P. D. Merica, S. W. Parr and co-workers, H. F. Rech, F. G. Straub, A. Pomp and P. Bardenhauer, B. Neumann, D. Splittgerber, H. E. Wallsom, M. Werner, R. S. Williams and V. O. Homerberg—*vide supra*, the action of alkali-lye on iron. F. C. Lea, F. G. Straub, M. Majima, and M. Okochi studied the embrittling action of hydrogen in electrodeposited iron. This is not the same as the embrittling of metals by contact with chemical agents discussed by C. H. Desch, and J. A. Jones.

G. T. Moody found that pieces of iron can be exposed to the combined action of purified air and water without forming rust; and where the metal rested in contact with the glass, a slight corrosion occurred in the course of a few days, presumably due to a reaction between the metal and the glass—silicic acid. No corrosion occurred when the ends of the pieces of metal which came in contact with the glass were protected by acid-free paraffin wax. The metal in some cases was washed with chromic acid to remove from the surface of the iron only those constituents which would otherwise yield acids on exposure to water and oxygen. G. T. Moody found that when carbonic acid is entirely excluded, no interaction takes place between oxygen and iron in the presence of water. Under such conditions, oxygen alone is unable to endure oxidation of the metal, but as soon as air containing its normal quantity of carbon dioxide is admitted, vigorous rusting occurred. W. H. Walker and co-workers confirmed the results of G. T. Moody's experiments made without the use of chromic acid; but W. R. Dunstan could not do so, and he assumed that the alkali dissolved from the glass inhibited the corrosion of the metal in G. T. Moody's experiment. W. H. Walker and co-workers, W. A. Tilden, and J. A. N. Friend said that the chromic acid employed by G. T. Moody may have rendered the metal passive; H. B. Baker was unable to make iron indifferent towards ordinary water by treatment with dil. soln. of chromic acid; and G. T. Moody observed that (i) the iron was not passive when and where it came in contact with the containing glass tube, and (ii) that rusting began when ordinary air was allowed to enter the tubes. This would not have occurred had the metal been passivated. J. A. N. Friend concluded that his modifications of the experiments demonstrated "in a remarkably clear and decided manner that pure water and air combined are without visible action on pure iron." The demonstration is by no means complete. In order to adapt a colloidal theory of corrosion of rusting, J. A. N. Friend said that iron dissolves in water as ferrous ions, and that these are rapidly converted into a hydrosol of ferrous hydroxide. He also said that the fact that weakly alkaline soln. of many salts readily induce corrosion, disposes of the idea that an acid must necessarily be present in the free state. The evidence is a remarkable testimony to the influence of predisposing opinions on judgment. The ionic theory of corrosion enables its disciples to show experimentally that purified iron will corrode in contact with a soln. of oxygen in purified water because the water is slightly ionized, and the metal can pass into soln. as ferrous iron-ions with the liberation of hydrogen: $Fe+2H^{\cdot}+2OH'=Fe^{\cdot\cdot}+2OH'+H_2$. The ferrous hydroxide present in soln. is oxidized in the presence of oxygen to form rust. On the other hand, the acid theory of corrosion enables its supporters to show experimentally that corrosion cannot take place under these conditions, but that an acid, or something which can play a similar rôle, must be present. The chemical form of the dress which the acid theory assumes has been described by A. C. Brown—*vide supra*; but it may also be attired electrochemically.

The electrochemical nature of the process of rusting in general.—In 1819, an anonymous writer—assumed to be L. J. Thénard—and R. Mallet expressed the opinion that rusting is an electrochemical phenomenon; and H. Davy probably held the same opinion; while M. Faraday persistently emphasized the electrochemical nature of chemical reactions. A. de la Rive stated that the fact that iron does not rust in moist air if no water is deposited on the surface proves that the oxidation of a metal in air is not merely the result of a direct combination:

> Actually, a more complicated phenomenon occurs, that is, a voltaic action; the metal decomposes the water on account of a local voltaic action which is aided by the presence of dissolved oxygen acting on the hydrogen formed. The presence of carbonic acid facilitates the action inasmuch as it renders the water a better conductor.

The idea was utilized by T. Ericsson-Aurén, and T. Ericsson-Aurén and W. Palmaer; while W. Palmaer said that:

> If in the acid soln. a depolarizer for hydrogen is present, that is, a substance which may successively oxidize the hydrogen formed, it is evident that the counter e.m.f. of the local element diminishes, and the dissolution of the metal is facilitated. Direct evidence of this was supplied by J. M. Weeren, who, however, interpreted the phenomenon another way.

H. E. Armstrong emphasized his belief that that hypothetical substance pure water is not an electrical conductor. The presence of a trace of "electrolyte" is necessary for electrical conduction. He said: The rusting of iron can occur either in a circuit from which oxygen is absent, or in one in which it is present. In the one case, when iron - coupled with an electronegative conductor—is brought in contact with an acid soln., it is dissolved as a ferrous salt—say, as ferrous hydrocarbonate: $Fe+2H_2CO_3=Fe(HCO_3)_2+H_2$, or, in the case of dil. soln., as ferrous hydroxycarbonate: $Fe+H_2O+H_2CO_3=Fe(OH)(HCO_3)+H_2$. When the ferrous salt in soln. is brought in contact with oxygen, it is converted into a ferric salt, and rust is formed by the hydrolysis of this salt. The action may be represented diagrammatically: $2Fe(OH)(HCO_3)+(O+H_2O)=2Fe(OH)_2(HCO_3)$, followed by $Fe(OH)_2(HCO_3)+H_2O=Fe(OH)_3+H_2CO_3$. The rust may be formed by the condensation of several simple molecules, attended by a more or less complete dehydration of the hydrated ferric oxide. Here the rust is formed in *solution*, as it were, away from the iron. This is demonstrated by the following experiment due to G. T. Moody:

> The lower end of a glass cylinder was packed with ordinary iron-wire nails, then the nails covered with water to the depth of an inch or two after placing above them a disc of white filter-paper. On observing the cylinder at intervals, it was seen that the nails undergo little, if any, perceptible change, but that rust gradually separates out from the liquid and settles on the paper disc above them.

H. E. Armstrong continued: In the second case, when oxygen is present together with an acid in a soln. bathing an iron surface, it is included in the circuit of change, and acts as a depolarizer, and no hydrogen is then evolved. Initially, when no ferrous salt is present, the interaction may be represented: $Fe+2H_2CO_3+O_2=Fe(HCO_3)_2+H_2O_2$; and when a ferrous salt is also present, some may be included in the circuit of change and converted into ferric salt: $Fe+2H_2CO_3+H_2O_2+2Fe(HCO_3)_2=Fe(HCO_3)_2+2Fe(OH)(HCO_3)_2$—*vide infra*, for the hydrogen dioxide theory of corrosion. In other words, while iron dissolves as ferrous salt, ferrous salt which has been produced previously is converted into a basic ferric salt; in the final stage this latter salt is acted upon by water and converted into rust and acid, the which acid is then available to dissolve a further quantity of iron. It is to be supposed that when, in presence of oxygen, the hydrogen displaced by iron in dissolving is oxidized effectively in the primary circuit (entirely to water) a large additional amount of energy is developed in the circuit, so that the electromotive force is raised about 1½ volt beyond that of a single fluid iron-acid cell. The part oxygen plays is therefore a very important one in so far as it is included in the primary circuit in which corrosion is effected. It is well known that when iron has once begun to rust in air, corrosion proceeds more rapidly, the rust appearing to promote attack. There is little doubt that this is in some measure due to the fact that the finely-divided oxide serves to attract and condense moisture. It has been supposed that the rust also promotes corrosion by its electro-negative character. It may be doubted whether ferric oxide itself has much influence on this account, but inasmuch as the electronegative impurities in steel are set free as corrosion proceeds, it is easy to understand that as these accumulate on the iron surface they may well exercise a considerable influence in lowering the resistance in the circuit of change by increasing the area of the electronegative element.

The electrochemical nature of rusting, from one point of view, has been indicated in connection with the ionic hypothesis of rusting. In its present form it has been called the *local element theory of rusting*, and it was discussed by K. P. Grigorowitch,[11] W. M. Thornton and J. A. Harle, F. Goudriaan, W. Guertler and B. Blumenthal, A. Thiel, J. Eckell, F. Förster, E. Heyn and O. Bauer, T. Fujihara, W. D. Bancroft, G. Chaudron, G. V. Akimoff, S. Rachwal, U. R. Evans, F. N. Speller and co-workers, and G. D. Bengough and co-workers—*vide infra*. The electrochemical phenomena—*vide infra*, electromotive force of iron—associated with the corrosion of metals were studied from the point of view of the anode and cathode by U. R. Evans, W. R. Fleming, W. W. H. Gee, G. Gore, G. Grube, A. Günther-Schulze, R. Hadfield and E. Newbery, E. Liebreich, C. Michalke, D. Reichinstein, E. K. Rideal, E. P. Schoch, and A. Thiel; anodic corrosion due to an externally applied e.m.f., by A. J. Allmand and R. H. D. Barklie, H. Beeny, F. Bergius and P. Krassa, W. R. Cooper, J. Eckell, W. W. H. Gee, J. L. R. Hayden, R. Kremann, B McCollum and G. H. Ahlborn, R. Saxon, E. P. Schoch and C. P. Randolph, W. M. Thornton and J. A. Harle, and G. R. White; and overvoltage or overpotential in relation to corrosion phenomena, by C. W. Bennett and J. G. Thompson, J. I. Crabtree, E. Denina and G. Ferrereo, H. J. T. Ellingham and A. J. Allmand, U. R. Evans, C. Hambuechen, N. Isgaricher and S. Berkmann, M. Knobel, M. Knobel and D. B. Joy, E. Liebreich, E. Liebreich and W. Wiederholt, D. A. MacInnes, F. Meunier, W. R. Mott, E. Newbery, T. Onoda, J. W. Richards, and O. P. Watts and co-workers.

According to U. R. Evans and co-workers, the electric currents flowing between the anodic and cathodic portions of a corroding metal are equivalent to the corrosion produced, not only (*a*) in cases when the anodic and cathodic areas consist of different metals, but also (*b*) in cases where the whole specimen consists of one metal, the anodic and cathodic areas being determined by differences in oxygen-concentration, so that *the problem of corrosion velocity resolves itself into a study of the electrochemical factors which determine the strength of this current.* Owing to polarization, the cathodic and anodic potentials tend to approach one another as the current flowing is increased. The strength of the current can never exceed the value which would cause the two potentials to meet. This sets a limiting value for the corrosion-rate under any particular conditions, which can never be exceeded, however low the resistance of the circuit is made; the current-strength cannot be obtained by assuming a fixed value for the e.m.f. and dividing this by the resistance. There is an approximation to " equipotential conditions " at fairly high concentrations, but the anodic and cathodic potentials remain far apart in dil. soln., where, owing to the low sp. conductivity, an appreciable residual e.m.f. is needed to force even the small corrosion-current round the circuit. It is possible that in certain cases the part of the circuit between the anodic circuit and the anodic tubulus may have an appreciable resistance; this may occur, for instance, (1) when the primary skin has only occasional weak points (as on stainless steel), (2) if the anodic surface becomes covered with an undissolved layer of the anodic product (which may conceivably occur with ordinary iron or steel in conc. soln.). In most cases, the polarization which limits the corrosion-rate, occurs at the *cathodic area*, and is due to *limitations in the rate of oxygen-supply.* Cathodic polarization curves, under controlled conditions of oxygen-supply, have been traced for a number of metals. These curves end at high potentials in a horizontal branch which serves to indicate the law governing the ratio of anodic and cathodic areas. When corrosion starts at a weak point in the invisible film covering the surface of a metal, *the area undergoing attack extends (or contracts) until the cathodic current density on the part remaining unattacked is equal to the "protective value"*; the current flowing under these conditions will define the rate of corrosion. The protective value is the current density which will cause any incipient attack on a weak point within the area in question to lead to the precipitation of rust so close to the surface as to seal the defect.

The rapid action of acid on commercial zinc is connected with the presence of impurities which exist as a separate phase; a perfectly homogeneous metal, or a one-phase solid soln., may dissolve more slowly or more quickly than the pure metal. An impurity which exists as a separate phase will assist corrosion if it be nobler than the dominant metal and has a smaller overvoltage. Using a figure of speech, when two metals are in contact and conjointly exposed to chemical influence during long periods of time, one metal sacrifices itself to ensure the other's preservation. Actually, one metal acts as anode and the other metal as cathode. Thus, there may be a rapid local attack on iron railings fixed in position by lead where iron is the sacrificial metal. In the case of iron in aerated water, ferrous iron may at first dissolve leaving an equivalent amount of hydrogen as a polarizing film on the surface of the metal. Oxygen removes this layer. Hence, iron should dissolve faster when it is in contact with a more electronegative metal like platinum, for the hydrogen would preferably collect on the platinum plate rather than on the iron. G. J. Burrows and C. E. Fawsitt[12] found this to be the case. Thus, iron lost 0·218 per cent. when alone and 0·399 per cent. when in contact with platinum for 17 days; and respectively 0·286 and 0·504 during 35 days. O. P. Watts and H. C. Knapp cited an extraordinary case of a yacht constructed of the non-corroding monel metal, with a steel stem, keel, stern post, and rudder-frame. Before the vessel had made a single voyage, the steel parts were rendered useless by corrosion—the steel acted as anode, and the monel metal as cathode. On ships, steel is very liable to corrode in contact with brass, bronze, or other copper alloy. J. B. Hartley reported that brass had the power to preserve cast and wrought iron from attack by sea-water, but E. Davy, and C. F. Schönbein doubted the statement, and R. Mallet said a more destructive practice than the use of this supposed preserver can scarcely be conceived or more fatally applied. E. Heyn and O. Bauer observed that contact with brass had very little influence on the corrosion of cast iron. H. Davy in his paper on the preservation of the copper sheathing of ships by using zinc as the sacrificial metal, stated that cast or wrought iron can be preserved by using zinc or tin as sacrificial metals. H. Davy was wrong with regard to tin, because A. van Beck, M. Meyer, G. J. Mulder, and E. Davy showed that iron acts as sacrificial metal and preserves tin, but zinc will preserve both iron, and tin. A. van Beck said that H. Davy was misled by observing that tin is positive to iron in atm. air, but the relations are reversed when the couple has been for half an hour in sea-water. In the tinning of iron, described by E. Trubshaw, and P. Flower the iron (sacrificial metal) is covered with a thin layer of tin. The iron is protected from corrosion only so long as the tin coating remains intact; once the iron is exposed, rusting proceeds more quickly than if the tin were absent. F. Ulzer showed that the tin surface usually breaks down at a number of isolated points, and not in continuous patches. This shows that the tin surface contains a number of pinholes. M. F. von Wurstemberger discussed what he called the selective corrosion of metals; the dissolution of iron in acids, and the rusting of iron in contact with other metals. A. Stansfield observed that in electrolytic iron, which is considered to be pure and homogeneous, local action may occur because of the different orientations of the atoms in different grains, so that even if the metal is homogeneous, local action can occur through differences in the crystals of the metals, and differences in the concentration of the oxygen in different parts of the same metal.

Anodic corrosion due to local e.m.f.—*e.g.* the corrosion of "tinned" iron—galvanic couples, and concentration cells were discussed by T. Andrews, J. Aston, R. Auerbach, O. Bauer and O. Vogel, G. D. Bengough and co-workers, L. H. Callendar, H. Cassel, M. Centnerszwer and M. Straumanis, G. Chaudron, G. C. Clifford, H. J. Donker and R. A. Dengg, J. W. Cobb, C. Bach, J. T. Corner, E. Cumberland, A. S. Cushman, H. E. Davies, P. Debye, C. H. Desch, C. M. van Deventer, J. Eckell, U. R. Evans and co-workers, J. Farquharson, R. H. Gaines, W. W. H. Gee, W. Guertler and B. Blumenthal, H. H. Hanson and W. K. Lewis, E. S. Hedges and J. E. Myers, E. Heyn and O. Bauer, A. L. Hughes, W. E. Hughes, W. P. Jorissen, K. Kieper, E. F. Kohman and N. H. Sanborn, G. von Knorre, R. H. Lueck and H. T. Blair, A. L. McAulay and F. P. Bowden, R. J. McKay, C. L. Mantell and W. G. King, E. Maurer, P. D. Merica, W. Palmaer, T. E. Perks, A. Phillip, F. H. Rhodes and E. B. Johnson, W. Schmid, E. C. Sherman, J. W. Shipley, A. Sinclair, M. Straumanis, A. T. Stuart, R. Stumper, G. Tammann and F. Neubert, F. Tödt, W. H. J. Vernon, F. Ulzer, W. H. Walker and co-workers, G. C. and M. C. Whipple, W. G. Whitman and co-workers, and W. G. Whitman and R. P. Russell. The increased corrosion of iron by segregations was discussed by C. V. van Brunt, W. H. Walker, and G. R. Woodvine and co-workers. The effect of graphite in cast iron on corrosion was discussed by O. Bauer and co-workers, U. R. Evans, P. Kötzschke and E. Piwowarsky, E. Liebreich and W. Wiederholt, H. Nipper and E. Piwowarsky, W. Palmaer, J. W. Shipley and I. R. McHaffie, F. N. Speller, R. Stumper, and A. Thiel and co-workers; the effect of slag and non-metal inclusions in iron, by C. Benedicks and H. Löfquist, H. le Chatelier and B. Bogitsch, J. W. Cobb, C. H. Charles, H. D. Hibbard, C. E. Homer, E. F. Law, P. Oberhoffer and co-workers, L. T. Richardson, and R. S. Weston; and gas inclusions, by O. Bauer, and M. Schromm. J. Walter, M. Rudolph, O. Gross, W. Bennett, and U. R. Evans attributed the corrosion of rivet-heads in boilers, and at discontinuities in metal coatings to electrolytic action.

H. Davy was right with respect to zinc, as was shown by E. Davy, W. H. Pepys, M. Meyer, the 1840 patent of S. Sorel for "zincking" or galvanizing iron with zinc, and the 1791 patent of G. le R. de Jeaucourt for preserving metals from rust by covering them with an alloy of zinc, bismuth and tin. The subject was discussed by W. H. Walker. G. von Knorre observed that iron in contact with the noble metals and alloys is strongly attacked, whereas in contact with zinc it becomes inert. The feasibility of zinc as a protector for iron ships has been discussed by R. Mallet, and B. Bell; and its use for protecting boilers from acidic feed-water, by G. Richardson, and W. Parker.

G. Gallo, and others have shown that the greater the difference of potential of iron and a soln. with which it is in contact, the more readily does rusting occur. O. Bauer and O. Vogel, and E. Heyn and O. Bauer measured the electrochemical series of the metals in a 1 per cent. soln. of sodium chloride, at 18°, and found the approximate order: Mg, Mn, Zn, Fe, Cd, Al, Te, Pb, Sn, Si, Sb, W, Cu, Bi, Mo, Ni, Ag, Hg, Te, Cr, Au, Pt, $C_{\text{graphite}}+$; and H. Diegel found the corrodibility of some metals in sea-water to be: Zn, Al, Fe, Sn, Al—and Sn bronzes, Cu, Phosphor-bronze+. E. Davy found that iron in contact with *copper* in soln. of electrolytes is corroded, and the subject was studied by E. Davy, H. Diegel, O. Bauer, and O. Vogel, H. Cassel, U. R. Evans, E. Heyn and O. Bauer, G. von Knorre, and W. G. Whitman and R. P. Russell. O. Bauer and O. Vogel found that iron in contact with *silver* is corroded, and similar results were obtained with iron in contact with *gold*, and the reaction was studied by W. S. Landis. O. Bauer and O. Vogel observed that the iron is protected when in contact with *magnesium* in soln. of electrolytes; iron in contact with *zinc* is also protected, as was observed by O. Bauer and O. Vogel, W. R. Dunstan, U. R. Evans, C. Lindet, M. Meyer, and W. H. Walker and co-workers. O. Bauer and O. Vogel, and U. R. Evans observed that iron is also protected when in contact with *cadmium*. O. Bauer and O. Vogel found that iron is incompletely protected when in contact with *aluminium*. The reaction was studied by A. T. Stuart, and H. Bauermeister. The rusting of iron in contact with *tin* is accelerated, and the reaction was studied by O. Bauer and O. Vogel, U. R. Evans, R. H. Lueck and H. T. Blair, and M. Meyer—*vide infra*. O. Bauer and O. Vogel, F. Enslin and F. Buschendorf, U. R. Evans, and H. H. Hanson and W. K. Lewis found that the corrosion of iron is accelerated when that metal is in contact with *lead*. O. Bauer and O. Vogel also found that iron is more susceptible to corrosion when it is in contact with *bismuth*. R. Irvine reported that when wrought *iron* is in contact with cast iron, the former metal is preferentially corroded. A. Schleicher and co-workers found that iron is attacked when in contact with passive wrought iron, rusty cast iron, clean wrought iron, passive cast iron, and clean cast iron, and this order is the order electrochemically. Oxidized iron is positive to clean iron. The subject was discussed by E. Heyn and O. Bauer, and G. von Knorre. O. Bauer and O. Vogel found that the corrosion of iron is favoured by contact with *nickel*, and the reaction was studied by U. R. Evans, W. Schlötter, and O. P. Watts and P. L. de Verter. A. Brochet and J. Petit found that the corrosion of iron is favoured by contact with *platinum* in soln. of potassium cyanide. Iron becomes passive in contact with platinum—*vide supra*, the passive state of iron.
